We oriented our search with the Health Level Seven International (HL7) standards and definitions[5] with the IT architecture and guidelines of our institution. To ensure fulfillment of the HL7 v2.3.1 requirements, we selected the following data components: medication name, Pharmacy Central Number (PZN), institution-specific material number used in the electronic medical record (EMR), Pharmacy Product Number (PPN), Global Trade Item Number (GTIN), National Trade Item Number (NTIN), Anatomical Therapeutic Chemical (ATC), *Arzneistoffkatalog*/German drug substance catalogue (ASK), and EDQM standards for administration method, intended site, and routes of administration. Finally, we compiled the data into a single data set.

Results: Most medications documented data was not digitalized and therefore not interoperable (e.g. pharmacy and PDMS databases). Moreover, we found that it is difficult to access the data mostly due to a deep fragmentation throughout the stakeholders. We observed that the interoperability problems were not a specific difficulty of our hospital but a nationwide challenge, due to the lack of standardization. Nonetheless, we could build a unified and standardized database out of the information of each mentioned database according to the HL7 guidelines of our institution, which led us to generate examples of codes for communication between different IT systems. We present an example below (Figure 1).

Figure 1: Example order message with instructions for administration of a medication to a patient

(MSH: Message header, RDE: Pharmacy/treatment encoded order message; PID: Patient identification; PV1: Patient visit; AL1: Patient allergy information; ORC: Common order; RXE: Pharmacy/treatment encoded order; RXR: Pharmacy/treatment route)

Conclusion: Our results show that it is a challenge to achieve standardization and therefore interoperability of medical records within the different IT platforms used in intensive care medicine. However, we proposed a solution based on international standards that may be applied to a broader spectrum of processes, such as the digitalization of the discharge medication from the ICU to the normal ward.

Intensive Care Medicine Experimental 2020, **8(2)**: 000899

Introduction: Best of breed informatics systems have an unclear evidence base for delivering clinically effective support over paper-based systems or large institutional electronic health records (Rubenfeld, 2004; Morrison, 2008). During the COVID 19 pandemic, King's College Hospital admitted over 2000 patients with COVID 19, 190 of whom required an admission for critical care. Severity in our population was higher than seen in other UK centres, in part due to the high incidence of renal failure (50%). We assessed the use and effectiveness of a best-of-breed critical care informatics system in this unprecedented period of operational and clinical strain.

Objectives: To use SQL reports and general database to assess the scope and effectiveness of a rapid electronic/informatics systems expansion during the COVID 19 pandemic in a central London critical care service.

Methods: The configuration of the ICCA system was compared post COVID 19 to that pre-COVID 19. In addition, pre-existing and new *ad hoc* SQL queries were constructed from the Intellivue, Critical Care & Anaesthesia Informatics System (ICCA, Philips HealthCare) database

using Sequel Server Management Studio 17. These were used to assess changes to configuration and workflow support; activity; electronic workflow alerts and adverse event capture.

Results: The ICCA informatics support system was rapidly expanded from 51 to 196 licensed support beds, including Census Page and Dashboard expansions. Over the pandemic period 1022 healthcare professionals were added to the system users database. 506 additional client computers were also added. Remote service review was set up for anaesthesia, renal, cardiology, diabetes, haematology and nutrition teams. The system and systems team provided a bespoke pathophysiological flowsheet and designed three clinical reports to support strategic management of overall clinical operations, renal replacement and airway management. 29 major urgent prescription changes were delivered to reflect supply chain breakdown and the need to deliver new COVID 19 trials. This included changes to sedation regimens, muscle relaxants, fluids and electrolyte replacement. There were also several hundred individual text changes to prescription/administration of medications to support the major category updates. System screening was used to issue 1288 workflow support alerts during the pandemic period. Commonest alerts were around sedation levels; ventilator driving pressure; patient allergies and patient identity. Importantly, several operationally important system updates were developed. A visual basic solution was written to provide a physical paper medication chart to go with the patient at discharge and the servers received improved power redundancy to decrease downtime. Finally, the system captured 159 adverse incidents that were not reported in the institutional 'Datix' system.

Conclusion: We have described the rapid and effective expansion of a critical care informatics system from 51 beds to 196 beds during the COVID 19 pandemic response of a large critical care service. The level of rapid adaptation may not have been possible on paper or across an institutional EHR.

Future FICE faculty: ensuring the standard of future faculty with a mentorship scheme

S. Morton¹; R. Fisher²; J. Powell-Tuck³; G. Zilahi⁴; J. Aron⁵

¹Intensive care, Chelsea and Westminster Hospital, London, United Kingdom; ²Intensive care, King's College Hospital, London, United Kingdom; ³Intensive care, St Thomas' Hospital, London, United Kingdom; ⁴Intensive care, St George's Hospital, London, United Kingdom; ⁵General intensive care unit, St. George's Hospital, London, United Kingdom

Correspondence: S. Morton

Intensive Care Medicine Experimental 2020, **8(2)**: 000008

Introduction: Focused Intensive Care Echo (FICE) is a training scheme developed by the UK Intensive Care Society to train clinical practitioners in the use of echocardiography in intensive care. [1] Learning a new physical skill normally requires one-to-one tuition. With an increasing demand for FICE courses there is therefore increasing demand for faculty; ensuring the quality of the faculty is maintained can become difficult. For many faculty intensive courses (such as Advanced Life Support), instructor courses and mentorship schemes exist to ensure the future faculty meet the expected standard.[2] Currently there is no such scheme for FICE faculty.

Objectives: Our aim was to develop a mentorship scheme for prospective faculty to ensure new faculty were supported through the course and to ensure standards were met to guarantee the quality of teaching desired on our FICE course.

Methods: Nine prospective faculty candidates, who were all FICE (or equivalent) qualified, were recruited to teach on two FICE courses held on consecutive days in October 2019. Prior to the course an anonymous online survey was conducted to gain background information and their pre-course teaching confidence. Throughout the course the candidates were then paired with experienced FICE faculty to support their teaching; at the end of the course candidates received written

feedback, including an overall assessment as to whether it was felt they could be recommended as full faculty in the future. Following this another anonymous online survey was conducted to review the experience of the faculty candidates and to assess any changes in confidence.

Results: Table 1 shows the demographics of the faculty candidates:

	Number
Qualified \leq 5 years	2
Qualified > 5 years	7
Echo experience \leq 2 years	7
Echo experience > 2 years	2
Had previously received formal teaching instruction e.g. GIC course?	5
Had previously taught on echo courses?	3

Seven of the faculty candidates completed the post course questionnaire. Confidence improved in all aspects assessed (Figure 1) with every candidate at least feeling "OK/assistance only needed occasionally" following the course. Comments relating to the mentorship included "well supported", "constructive" and "good opportunity". 86% of candidates agreed absolutely that all people who want to mentor on a FICE course should do something similar and that it will improve the quality of mentorship. 71% found the paper feedback useful. All faculty candidates apart from one were recommended as full faculty; the one not recommended has been invited to attend again as a faculty candidate to increase their confidence.

Conclusion: With the increasing need for FICE faculty we have shown that a faculty mentorship scheme is practical and well received by the faculty candidates. This is a low cost method of providing structured mentorship to prospective faculty, without the need for specialised instructor courses. We believe that by rolling this mentorship scheme out nationwide it will ensure that we continue to develop a pool of quality faculty to meet the increasing demand for FICE courses.

Point of care ultrasound in medical ICU patients with intra-abdominal hypertension

Z. Bitar¹; O. Maadrani¹; M. Alsamari¹; T. Zaalouk¹

¹Critical care unit, New Ahmadi hospital KOC
مستشفى الاحمدي الجديد, Ahmadi, Kuwait

Correspondence: Z. Bitar

Intensive Care Medicine Experimental 2020, **8(2)**: 000031

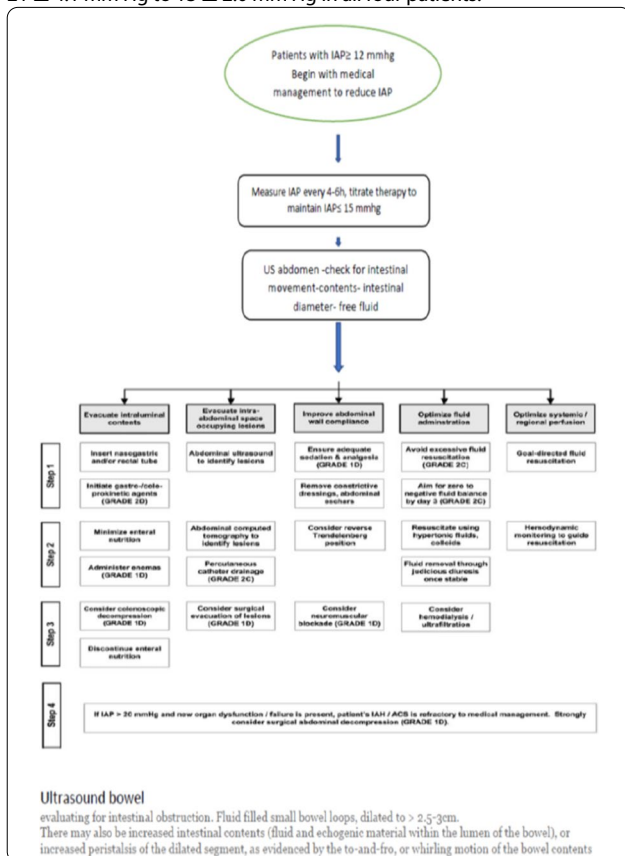

Introduction: Intraabdominal hypertension (IAH) is well-documented causes of morbidity and mortality in the critically ill and may affect almost every organ system (1). The Abdominal Compartment Society (WSACS) developed a medical management algorithm with a stepwise approach according to the evolution of the intra-abdominal pressure

and aiming to keep IAP ≤ 15 mm Hg (2). Point of care ultrasound as a bedside modality in the critical care patients, could be used as an adjunct point-of-care tool during IAH management.

Objectives: To test the role of Point of Care Ultrasound (POCUS) in the medical management of patients with IAH.

Methods: We conducted a Prospective observational study and enrolled fifty-three consecutive adult critically ill patients admitted to the medical critical care unit (CCU) of Ahamdi hospital with risk factors for IAH. Those who met the inclusion criteria were allocated to undergo POCUS and small bowel ultrasound as an adjuvant tool in their IAH management

Results: A total of 22 patients met the inclusion criteria and were included in the study (Table 2) Following step 1 of the WSACS IAH medical management algorithm, ultrasound was used for NGT placement, confirmation of correct positioning, and evaluation of stomach contents. Ultrasound was comparable to abdominal X-ray but shown to be superior in determining the gastric content (fluid vs. solid) and diagnoses gastric paresis in 2 cases. Ultrasound also proved useful in (table 3): (1) evaluating for intestinal obstruction. ((2) identification of large bowel contents; (3) identification of patients that would benefit from bowel evacuation (enema) as an adjuvant to lower IAP; (4) and in the diagnosis of moderate to large amounts of free intra-abdominal fluid. Small bowel obstruction and were present on four patients and confirmed with CT abdomen, and two of the patients underwent surgical intervention for mesenteric vessel occlusion and transmesenteric internal hernia. Six patients were identified to have ileus in septic patients and responded to prokinetic drugs. Enema treatment was found to empty the bowel incompletely in 72%, 56% and 42% of the times on days 1, 2 and 3 respectively. colonoscopy decompression was not needed in any of our patients. Four patients with cirrhosis that were admitted with upper gastrointestinal bleeding and hepatic encephalopathy (out of a total of 8) were found to have large amounts of ascites and the US-guided paracentesis was carried out. The average amount of ascites removed was 3600 ± 1.6 mL and resulted in a significant drop in the IAP average from 21 ± 4.1 mm Hg to 13 ± 2.0 mm Hg in all four patients.

Conclusion: POCUS can be used in nonoperative management of IAH and ACS. It is an important tool in the diagnosis and treatment in patients with IAH.

Intensive Care Medicine Experimental 2020, **8(2)**: 000175

Introduction: International guidelines do not recommend a specific probe for assessment of lung aeration using Lung Ultrasound (LUS). The aim of this study was to assess the concordance between linear and sector array probes of a handheld ultrasound device in assessment of lung aeration in invasively ventilated Intensive Care Unit (ICU) patients.

Methods: This study included invasively ventilated patients admitted to the ICU expected to be ventilated > 24 hours. A trained examiner performed a 12–region LUS exam with a linear and a sector array probe. In each image the LUS aeration score and the ‘number of B–lines’ was determined. The LUS aeration score was defined as; ‘0’, A–pattern; ‘1’, B1–pattern; ‘2’, B2–pattern; or ‘3’, C–pattern. Adding LUS aeration scores of all regions resulted in a global LUS aeration score [Crit Care. 2007;11(1):205]. Agreement between the two probes was calculated using intraclass correlation coefficients (ICC).

Results: 30 LUS exams were performed in 19 mechanically ventilated ICU patients resulting in a total of 328 pairs of images. 29 pairs of images were excluded for analysis because the images from the linear probe were unable to score (UTS) (Table 1). ICC’s calculated for the remaining images revealed a good concordance for the LUS aeration score for individual images, ICC: 0.73 (CI: 0.67–0.78), ‘number of B–lines’, ICC: 0.79 (CI: 0.72–0.83) and global LUS aeration score, ICC: 0.74 (CI: 0.52–0.87).

Table 1. Cross tabulation of LUS patterns scanned by linear and sector array probe

		Linear probe					Total
		A	B1	B2	C	UTS	
Sector array probe	A	185	7	2	4	14	212
	B1	23	10	1	2	8	44
	B2	6	7	23	1	3	40
	C	5	1	1	21	4	32
	UTS	0	0	0	0	0	0
Total		219	25	27	28	29	328

Conclusion: There is a good concordance between linear and sector array probes of a handheld ultrasound device in assessment of lung aeration patterns in mechanically ventilated ICU patients. However, in roughly 10% of the images acquired using the linear probe the aeration pattern could not be scored.

Intensive Care Medicine Experimental 2020, **8(2)**: 000415

Introduction: The lung interference due to mechanical ventilation is known to cause poor acoustic window making transthoracic echocardiography difficult. Interference of the lungs is least during expiration however, this period is too short for interpretation. End Expiratory hold has potential to improve acoustic window by reducing lung interference. End Expiratory hold of 15 seconds acts like a fluid bolus and changes cardiovascular physiology especially during last five seconds limiting its application solely for improving acoustic window. We hypothesized that a Short End Expiratory Hold (SEEH) of eight seconds improves acoustic window leading to superior echocardiographic image quality without significant hemodynamic changes.

Objectives: Primary objective of the study was to determine effect of SEEH on image quality score. Secondary objectives of the study were to determine the change in IVC diameter and Carotid Doppler peak velocity (Δ CDPV) with SEEH. Tertiary objective was to look for presence of any Auto-PEEP revealed during SEEH.

Methods: Twenty patients on mechanical ventilation with poor acoustic window during point of care echocardiography examination were assessed for both apical four chamber (A4C) and parasternal short axis (PSAX) view, video clips of six second duration were recorded both with tidal ventilation and with eight second SEEH. Assessors blinded to the intervention scored the video clips based on the quality of the image using a previously validated scoring criteria. Clips were scored from 0 (no image visualization), 1 (visualization of less than 70% of the left ventricle (LV) walls), 2 (Visualization of 70% to 95% of the LV walls) to 3 (visualization of 95% to 100% of the LV walls). Increase in one or more point was considered significant. To determine hemodynamic effects of SEEH on change in IVC diameter and Carotid Doppler peak velocity (Δ CDPV) were noted at the baseline and just before end of SEEH. Any change (Δ) more than 14% was considered as significant. Auto-PEEP displayed on the ventilator at the end of SEEH was noted.

Results: In A4C view baseline worst median image quality score during tidal ventilation was 1 (Interquartile range (IQR) 1-1) and in PSAX view was 1 (IQR 0.25-2) which with SEEH improved to 2 (IQR 2-3) for A4C view and 3 (IQR 1-3) for PSAX. 18 out of 20 (90%) patients in A4C view and 11 out of 20 (55%) patients for PSA had at least one point increment in worst image quality score with SEEH. The median Δ CDPV was 1.95% (IQR 1-3.175) and median change in IVC diameter was 4.45% (IQR 0-7.925) indicating no significant hemodynamic change due to SEEH. Median auto-PEEP was found to be 0.55 (IQR 0-1.075) cm H₂O indicating absence of auto-PEEP.

Image Quality Score Of Clips	visualization	NUMBER OF PATIENTS			
		Apical four chamber view		Parasternal short axis view	
		Tidal ventilation (Control)	Short end expiratory hold (Intervention)	Tidal ventilation (Control)	Short end expiratory hold (Intervention)
0	No image visualization	2	1	5	2
1	Visualization of less than 70% of the LV walls	15	2	9	4
2	Visualization of 70% to 95% of the LV walls	3	8	2	3
3	Visualization of 95% to 100% of the left ventricle (LV) walls.	0	9	4	11

Conclusion: In mechanically ventilated critically ill patients with poor acoustic window, SEEH causes significant improvement in echocardiography image quality without significant change in hemodynamic parameters. This improvement occurs in the absence of auto-PEEP.

The impact of thoracic ultrasound on ICU management: a prospective observational studyM. Heldeweg¹; P. R. Tuinman²¹Intensive Care Adults, Amsterdam UMC, locatie VUmc, Amsterdam, Netherlands; ²Intensive care, Vrije Universiteit Amsterdam, Amsterdam, Netherlands**Correspondence:** M. Heldeweg*Intensive Care Medicine Experimental* 2020, **8(2)**: 000567**Introduction:** Point-of-care-ultrasound is a useful diagnostic instrument on critical care units. Its diagnostic accuracy supersedes chest x-ray and is similar to chest CT(1). However, the effect it has on management strategies is less clear.**Objectives:** Our objective is to quantify the impact of thoracic ultrasound on ICU management.**Methods:** This prospective observational study was conducted at a tertiary ICU. The study was approved by the local medical ethics committee and the need for consent was waived. A treating intensivist recorded a diagnosis and management plan before and after a thoracic ultrasound. Changes in management and diagnoses were recorded. Patient characteristics, fluid balance and whether the changes were carried out within 8 hours were extracted from the electronic health records.**Results:** Thirty-seven thoracic ultrasound examinations were included. Management changes occurred in 22 (59.5%). Seventeen (77.3%) out of these 22 had their management changes carried out within 8 hours. The thoracic ultrasound yielded a new diagnosis in 13 (35.1%) examinations. No significant effect was observed for management changes, patient characteristics, or fluid balance within 8 hours.**Conclusion:** This single-arm observational study shows that a majority of thoracic ultrasounds alter patient management plans with feasible changes. More research is needed to give conclusive evidence regarding patient centric outcomes like mortality, duration of mechanical ventilation and time to discharge.**Reference(s) and grant acknowledgment(s)**

Serial lung ultrasounds for detection of pulmonary complications in critically ill obstetric patients: preliminary findings from a prospective observational study in a low-resource settingL. Pisani¹; A. De Nicolò²; M. Schiavone³; AO. Adeniji⁴; EE. Emuveyan⁵; S. Grasso⁶; E. Henciles⁷; MM. Koroma⁸; M. Schultz⁹¹Department of intensive care, Amsterdam UMC, locatie AMC, Amsterdam, Netherlands; ²Intensive care unit, department of emergency and organ transplantation (deto), University of Bari, Bari, Italy; ³Thoracic surgery unit, department of emergency and organ transplantation (deto), University of Bari, Bari, Italy; ⁴Department of obstetrics and gynecology, Princess Christian Maternity Hospital, Freetown, Sierra Leone; ⁵Department of obstetrics and gynaecology, Princess Christian Maternity Hospital, Freetown, Sierra Leone; ⁶Department of emergency and organ transplants (deto), anesthesiology and intensive care, University of Bari Aldo Moro, Bari, Italy; ⁷Department of anesthesia and intensive care, Connaught Hospital, University of Sierra Leone, Freetown, Sierra Leone; ⁸Department of anesthesia, Princess Christian Maternity Hospital, Freetown, Sierra Leone; ⁹Intensive care, Amsterdam University Medical Centers, University of Amsterdam, Amsterdam, Netherlands**Correspondence:** L. Pisani*Intensive Care Medicine Experimental* 2020, **8(2)**: 000578**Introduction:** Critically ill parturients have an increased risk of developing pulmonary complications. Lung ultrasound could be effective in addressing the cause of respiratory distress in limited-resource settings[1] with high maternal mortality.**Objectives:** To determine the frequency, timing of appearance and type of pulmonary complications in critically ill parturients in an obstetric unit in Sierra Leone.**Methods:** Prospective observational study conducted between July 2018 and February 2019 in critically ill parturients admitted to the high dependency unit (HDU) of Princess Christian Maternity Hospital in Freetown, Sierra Leone. Twelve-regions lung ultrasound examinations were performed on admission, after 24 and 48 hours, and in case of respiratory deterioration, using a low frequency (2.5–5 MHz) convex probe.

Primary endpoint was the proportion of parturients with one or more pulmonary complications, stratified for presence of respiratory distress. Secondary endpoints included timing and types of complications, and their association with 'poor outcome', defined as a composite of transfer for escalation of care or death. The study was approved by the Sierra Leone Ethical Research Committee on June 5, 2018 and registered at clinicaltrials.gov (NCT 03828630).

Results:Measurements and main results. 166 patients were enrolled (median age 25 years [IQR 22-30]). A total of 383 LUS examinations, median 2 [2–3] LUS per patient, were performed. Of all patients, 34% presented with or developed respiratory distress during HDU stay; 35 patients (21% [95%–confidence interval 15 to 28%]) had one or more pulmonary complications, the majority diagnosed on admission.

Acute respiratory distress syndrome (period prevalence 4%) and hydrostatic pulmonary edema (4%) were only observed in patients with respiratory distress. Pneumonia (2%), atelectasis (10%) and pleural effusion (7%) were present irrespective of respiratory distress. In patients in whom ultrasound excluded pulmonary complications, respiratory distress was related to anemia or metabolic acidosis. In total, 18 out of 166 patients met the composite endpoint of a poor outcome (11%). Pulmonary complications were associated with an increased risk of poor outcome (odds ratio, 5.0 [95%–confidence interval 1.7 to 14.6]; P=0.003).

Conclusion: One out of five critically ill parturients admitted to the HDU of a resource-limited obstetric unit developed one or more pulmonary complications. Lung ultrasound contributed to address the cause of respiratory distress by identifying or excluding ARDS, pulmonary edema, pneumonia, atelectasis and pleural effusion. These complications were associated with a poor outcome.**Reference(s) and grant acknowledgment(s)**

Diagnostic accuracy of early sonographic signs in COVID-19 pneumoniaZ. Bitar¹; M. Shamsah²; H. Al-Foudari³¹Critical care unit, New Ahmadi hospital KOC - مستشفى الاحمدي الجديد, Ahmadi, Kuwait; ²Intensive care department, Adan Hospital, Hadiya, Kuwait; ³Head of intensive care department and anesthesia, Adan Hospital, Hadiya, Kuwait**Correspondence:** Z. Bitar*Intensive Care Medicine Experimental* 2020, **8(2)**: 000619**Introduction:** Chest radiography (CXR) and computerized tomography (CT) scan are the standard methods for lung imaging in diagnosing COVID-19 pneumonia in the intensive care unit, despite their limitations. This study aimed to assess the performance of bedside lung ultrasound examination by a critical care physician, in the diagnosis of COVID-19 pneumonia in acute admission to the ICU.**Methods:** The study is an observational, prospective, single-center study conducted in the intensive care unit of Adan General Hospital

from Apr 10, 2020, till May 10, 2020. Adolescent or adult with suspicion of COVID-19 infection transferred to ICU with fever or suspected respiratory infection, plus one of the following: respiratory rate > 30 breaths/min; severe respiratory distress; or SpO2 < 93% on room air (1). Patients admitted directly from ER to ICU after performing the reverse transcriptase-polymerase chain reaction (RT-PCR) and send to the central virology in Kuwait. A certified intensivist in critical care ultrasound performed the lung ultrasound within 12 hours of admission to ICU and blinded to the result of the RT-PCR, if available at the time of examination. The four signs at lung ultrasound COVID-19 pneumonia are (2):

1. B-lines as Bilateral patchy distribution of multiform clusters, both in separate and coalescent forms, sometimes giving the appearance of a shining white lung. They can arise from one point of the pleural line and small peripheral consolidations and spread down like rays maintaining their brightness until the edge of the screen without fading.
2. Bilateral diffuse irregularities of the pleural line.
3. Absence of significant pleural effusion.
4. Presence of multiple subpleural consolidations of various size.

The treating physician confirmed the diagnosis of COVID-19 pneumonia by a set of clinical features, inflammatory markers, biochemical profile studies, RT-PCR test, and CXR.

Results: Out of 57 patients with suspected COVID-19 pneumonia, 46 (80.7%) were confirmed. Mean age 51 with a range of 39 to 69 years and 32 (76%) men.

In the group of patients with confirmed COVID-19 pneumonia (table 1), 44 (98.6%) LUSs revealed the four signs suggestive of COVID-19 pneumonia (sensitivity 95.6%, CI 85%-99.5%). Two patients presented with unilateral lobar pneumonia and without other ultrasonic signs of COVID-19 pneumonia but positive RT-PCR. The group without COVID-19 pneumonia and negative RT-PCR were 10 (90%) had LUS negative for COVID-19 pneumonia (specificity 90.91%, 95% CI 58.72%-99.77%). One case declared positive by LUS, and with negative RT-PCR, it was a case of non-Hodgkin lymphoma post-radiation pulmonary fibrosis and presented with hypertensive pulmonary edema. The other cases of negative LUS and negative RT-PCR were three cases on chronic dialysis and pulmonary edema, a 25-year-old woman with miliary tuberculosis and severe myocarditis, three cases of NSTEMI and pulmonary edema, a 26-year-old man with uncontrolled hypertension, renal failure and possible vasculitis, one case of diabetic ketoacidosis and right basal pneumonia and another case of hypertensive pulmonary edema with UTI.

Two cases were considered COVID-19 pneumonia by the treating team despite negative RT-PCR because the clinical picture, lab findings, and CT chest finding keeping with COVID-19 pneumonia in concert with the ultrasound chest. Pleural effusion was not detected in any patient with confirmed COVID-19 pneumonia.

Table 1. Lung ultrasound and RT-PCR profile in patients with respiratory distress and suspicion of COVID-19 in ICU (N = 57)

Diagnostic Tool	Confirmed COVID-19 (N 46)		Sensitivity, %	Specificity, %	PPV, %	NPP, %	PLR, %	NLR, %
	Present	Absent						
LUS								
LUS+	44	1	95.6	90.9	97.8	83.3	10.5	0.05
LUS-	2	10						
RT-PCR								
RT-PCR+	44	0	95.6	100	0.04	100	84.6	
RT-PCR -	2	11						

LUS, lung ultrasound; positive (+) or negative (-) for the abnormality; COVID-19 pneumonia present or absent based on final diagnosis;

Conclusion: LUS pattern is sensitive and specific for diagnosing COVID-19 pneumonia in acutely admitted patients to ICU with respiratory involvement.

Deep vein thrombosis screening of COVID-19 patients in intensive care

C. McGovern¹; C. Mccue¹; G. Bainbridge¹; J. Selfridge¹

¹Intensive care unit, glasgow royal infirmary, NHS Greater Glasgow and Clyde, Glasgow, United Kingdom

Correspondence: C. McGovern

Intensive Care Medicine Experimental 2020, **8(2)**: 000717

Introduction: Patients infected with COVID-19 are at increased risk of thromboembolic complications as demonstrated in autopsy findings(Wichmann et al) and observational clinical studies(Helms et al).

Recognising this increased risk, our intensive care unit started a screening programme using compression ultrasound to detect venous thrombosis.

Methods: From 1st April 2020, any patient admitted to our adult intensive care unit with proven or suspected COVID-19 underwent compression ultrasound of the external iliac veins to popliteal trifurcation and the internal jugular veins. This scan was carried out shortly after admission to ICU and repeated weekly until ICU discharge.

Scans were performed by medical staff trained in compression ultrasound. Any scans felt to demonstrate thrombus meriting anticoagulation were reviewed by a senior clinician with experience in compression ultrasound. Any doubt or disagreement prompted further assessment by a radiologist or sonographer.

Results: Twenty-two consecutive patients with a diagnosis of COVID-19 pneumonia were cared for in ICU during this project. The demographics are summarised below.

	n=22
Age - median (IQR)	60.5 (55-66)
Male - n. (%)	17 (77.3)
BMI - median (IQR)	31.5 (25.5-36.7)
Co-morbidities - n. (%)	
Cardiovascular disease	9 (40.9)
Previous cancer	2 (9.1)
Previous VTE	1 (4.5)
Diabetes	3 (13.6)
Hypothyroid	3 (13.6)
Asthma/COPD	5 (22.7)
CKD	2 (9.1)
Disease Severity	
APACHE Score - median (IQR)	16 (14-19)
APACHE Mortality - median (IQR)	23.4 (19.2-28.6)
Interventions - n. (%)	
Invasive mechanical ventilation	22 (100)
Muscle relaxant infusion	21 (95.5)
Prone position	19 (86.4)
Renal replacement therapy	8 (36.4)

Fifteen patients (68.2%) were found to have thrombus of varying severity on compression ultrasound. Eight were judged to merit treatment with anticoagulation.

Of the eight patients that were anticoagulated, 7 were diagnosed on compression ultrasound screening. Five were found to have lower

limb DVTs, 2 of which were bilateral. Two patients had occlusive thrombus in an internal jugular vein. One patient was anticoagulated following thrombolysis for a clinical diagnosis of massive pulmonary embolus.

Patients with proximal femoral vein DVTs were treated in the prone position more times (median 5 [4-6]) than those without (median 2 [1-5]). They were also more likely to have a higher Body Mass Index (median 32 [31-36] vs 27.5 [25-36]).

Eight patients had non-occlusive thrombus in an internal jugular vein, not considered large enough to merit systemic anticoagulation and all were associated with central venous catheters sites.

Five patients underwent computed tomography pulmonary angiograms (CTPA), all of which were negative.

Two patients suffered bleeding complications during anticoagulation therapy, one developed minor haematuria and one life threatening spontaneous retroperitoneal haemorrhage requiring embolisation.

Conclusion: Given the recognised risk of thromboembolic complications in critically unwell COVID-19 patients, the higher prevalence of severe disease in obese patients (Simonnet et al, Caussy et al) and the frequent use of prone position ventilation, we feel that DVT screening merits consideration as a routine part of the care of these patients. Compression ultrasonography is a simple, non-invasive bedside investigation that uses existing technology that is familiar to critical care staff.

Intensive Care Medicine Experimental 2020, **8(2)**: 000787

Introduction: Acute Kidney Injury (AKI) is a common complication of COVID-19 critical illness but the pathophysiology is uncertain. Much of the limited current evidence comes from autopsies demonstrating the presence of viral inclusion bodies within tubular epithelial cells alongside endothelial injury and erythrocyte aggregation within peritubular capillaries. These findings contribute to the hypothesis that COVID-19 disease induces widespread changes in vascular endothelial cells and that resultant changes in regional blood flow may be important in the pathogenesis of COVID-19 related critical illness. We used contrast enhanced ultrasound (CEUS) and echocardiography to study renal perfusion and global blood flow and compared our findings with measurements taken in a group of septic shock patients and healthy volunteers.

Methods: Prospective case-control study. Renal perfusion variables were assessed with contrast enhanced ultrasound (CEUS); macrovascular blood flow was assessed using Doppler analysis of large renal vessels; echocardiography was used to assess right and left heart function and cardiac output.

Results: CEUS derived parameters were reduced in COVID-19 associated AKI compared to healthy controls (perfusion index 3415 v 548 a.u., $p=0.001$; renal blood volume 7794 v 3338 a.u., $p=0.04$). Renal arterial flow quantified using time averaged peak velocity (TAPV) was also reduced compared to healthy controls (36.6 v 20.9 cm/s, $p=0.004$) despite cardiac index being similar between groups (2.8 v 3.7 L/min/m², $p=0.07$) and right heart function being normal. There were no differences in CEUS derived or cardiac parameters between COVID-19 and septic shock patients but patients with septic shock had more heterogeneous perfusion variables.

Conclusion: Both large and small vessel blood flow is reduced in patients with COVID-19 associated AKI compared to healthy controls, which does not appear to be a consequence of right or left heart dysfunction. A reno-vascular pathogenesis of COVID-19 AKI seems likely

Intensive Care Medicine Experimental 2020, **8(2)**: 000929

Introduction: Weaning from mechanical ventilation in critically-ill patients is associated with many factors, baseline muscle thickness is one of them [1,2].

Objectives: To determine whether baseline diaphragm (Tdi), rectus femoris (RF) and vastus intermedius (VI) muscle thickness (TRF and TRF+VI) are associated with weaning.

Methods: The study was performed between 1st April-30th June 2019 and 1st October 2019-31st March 2020. Right Tdi, TRF and TRF+VI were measured by ultrasonography within 36 hours of intubation and diaphragmatic excursion (DE) was evaluated at the first spontaneous breathing trial in adult critically-ill patients. Successful weaning was defined as extubation without reintubation within 7 days after extubation. Reintubation or death within 7 days after extubation were grouped as weaning failure. Two groups were compared in terms of ultrasonographic measurements and clinical features.

Results: A total of 62 patients were enrolled in the study. The patients (n=24) who had no attempt for weaning were excluded from the analysis. Clinical features and ultrasonographic measurement results of weaning groups are shown in the Table. In the weaning failure group (n=15), the median body mass index (BMI), DE, TRF+VI were lower while the median clinical frailty scale (CFS), duration of mechanical ventilation, ICU and hospital mortality rate were higher. The median baseline diaphragm thickness was similar in two groups. In ROC analysis, AUC for TRF+VI was 0.71 (95% CI: 0.51-0.90; $p=0.035$), with 21 mm cut-off having sensitivity of 82% and specificity of 57%. Logistic regression analysis revealed TRF+VI<21 mm as the only predictor

of weaning failure with an odds ratio of 7.6 (95% CI: 1.1-52.8, p=0.04) after adjusting for BMI and CFS.

Table: Clinical features and ultrasonographic measurements of patient groups

	Weaning success n=23	Weaning failure n=15	p value
Age, years	61 [50-70]	71 [55-80]	0.15
Female sex*	8 (34.7)	4 (26.6)	0.72
Body mass index, kg/m2	26.1 [24.1-31.3]	23.5 [21.1-25.6]	0.04
Charlson co-morbidity score	3 [1-5]	4 [3-6]	0.22
Nutrition risk in the critically-ill (NUTRIC) score	5 [4-6]	5 [4-6]	0.26
Clinical frailty scale	4 [3-6]	6 [5-7]	0.02
APACHE II	24 [13-26]	16 [14-21]	0.06
SOFA	7 [5-9]	8 [6-10]	0.40
Prealbumin, mg/dl	12.2 [8.8-20.0] (n=14)	11.8 [6.5-13.9] (n=10)	0.34
PaO2/FiO2	171 [90-208]	106 [88-179]	0.15

Table: Clinical features and ultrasonographic measurements of patient groups

	Weaning success n=23	Weaning failure n=15	p value
pH	7.37 [7.20-7.45]	7.37 [7.31-7.44]	0.34
PaO2, mmHg	69.0 [60.0-89.0]	62.2 [55.4-83.1]	0.15
PaCO2, mmHg	37.0 [28.5-52.0]	37.8 [32.1-55.4]	0.28
ICU length of stay, days	18 [11-34]	26 [21-52]	0.12
Hospital length of stay, days	31 [17-54] (n=21)	37 [26-64]	0.42
Mechanical ventilation duration, days	8 [4-14]	18 [8-23]	0.004
ICU mortality*	2 (8.6)	14 (93.3)	<0.001
Hospital mortality*	2 (9.5) (n=21)	14 (93.3)	<0.001
Time to first spontaneous breathing trial, days	7 [4-11]	8 [4-15]	0.47
Tdi, mm	2.0 [1.7-2.4]	1.9 [1.5-2.3]	0.26
DE, mm	25.9 [19.3-38.5] (n=19)	19.4 [14.6-24.0] (n=8)	0.045
TRF, mm	12.7 [11.7-16.4]	7.2 [5.9-15.3] (n=14)	0.06
TRF+VI, mm	23.6 [21.3-27.1]	14.0 [12.3-26.2] (n=14)	0.03

*number (%), others median [IQR]; Tdi: diaphragm thickness, DE: diaphragmatic excursion, TRF: rectus femoris thickness, VI: vastus intermedius

Conclusion: TRF+VI lower than 21 mm, measured by ultrasonography within 36 hours of intubation, was associated with weaning failure among critically-ill patients.

Point of care lung ultrasound and focused echocardiography findings in a cohort of patients with severe COVID-19

B. Shuker¹

¹Department of Anaesthesia, Warwick Hospital, Warwick, United Kingdom

Correspondence: B. Shuker

Intensive Care Medicine Experimental 2020, **8(2)**: 000974

Introduction: Point of care ultrasound (POCUS) is a valuable tool in intensive care medicine. During the COVID-19 pandemic there has been significant interest in the utility of POCUS as an aid to management of critical illness.

Preliminary work indicated characteristic lung ultrasound findings in COVID-19: pleural thickening, pleural irregularity, presence of B lines, consolidations, absence of pleural effusions, and resolution to A lines during recovery (1). Echocardiographic features associated with COVID-19 include: hyperdynamic cardiac function, acute cardiomyopathy, right ventricular dysfunction, and diffuse myocardial inhibition (2).

Objectives: We aimed to validate these preliminary findings in a UK cohort of ICU patients with severe COVID-19.

Methods: All invasively ventilated patients admitted to a single ICU in a single centre in the UK with severe COVID-19 illness confirmed by RT-PCR who underwent routine POCUS examination during their admission were included. Lung ultrasound and focused echocardiography were performed using standardised protocols (3).

Results: Five patients with a mean age of 58.4 years were included. Except for a previously well slim female, all were overweight or obese male patients with pre-existing hypertensive disease. The patients were severely ill with a mean APACHE II score of 27 (range 17-34) and mean P:F of 14.2 kPa (7-27).

Patients were scanned between day 5 and 10 of their ICU admission (mean day 7.8). None had been treated prone. All patients had evidence of pleural thickening, irregularity of the pleural lines, and presence of B lines. Only 2 patients had evidence of subpleural or overt consolidations. One patient had a small pleural effusion.

Three patients were receiving vasopressor therapy. One demonstrated hyperdynamic heart function associated with left ventricular systolic impairment. Three patients exhibited signs of right ventricular dysfunction.

Conclusion: In a cohort of severely ill mechanically ventilated patients with COVID-19 in the UK, we identified similar POCUS features to the preliminary findings reported by clinicians working in China notably a universal presence of pleural irregularity and a high burden of right ventricular dysfunction. An important finding in our cohort was the infrequency of lung consolidations, a finding thought to be present in the most severe loss of lung aeration (4).

Introduction: of lung ultrasonography (LUS) in ICU: a single center experienceX. Vanderspikken¹; T. Ecker¹; T. Fizez¹; M. Vander Laenen¹; W. Boer¹¹Department of Anesthesiology, Intensive Care Medicine, Emergency Medicine and Pain Medicine, Ziekenhuis Oost-Limburg, Genk, Belgium**Correspondence:** X. Vanderspikken*Intensive Care Medicine Experimental* 2020, **8(2)**: 000993

Introduction: Since 1989 when Jardin (1) introduced bedside ultrasonography in his ICU, lung US has become increasingly popular in the ICU community. In our center, the value of LUS is becoming apparent and fellows in training are interested in learning this important technique. We initiated a simple learning program and followed 2 fellows in their learning trajectory.

Objectives: To determine the time needed to develop basic LUS skills in the ICU.

Methods: After a literature review the modified Bedside Lung Ultrasound in Emergency (BLUE)- protocol (2) was selected for implementation, (excluding the venous vascular part of the protocol for deep vein thrombosis). An introductory session was organized, lead by an experienced lung US specialist, entailing a 30-minute instruction for knobology and a protocol trial run in 2 patients. Patients selected were admitted to ICU and in need of O₂-therapy. Patients below 18 year of age, patients after thoracic and cardiac surgery and morbidly obese in whom limited LUS resolution was expected, were excluded. Patients were selected, in whom objectifiable lung lesions were most expected. Patients could only be included once. Length of time for the examination was noted and findings describing the different LUS study points were noted and retrospectively compared to classic radiological findings (chest X-Ray (CXR) and/or CT) and medical history. These data were subsequently analyzed.

Results: A total of 63 patients were included in the study over a period of 1 month divided over 2 ICU fellows. One fellow performed 45 examinations (71%), the other 18 (29%). *Time of study.* Mean study time of all examinations (n=63) was 254 seconds (sd=104). In the first 15 examinations mean time was 380 s (sd=106), the second was 261 s (sd=33), the third 246 s (sd=52), dropping to a mean of 148 s (sd=31), in the last 18 examinations (p<0.001 compared to all previous periods). The maximum time of examination in the last period was 195 s. *Findings according to BLUE protocol.* In a total of 63 patients: PLAPS profile 15 (23.8%); A profile: 29 (46%); A' profile 2 (3.2%); B profile: 8 (12.7%); B' profile 2 (3.2%); AB profile 2 (3.2%); undetermined 5 (7.9%). *Comparison of LUS to CXR and medical history.* In 50 (79.4%) patients findings on LUS confirmed CXR and medical history. In 7 (11.1%) patients LUS likely fell short. In 6 (9.5%) patients LUS had added value to previous findings on CXR and from medical history.

Conclusion: The learning curve for LUS in the ICU is steep. After a short introduction, within about 50 examinations fellows could perform lung US with confidence within just over 2 minutes. LUS findings proved robust or had added value compared to CXR and medical history in 89% of examinations, comparable to results in the literature.

Sánchez González*Intensive Care Medicine Experimental* 2020, **8(2)**: 001133

Introduction: During the months of March to May we have experienced in Spain the consequences of the COVID 19 pandemic. Different factors can be related to the evolution of a pathology, both those of the pathology and the patient, as well as those derived from the high number of cases in a short period of time. Below we intend to analyze the different factors that are related to the evolution of COVID-19 pneumonia in our area.

Objectives: Describe the distribution and main characteristics of the patients. admitted to the ICU for COVID-19 pneumonia during the pandemic period.

Methods: Descriptive study carried out in a multipurpose ICU with 12 beds of critical care and 21 semi-critical care. All the patients admitted for COVID-19 related pneumonia admitted during the pandemic period were included.

Statistics: Qualitative variables are expressed as percentages and quantitative variables they are expressed as means and standard deviations (SD).

Results: 95 patients were admitted from March 14 to April 24. Were enabled 50 ventilators in 5 critical areas, reaching 40 intubated patients simultaneously. Figure 1: shows the distribution of income by week. 60% of admissions occurred in the first 2 weeks. Table1: describes the main characteristics of the patients.

100% of patients received Kaletra, Hydroxychloroquine and Azithromycin, 40% also received Tozilucimab, 34% Interferon and 58% corticosteroids. Table 2: describes other clinical characteristics and aspects related to mechanical ventilation.

	Renal insufficiency (%)	11.6
	Adverse events (%)	

Conclusion: The distribution of ICU admission for COVID-19 related pneumonia required quadrupling the capacity of ventilated patients in the first 2 weeks of the pandemic. The characteristics of the admitted patients, their location and resources used for treatment were conditioned by this aspect.

Community acquired urosepsis: a surgical intensive care experience

N. Shaikh¹; S. Ahmed²; T. Kazi³; M. Muna⁴

¹Hamad Medical Corporation, Doha, Qatar; ²Clinical pharmacy, HMC, doha, Qatar; ³Micu, HMC, Doha, Qatar; ⁴Cdc, CDC, Doha, Qatar

Correspondence: N. Shaikh

Intensive Care Medicine Experimental 2020, **8(2)**: 000013

Introduction: Urosepsis contributes significantly to the epidemiology of sepsis. Urosepsis is divided into community-acquired or hospital-acquired, depending upon the origin of infection acquired either from the community or from the health care setup. The literature about community-acquired urosepsis (CAUs) is limited and studies are small powered.

Objectives: Aim of our study was to know the epidemiology, bacteriology, severity and outcome of CAUs patients.

Methods: All patients admitted from the emergency department to the surgical intensive care unit (SICU) with urosepsis over a period of 10 years were identified and included retrospectively from the SICU register.

Results: During the study period 302 patients admitted with CAUs. The common etiology was obstructive uropathy (60%). Local Arabic population outnumbered the non-Arabic population (164/54.3%) and there were equal number of patients from both genders, 75% had acute kidney injury (AKI). Thirty eight percent patients had percutaneous nephrostomy and 24.8% patients underwent endoscopic stent insertion to relieve the obstruction. Ninety three percent patients were admitted with septic shock and 71.5% had bacteraemia.

The common bacteria (36.1%) was extended-spectrum beta-lactamase (ESBL) producing bacteria, with a predominance of *E. coli* (ESBL) (31.5%) and 54% required change of antibiotics to carbapenem. Eighty two percent patients had ARDS (acute respiratory distress syndrome). Patients with bacteraemia had a statistically significant AKI, ARDS and septic shock ($P < 0.001$). Male patients had significantly higher incidence of oliguria, intubation and ARDS ($P < 0.05$). Eight patients died of urosepsis giving mortality of 2.6%.

Conclusion: Patients obstruction to the flow of urine was the common cause for the CAUs. Urosepsis patients had a higher bacteraemia rate, corresponding to higher incidence of organ dysfunction and septic shock. ESBL bacteria were frequently causing urosepsis, requiring initial antibiotic to be changed to carbapenem. Mortality of our urosepsis patients were lower than mentioned in the literature.

"Find It, quick!": the challenge of finding the source of CPE bacterium in ICU

RY. G.¹; HY. Y.¹; PZ. N.¹; N. V.¹; SY. T.¹; ML. R.¹

¹Icu. sheba medical center, Emek Haela 9, Ramat Gan, Israel

Correspondence: R. Mor Levy

Intensive Care Medicine Experimental 2020, **8(2)**: 000068

Introduction: The Respiratory Intensive Care Unit at the Sheba Medical Center consists of 14 beds with ~ 470 admissions per year. The patient are exposed to infectious risk factors, suppressed immune status and are monitored via many central line catheters. Therefore, they are unable to cope with further infections. The data from the hospital's infection prevention unit were shown to be alarming in

terms of Carbapenemase-producing Enterobacteriaceae (CPE). CPE can produce a broad spectrum of infections; it is associated with high mortality and very limited therapeutic options. CPE cases outbreaks are mostly attributed to patient-to-patient transmission via healthcare workers. The challenge we faced with was to locate the source of the infection and solve it.

Methods: Active CPE surveillance included twice-weekly rectal screening of all patients. A case was defined as a patient detected with OXA-48 CPE >72 hours after admission. Several meetings were scheduled between hospital's infection prevention unit and the department staff, in order to define the source of the outbreak. Over the course of the several months samples were calculated from patients and their units. A root-cause analysis "Fish Bone" method was used to investigate the results. The clone was detected in 16 sink traps.

Results: From January 2016 to May 2017, 32 OXA-48 CPE cases were detected, 81% of these were *S. marcescens*. The common factor in all cases was the use of relatively large amounts of tap water. Educational intervention that engaged the ICU team led to high adherence to 'sink-contamination prevention guidelines'. No additional infections detected for 12 months.

Conclusion: Finding the source of CPE outbreak was necessary for the educational intervention and collaboration with the team of ICU to reduce the contagion of OXA-48 producing *Serratia marcescens*. Due to the fact that it is not possible to predict where the next infection will stem from, it is important to sample all sites of the patient environment, to conduct a multidisciplinary brainstorming session to increase the chances of finding the source.

Intensive Care Medicine Experimental 2020, **8(2)**: 000092

Introduction: Patients admitted to the ICU are exposed to risk factors such as: use of antibiotics, prolonged fasting, enteral and / or parenteral nutrition and proton pump inhibitors (PPI). These factors influence and promote an imbalance in the intestinal microbiota (Dysbiosis). As a result, there are multiple alterations that can develop locally and systemically, such as the increase in antibiotic resistance, decrease in immunoregulation and increase in pathogenic bacteria.

Objectives: Our objective was to study with molecular (metagenomic) techniques the variation suffered by the intestinal microbiota of the previously healthy patient who enters the ICU and the possible dysbiosis generated during the time of admission.

Methods: Patients admitted to the ICU are exposed to risk factors such as: use of antibiotics, prolonged fasting, enteral and / or parenteral nutrition and proton pump inhibitors (PPI). These factors influence and promote an imbalance in the intestinal microbiota (Dysbiosis). As a result, there are multiple alterations that can develop locally and systemically, such as the increase in antibiotic resistance, decrease in immunoregulation and increase in pathogenic bacteria.

Our objective was to study with molecular (metagenomic) techniques the variation suffered by the intestinal microbiota of the previously healthy patient who enters the ICU and the possible dysbiosis generated during the time of admission.

Results: The fecal microbiome of 30 patients was analyzed, 21 of them with three samples (M1, M2) and the remaining 9 with two samples (M1, M2 and M3). A total analysis of 81 rectal swabs was

done. According to the UniFrac (unweighted) beta diversity analysis, samples from previously healthy ICU patients show a different overall composition of the intestinal microbiota than they have one week after admission. Alpha diversity decreased significantly in the M3 samples compared to the admission samples. Taxonomic alterations in the samples (M3) included the enrichment of intestinal pathogens such as *Enterococcus* and the disappearance of several usual pathogens such as *Prevotella* and *Peptoniphilus*.

Conclusion: Our study showed that critical patients undergo rapid dysbiosis after admission to the ICU, promoting the development of possible infectious complications. Such alterations could be a target to study and develop therapies aimed at restoring a healthy microbiome in critical patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000122

Introduction: Infections affect 54% while antimicrobials (AM) are prescribed to 70% of ICU patients [1]. The heterogeneity managing infectious diseases (ID) in different ICUs remains a main obstacle for stewardship programs. Easy, fast transmissibility and AM resistance are of global concern. Altogether, they make the assessment of management, knowledge and training for intensivists an essential step toward improving outcome from ID in the ICUs.

Objectives: To explore the practice of Infectious diseases management in different ICUs.

Methods: An International cross sectional descriptive and analytical internet based open survey of Intensivists. The survey consisted of 25 closed and open-ended questions divided into 4 sections including free text annotations. Likert and semantic scales were used in 4 questions. After external peer-review, it gained endorsement by the ESICM. It was hosted on SurveyMonkey (July 30, 2019) and was available for 82 days. Invitations were shared on social media and by emails sent to the ID section members of the ESICM.

Results: The survey was initiated by 561 respondents from 82 countries. The 470 (83.8%) respondents who completed the survey were analysed. Respondents had a median ICU experience of 10 years (IQR 5-19) and were trained in Intensive Care Medicine as a sole specialty (30%), or dual along with anaesthesia (35.3%) or medicine (30.2%). 76.2% of the respondents were practicing as full-time Intensivists and 63.4% in University hospitals. 34% of the participants were from low- and middle-income countries (LMICs). The latter were more frequently working in smaller hospitals in the private sector compared to those from high-income countries (HICs) (23.1% versus 9%, $p < 0.001$ and 32.5% versus 8.1%, $p < 0.001$ respectively).

Only 2/3 of participants had adequate knowledge of the ID diagnostic capabilities in their hospitals. Despite expert opinion is available within 1 hour for 82.5% of them, the initiation of AM was protocolised in 68.5% of cases, and half of Intensivists seldom request non-ICU opinion. Most frequently, Intensivists sought non-ICU expert opinion in immunocompromised patients and in case of Extended or Pan-resistant microorganisms as well as fungal infections (63%, 43%, 55%, and 32% respectively). At the time of the survey, only 27.2% of Intensivists felt a need for expert opinion in case of viral infections.

Stewardship program was in place in just 66% of ICUs, and a regular microbiology round is lacking in about 40% of them. The implementation of Stewardship programs differed significantly between LMICs and HICs (61.9% versus 68.1%, $p = 0.013$).

Satisfaction with ID training and knowledge among Intensivists was low at 43.2%; even less in those working in LMICs (28.8%, $p < 0.001$). 95.5% of Intensivists think addressing such gap can improve patients' outcome and decrease cost and AM resistance.

Conclusion: From Intensivists' prospect, there is a need to improve training and knowledge in the field of ID. Stewardship programs are not universally implemented and ID management follow mostly a protocolised approach.

Intensive Care Medicine Experimental 2020, **8(2)**: 000129

Introduction: The increasing emergence and spread of drug-resistant pathogens all over the world has become catastrophic world health problems. In fact, we experienced an uncontrollable outbreak of multidrug-resistant pathogens and ICU closure for 3 weeks in January 2013. Based on the experience, we built an infection control bundle including contact precautions for every patient in the ICU, carrying personal alcohol-based hand rubs, cohorting patients who acquired drug-resistant pathogens, active surveillance cultures once a week, and enhanced environmental disinfection in January 2013.

Objectives: The purpose of this study is to evaluate the effectiveness of the systemic infection control bundle approach against acquisition of drug-resistant pathogens.

Methods: This was a retrospective historical control study conducted from April 2008 to March 2019 in 18-bed ICU of a tertiary care hospital in Japan. Every patient admitted to the ICU during the study period was eligible. Patients were divided into 2 groups: Conventional (from April 2008 to December 2012) or Intervention (from January 2013 to March 2019). The primary outcome was the number of hospital-acquired MRSA. We defined hospital-acquisition as the isolation of MRSA after 48 hours of hospitalisation.

Results: A total of 13,047 patients were included during the study period. There were 5,128 patients in the control group (39.3%) from 2008 to 2012 and 7,919 patients in the intervention group (61.7%) from 2013 to 2019. The hospital-acquisition of MRSA was observed 284 patients (5.5%) in the control group and 150 patients (1.9%) in the intervention group. The interrupted time-series analysis suggested that the intervention was significantly associated with reduced hospital-acquisition of MRSA [risk ratio, 0.342(95% confidence interval, 0.282-0.416); <0.01].

Conclusion: The Bundle approach could be an effective strategy to prevent hospital-acquisition of drug-resistant pathogens in ICUs.

Intensive Care Medicine Experimental 2020, **8(2)**: 000130

Introduction: Catheter-related blood stream infection (CRBSI) is a common serious infection and associated with increased mortality in intensive care units (ICUs). One of the most important strategies to prevent CRBSI is to minimize the duration of central venous catheterization. So We built a medical team consisting of doctors, nurses and pharmacists in ICU to discuss whether patients needed central venous catheter (CVC) in terms of monitoring hemodynamics and administering drugs, and recommend catheter removal to attending physicians every day in April 2019.

Objectives: The purpose of this study is to evaluate whether our team-based approach could shorten the total duration of catheterization and reduce CRBSI.

Methods: This was a retrospective historical control study conducted from April 2018 to January 2020 in the ICU of a tertiary care hospital in Japan. Every patient admitted to the ICU during the study period was eligible if they were inserted CVC. Patients were divided into 2 groups: Conventional group (from April 2018 to March 2019) or Interventional group (from April 2019 to January 2020). We set the primary endpoint as onset of CRBSI. The secondary endpoints included the duration of central venous catheterization, the length of ICU stay and hospital mortality. CRBSI was defined as bloodstream infection in patients with CVC, not related to another site.

Results: We included 490 patients: 259 in the Conventional group and 231 in the Interventional group. The reduced tendency of CRBSI was observed in the Interventional group, though nonsignificant [hazard ratio, 0.249 (95% confidence interval, 0.054-1.141; $p = 0.067$)]. The Interventional group was significantly associated with reduced duration of central venous catheterization (5 days vs 7 days; $p < 0.001$). No difference was observed in the length of ICU stay and in-hospital mortality between groups.

Conclusion: The team-based approach to assess CVC necessity could shorten the duration of central venous catheterization and might reduce CRBSI.

Risk factors and clinical characteristics of *Stenotrophomonas maltophilia* bacteremia acquired in Intensive care unit : A Propensity Score-Matched Analysis

T. Kamo¹; K. Misumi¹; T. Koinuma¹; Y. Hagiwara¹; T. Ogura¹

¹Critical care medicine, Saiseikai Utsunomiya Hospital, Utsunomiya, Japan

Correspondence: T. Kamo

Intensive Care Medicine Experimental 2020, **8(2)**: 000163

Introduction: Bacteremia is an important problem in intensive care units (ICUs) due to high rates of antimicrobial resistance and mortality. Especially *Stenotrophomonas maltophilia* (SM) is an important pathogen that induced nosocomial infections. However, the risk factors for SM bacteremia in critically ill patients admitted to the ICU who are not immunocompromised, such as hematological tumor patients and malignant tumor patients, are unknown.

Objectives: We conducted a propensity score matching analysis using control patients with the other Gram negative bacteremia in ICU.

Methods: This study was conducted at ICU in the Saiseikai Utsunomiya Hospital, a critical care center in Tochigi, Japan. The medical charts of ICU-acquired bacteremia were retrospectively reviewed between January 2013 and March 2020. ICU acquired bacteremia was defined as at least one positive blood culture together with clinical features compatible systemic inflammatory response syndrome and occurring ≥ 72 hours after ICU admission. Gram-positive bacteremia and fungemia were excluded. Because, these bacteremia are likely to have different initial treatment options. Because of the relatively few SM group, for multivariable modeling we performed a propensity score analysis with 1:1 matching with age, sex, neutropenia, and APACHEII score.

Results: Of 345 bacteremia, 92 (27%) were included, and 15 (4%) of which were SM bacteremia.

Propensity score matching identified 14 patients in each cohort. With propensity score matching, there were no significant difference in 30 days mortality and 90 days mortality between SM bacteremia and the other Gram negative bacteremia.

However, the length of hospital stay was significantly longer in SM group (66 days vs 106 days, $P < 0.005$). Days to positive blood culture from ICU admission were longer in SM group (15 days vs 24 days, $p < 0.005$). The ratio of carbapenems and anti-MRSA drugs used in combination was significantly higher in the SM bacteremia group (28% vs 64%, $p < 0.05$), and the administration duration was also significantly longer than the other bacteremia group (0.8 days vs 6.0 days, $p < 0.05$). Use rate of the extracorporeal membrane oxygenation (ECMO), there was no significant difference but higher in SM bacteremia than the other bacteremia at 70% and 0%, respectively.

Conclusion: Our study showed that SM should be considered as the causative bacteria that developed after prolonged ICU stay. And, in addition to the previously known risk factor for immunosuppression, longer combination use of broad spectrum antibiotics use was could be risk factor of SM bacteremia in ICU settings. Although there was no significant difference in mortality, it was found that the acquisition of SM bacteremia in ICU prolongs the hospitalization period.

Previous infections as a risk factor for multidrug-resistant *Acinetobacter baumannii* in ventilator-associated pneumonia

S. J. Kwon¹; I. Jung¹; J. Son¹; J. Kim²; D. Kang¹; S. Park¹

¹Respiratory and critical care medicine, Konyang University Hospital, Daejeon, Republic of Korea; ²Respiratory and allergic medicine, Konyang University Hospital, Daejeon, Republic of Korea

Correspondence: S.J. Kwon

Intensive Care Medicine Experimental 2020, **8(2)**: 000242

Introduction: *Acinetobacter baumannii* (AB) has high resistant to carbapenems and other antibiotics and has become an increasingly important cause of intensive care units (ICU) nosocomial infections. Factors increasing significantly the risk of ventilator-associated pneumonia (VAP) due to *Acinetobacter* spp. include long duration of hospital stay, longer time on mechanical ventilation (MV), prior episode of sepsis, and prior antibiotic use. A preexistent acute-phase response can reduce the proinflammatory responses to AB, which is associated with an impaired bacterial clearance.

Objectives: The purpose of this study is whether the risk factors for VAP by multidrug-resistant AB (MDR-AB) are the previous infections, the prior antibiotic uses, and a longer duration of mechanical ventilation, or not.

Methods: Retrospectively analysis of medical records of 209 patients receiving bronchoscopy due to suspected VAP during mechanical ventilation in ICU from January 2011 to December 2019 in Konyang University hospital, South Korea. Pathogens were isolated by a quantitative bacterial culture and susceptibility test of the lower respiratory specimens using bronchoscopy.

Results: 116 patients excluding 93 patients that met exclusion criteria were available for analysis.

54 patients (46.5%) of VAP patients had MDR-AB. 48 patients (41.4%) of patients was received mechanical ventilation due to infections, including 44 pneumonia patients (91.6%). Although the 28 days mortality was 29.6% of VAP by MDR-AB, there was no significant difference between MDR-AB and other pathogens. There was no significant difference in late onset VAP between MDR-AB and other pathogens (85.2% vs. 80.6%, $p = 0.518$).

The previous infections including pneumonia were more frequent in those with VAP by MDR-AB than in those with other pathogens (51.9% vs. 27.4%, $p = 0.007$). The risk factor for VAP by MDR-AB was not associated to the prior antibiotic uses (OR = 6.737, 95% CI; 0.800-56.765, $p = 0.079$), but was associated with the previous infections in a logistic regression analysis (OR = 2.361, 95% CI; 1.061-5.250, $p = 0.035$).

Conclusion: The risk factor for VAP patients by MDR-AB are associated with the previous infections rather than the prior antibiotic uses, irrespective of the duration of mechanical ventilation.

Correspondence: S. Patil

Intensive Care Medicine Experimental 2020, **8(2)**: 000255

Introduction: IV fosfomycin is used particularly in difficult-to-treat or complex infections, caused by both Gram-positive and Gram-negative pathogens including multidrug-resistant strains. Despite its clinical use for almost five decades, data on the use of Intravenous (IV) fosfomycin in clinical routine is still limited. We intend to observe the effectiveness and safety of intravenous fosfomycin in real-life setting.

Objectives: The primary objective is to observe the current clinical use of IV fosfomycin. Secondary objectives are clinical outcome, impact of variables on mortality and adverse events.

Methods: Multicentric retrospective study conducted among recipients of IV fosfomycin for the treatment of multi-drug resistant organism (MDRO) infections from 4 tertiary care centers from India. Medical records were analyzed for clinical diagnosis, pathogen, fosfomycin posology, adverse events with CCI, Pitts, qSOFA score.

Results: Overall, 309 patients received IV fosfomycin of which 17% were immunocompromised. Main indications for fosfomycin administration were bacteremia (45.3%), pneumonia (15.8%), septic shock (14.3%), UTI (13.9%). Common pathogens were *K. pneumoniae* (43.3%), *E. coli* (21.7%), polybacterial (20.8%), *Pseudomonas* spp. (11.7%), *Staphylococcus* spp. (2.9%). Average dose of fosfomycin was 9.8 ± 4.06 g/d (Range: 1 g to 24 g/d) administered for average duration of 4.66 ± 3.68 days (Range: 1-16 days). Hypokalemia was the most

common (62.1%) adverse event observed followed by hypernatremia (24.2%). Overall clinical improvement was observed in 55% patients. Immunocompromised status, Pitts score, CCI, qSOFA score and hypernatremia were associated with significant impact on survival (Table 1).

Table 1: Comparison of variable among survivor and non-survivor (n=309)

Variables	Survivor (n=170)	Non survivor (n=139)	P value
Age	61.91 ± 15.24	58.99 ± 16.58	0.14
Sex (M)	98 (57.64%)	95 (68.34%)	0.05
Charlsons comorbidity index (CCI)	1.11 ± 1.11	3.22 ± 1.96	<0.0001
Immunocompromised	22 (12.94%)	30 (21.58%)	0.04
Septic shock	19 (11.17%)	25 (17.98%)	0.10
Pitts score (Overall)	2.32 ± 2.52	3.51 ± 2.22	<0.0001
qSOFA score	1.44 ± 0.86	1.85 ± 0.95	0.0003
Enterobacteriaceae	101 (59.41%)	87 (62.58%)	0.63
Complicated UTI	42 (24.7%)	11 (7.9%)	0.0001
Average dose (g/d) (Excluding ≥ 24 hrs dosing)	11.88 ± 3.83 (n=134)	11.62 ± 4.32 (n=117)	0.92
Average duration (d)	4.71 ± 3.81	4.50 ± 3.21	0.77
Hypokalaemia	110 (64.7%)	82 (58.9%)	0.34
Hypernatremia	31 (18.2%)	44 (31.6%)	0.007

Conclusion: IV fosfomycin was used across different indications and sites of infection in critically ill patients with clinical improvement in 55% patients. Hypokalemia is very common adverse event in practice; however, hypernatremia is associated with increased association with mortality in our study.

Intensive Care Medicine Experimental 2020, **8(2)**: 000305

Introduction: Carbapenem resistant Gram-negative bacterial (CRB) infections constitute a significant menace for healthcare systems, especially in high endemicity countries, such as Greece. Limited therapeutic options and high mortality rates call for prompt recognition and isolation of CRB carriers, preventing patient-to-patient transmission.

Objectives: To evaluate the prevalence of intestinal colonization with CRB on admission to Intensive Care Unit (ICU), assess the rate of CRB-related infections and identify risk factors.

Methods: This is a retrospective observational study that included all patients admitted to the ICU of a tertiary hospital in Greece, between September 2019 and March 2020. Rectal swabs for CRB detection were collected upon ICU admission in the first 24 hours. Medical records of the patients were reviewed for evaluation of age, sex, source of ICU admission, previous antibiotic therapy, comorbidities, CRB infections and length of ICU and hospital stay. Rectal swabs were cultured for screening at Brilliance CRE agar; in all positive results resistance to imipenem and meropenem was confirmed with susceptibility testing and phenotypical methods of carbapenemase production. We used chi-square with Yates' correction to compare categorical attributes, Kruskal-Wallis Test for the medians and t-test for the means of numerical variables, with a p value <0.05 statistically significant.

Results: A total of 158 patients were admitted to the ICU during a 6-month period. All of them were screened for intestinal colonization with CR-GnB. Among them, 27 patients (17%) were colonized with one or more Carbapenemase producing (CP)-CRB strains, with *Klebsiella pneumoniae* being the most prevalent (74%), followed by *Acinetobacter baumannii* (37%) and *Pseudomonas aeruginosa* (7.4%). Predisposing factors for CRB colonization were the presence of comorbidities, the source of ICU admission with over 85% transferred from another acute care setting (ICU, non-ICU ward), recent antibiotic exposure (100%), and hospital admission in the previous 6 months (52%) (table1). The rate of CRB infections among carriers was 52% (n=14/27). In all but three patients the colonizing and infecting strains were the same. Median time from rectal screening to infection was 10d. The most common site of infection was the lung in ten patients (37%), followed by primary bloodstream infection in seven (26%). Baseline characteristics among colonized patients with CRB infections and non-CRB infections were not significantly different, except for the length of ICU and hospital stay (table1).

Table 1.Characteristics of CRB infected and non infected cases among carriers

Variables	colonized patients (n=27)	non-CRB infection (n=13)	CRB infection (n=14)	P-value*
Median age (IQR), years ²	71(29-89)	72 (39-89)	69 (29-86)	0.13
Male gender [□]	21(77%)	9 (69%)	12 (86%)	0.32
Hospital stay pre-ICU ³	17.4 (14.6)	12.2 (13)	21.9 (14.4)	0.1
Hospital admission in the previous 6 mo [□]	14 (52%)	8 (62%)	6 (43%)	0.34
Heart disease [□]	18 (85%)	9 (69%)	9 (64%)	0.89
Diabetes mellitus II [□]	7 (26%)	4 (31%)	3 (21%)	0.91
Chronic pulmonary disease [□]	13 (48%)	7 (54%)	6 (43%)	0.85
Immunosuppression [□]				
Chronic Kidney Disease [□]	3 (11%)	1(7%)	2 (14%)	NA
Malignancy history [□]				
Length of ICU stay ²	8(5-26)	5 (4-8)	25.5(12.25-50.25)	0.0014*
Length of hospital stay ²	32.5(12.75-53)	14(10.5-27)	39(34-54.5)	0.008*
ICU mortality rate [□]	12 (44%)	5 (38%)	7 (50%)	0.83

[□]Chi-square Test, ²Kruskal-Wallis (days, median, IQR), ³t-test (days, mean, SD) *P<0.05

Conclusion: Our findings suggest that CRB carriers admitted to the ICU suffer from an increased risk of developing CRB infections with high mortality rate, and significantly prolonged ICU and hospital stay. Surveillance cultures on admission and early patient and staff cohorting may limit CRB transmission and guide empirical treatment in case of subsequent infection.

Intensive Care Medicine Experimental 2020, **8(2)**: 000332

Introduction: Studies of patients admitted to intensive care units (ICU) with sepsis have shown that thyroid function abnormalities are associated with adverse outcomes. It has also been suggested that patients' thyroid levels prior to critical illness could affect sepsis mortality, even at subclinical levels(1). As thyroid dysfunction is common in the general population, this may represent a modifiable risk factor for sepsis(2,3). To our knowledge, the association between thyroid status and risk of bloodstream infections (BSI) has not previously been investigated in a large population-based study.

Objectives: To determine if thyroid hormone levels in the general population is associated with future risk of BSI and mortality.

Methods: Thyroid function was measured in 35,263 Norwegian men and women participating in the second HUNT Study(HUNT2, 1995-97). Thyroid function was defined as Thyroid Stimulating Hormone (TSH) levels combined with free thyroxine (FT4) and total triiodothyronine (T3). HUNT2 data was linked to prospective information from the Mid-Norway Sepsis Register (MNSR), on clinically relevant BSI from local and regional hospitals until 2011. TSH levels were classified into six categories. Most of the BSI patients had sepsis. We evaluated the risk of first-time BSI, of all causative agents and by the most common infecting bacteria *E. coli*, *S. aureus* and *S. pneumoniae*. Risk of mortality was assessed within 30 days of BSI and all cause-mortality during the whole follow-up period. We used Cox regression to estimate hazard ratios with 95% confidence interval, using TSH 0,5-1,4 mU/L as reference.

Results: After excluding participants with known thyroid disease, 31,707 HUNT2 participants were eligible for follow-up of BSI. During a median of 14,8 follow-up years, 1,138 experienced at least one episode of BSI and 198 died within 30 days. Table 1 show the hazard ratios adjusted for age, sex, socioeconomic status, BMI and smoking. The higher TSH levels showed some association with development of BSI, but the results have a low precision and the confidence interval is also in agreement with no association. The results were robust for further adjustments of comorbidities (data not shown). The observed pattern displayed in Table 1 did not change across follow-up of sepsis due to *E. coli*, *S. aureus* and *S. pneumoniae* or for 30-day mortality after BSI.

Conclusion: We found an association between higher TSH levels and a lower risk of hospitalizations and mortality due to BSI. However, the width of the confidence intervals also coincides with no risk difference. All participants with abnormal levels of TSH were advised for further investigations, leaving a possibility that our associations could have been stronger in an untreated population.

Intensive Care Medicine Experimental 2020, **8(2)**: 000356

Introduction: Since December 2019 a pandemic of new acute respiratory distress syndrome due to coronavirus disease (C-ARDS) has been reported worldwide, with high need of intensive care admission and mechanical ventilation. A high frequency of obesity among patients admitted to ICUs for C-ARDS has been demonstrated; in previous studies, Body Mass Index (BMI) has been described as a major risk factor for ICU admission and ARDS severity.

Objectives: The aim of the study was to investigate if C-ARDS patients had a higher BMI compared to a previous population of ARDS patients.

Methods: We conducted a retrospective analysis of 140 consecutive C-ARDS patients admitted to the intensive care units of San Paolo Hospital in Milan and of Maggiore Hospital in Lodi from February 25th 2020 to April 19th 2020. All patients had a laboratory-confirmed SARS-CoV-2 infection diagnosis by RT-PCR on nasopharyngeal swabs. We compared C-ARDS patients with 247 consecutive ARDS patients enrolled in previous studies and ongoing studies.

Results: BMI was significantly higher in C-ARDS compared to ARDS (28 [25–31] kg/m² vs 25 [22–29] kg/m², p<0.0001). We found a significantly higher percentage of overweight and obese patients in C-ARDS than ARDS patients admitted to the ICU (49% vs 33% and 29% vs 16%, p<0.0001). At the time of ICU admission, mechanically ventilated C-ARDS patients had PaO₂/FiO₂ ratio significantly lower (120 [90–165] vs 169 [127–216] with positive end-expiratory pressure (PEEP) level significantly higher (12 [10–14] cmH₂O vs 10 [10–12] cmH₂O, p<0.0001). According to the ARDS Berlin definition, we found that the percentages of severe ARDS patients was significantly higher in C-ARDS patients (36% vs 13%, p<0.0001).

Conclusion: We found that, among patients admitted in ICU and requiring mechanical ventilation, C-ARDS population had both a higher percentage of patients with BMI ≥ 25 and higher percentage of patients with severe ARDS compared to "other ARDS". Our results suggest that a possible relationship between higher BMI and development of severe ARDS patients could exist among C-ARDS patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000359

Introduction: Healthcare personnel working in contact with severe patients are a risk group for which annual vaccination against influenza A is recommended.

Objectives: To identify the adherence rate to the influenza A vaccine among healthcare personnel in the Intensive Care Units (ICUs) of Catalonia during 2018-2019 season. Describe and analyze the reasons for non-vaccination in different worker groups.

Methods: Multicentre, observational and cross-sectional study based on an anonymous paper survey sent to healthcare personnel from 19 ICUs in Catalonia. Healthcare workers were classified as physicians (including residents and fellows) and non-physicians [nurses and Auxiliary Nursing Care Technician (TCNA)]. The survey included sociodemographic and basic clinical information related to knowledge regarding anti-influenza vaccination guidelines as well as attitudes regarding campaigns and recommendations made by the competent authorities. Reasons for non-vaccination were classified as either personal, professional or scientific. Chi-square and t-test were used for the statistical analysis and $p < 0.05$ was considered statistically significant. The study was approved by the PSMar Clinical Research Ethics Committee (No. 2019/8495/I).

Results: Among 917 answered surveys, 730 (69%) were properly completed and included in the study. 79% of the participants were women and the mean age of the total sample was 39 (12) years old. 170 surveys (23.3%) corresponded to physicians and 560 (76.7%) to non-physicians (421 nursing and 139 TCNA). Total vaccination rate was 43.4% and it was higher in physicians compared to non-physicians (66.5% vs. 36.4%; $p < 0.000$). Vaccination was more frequent in men than in women (57.1% vs. 39.8%, $p < 0.000$). Factors related to the decision of vaccination were self-protection (86%) and patient protection (63%). Reasons for non-vaccination in physicians ($n = 57$; 33.5%) and non-physicians group ($n = 356$; 63.6%) were scientific [no protection of the vaccine (8.7% vs. 23.7%, $p = 0.011$), financial motivations related to vaccination campaigns (5.3% vs. 19.5%, $p = 0.008$), the possibility of contracting the flu with the vaccine (1.8% vs. 17.3%, $p = 0.002$) and low effectiveness of the vaccine (28.1% vs. 36.5%, $p = 0.217$), personals [forgetfulness (24.6% vs. 8.1%, $p = 0.000$), lack of time (24.6% vs. 6.7%, $p = 0.000$) and fear of side effects (21.1% vs. 25.9%, $p = 0.433$)] and professional as inconvenience on the vaccination site (7% vs. 0.5%, $p = 0.004$). Overall 57% of healthcare personnel included in this study (31.6% of physicians and 5.9% of non-physicians; $p < 0.001$) has either no intention or doubts about being vaccinated in the 2019-2020 campaign. The most effective reported factor influencing the decision to vaccination were hospital teaching sessions (60%) and social media (40%).

Conclusion: Vaccination rate among ICU healthcare personnel is low, however it is higher in physicians than in non-physicians. Reasons for non-vaccination differ between both worker groups. A low percentage of ICU workers are decided to be vaccinated next season. To stress in the evaluated factors related to vaccination and non-vaccination could be helpful in design and establish measures to promote vaccination among ICU healthcare personnel

Intensive Care Medicine Experimental 2020, **8(2)**: 000390

Introduction: Our 350 bed center (10 ICU beds) assisted 2200 COVID-19 patients in the period March to June 2020, of whom 90 were admitted to ICU. A great healthcare challenge.

Objectives: To describe the characteristics of COVID-19 critically ill patients admitted to the ICU.

Methods: Retrospective descriptive study including critically ill COVID-19 patients admitted to the ICU from March 2020 to June 2020. Variables: sociodemographic, comorbidities, COVID-19 treatment, adverse drug reactions, severity scores at ICU admission, organ supports, complications, ICU and hospital stay/mortality. A descriptive analysis was performed. Continuous variables have been expressed as median/ interquartile range and categorical as percentage.

Results: 90 COVID-19 patients confirmed by PCR were included. 10 patients were excluded due to transfer to another hospitals. Mean age 65 years (56-72); 68% male; symptoms began 9 (7-15) days before admission. Main comorbidities were obesity 43% and hypertension 41%. Hospital stay before ICU admission was 3 (2-6) days. APACHE II 15 (10-18), SAPS 3 56 (48-65), SOFA at ICU admission 5 (3-8); 94% were admitted for severe respiratory failure, PaO₂/FiO₂ 85 (66-125), 84% required invasive mechanical ventilation (MV), 4% non-invasive MV, and 11% high flow nasal cannula. Videolaryngoscopy device was used to intubate in 95%; 74% needed prone position, with a median of 2 cycles (1-3) per patient, MV 9 (2-22) days, 23% needed tracheostomy, 56% required vasopressors, 4% continuous renal replacement therapy. At ICU admission the mean white blood cell count was 9300 μ L (6222-13330), absolute lymphocyte count 700 μ L, LDH 479U/L (350-582), D-dimer 1.97 μ g/ml (0.76-7.6). At the first 48 h ferritin levels was 1713 ng/ml (1020-2481) and IL-6 130 pg/ml (38-358). COVID-19 treatments: hydroxychloroquine 90%, lopinavir/ritonavir 91%, interferon beta-1b 41%, azithromycin 75%, tocilizumab 49%, remdesivir 1%, systemic glucocorticoids 75%, anticoagulation 40% prophylactic, 14% intermediate dose, 45% therapeutic dose. Adverse drug reactions were 26%; 12% suffered thromboembolic events and 16% haemorrhagic events, 46% required change of anticoagulant drug, 5% developed antiheparin antibodies. Nosocomial infection was diagnosed in 51%, with an outbreak of *Stenotrophomonas maltophilia* affecting 21% of patients. ICU stay: 12 (5-25) days, ICU mortality 53%, Hospital mortality 56%.

Conclusion: COVID-19 patients have shown a high mortality, conditioned by their respiratory evolution, with an infrequent use of non-invasive MV and high flow nasal cannula; associated with a high incidence of nosocomial infection and a delayed ICU admission.

Intensive Care Medicine Experimental 2020, 8(2): 000397

Introduction: Selective digestive decontamination (SDD) have been associated with reduced mortality and lower ICU-acquired rates. However, the effect SDD in areas where multidrug-resistant Gram-negative bacteria are endemic is of great interest.

Methods: This study was conducted in a 30-bed-medical-surgical ICU. All consecutive patients admitted to the ICU from October 1, 2011 to September 30, 2019 expected to require tracheal intubation > 48 hours were given SDD (SDD study group) with a 4-day course of intravenous cefotaxime, plus enteral colistin, tobramycin, nystatin in an oropharyngeal paste and in a digestive solution. Oropharyngeal and rectal swabs were obtained on admission and once weekly. We used ENVIN nosocomial infections (NI) criteria. We compared all patients admitted to ICU with ICU NI from October 1, 2010 to September 30, 2011 (non-SDD group) to the SDD study group. A univariate and a multivariate logistic regression analysis were performed. For each one of the infections the incidences per 1000 days of exposure in each cohort and the corresponding relative risks were obtained using the Poisson regression. Statistical significance was $p \leq 0.05$. We analyzed colistin- and tobramycin-resistant colonization and also antibiotic consumption as Defined antibiotics Daily Doses (DDD).

Results: Results are shown in Tables 1, 2 and 3.

Secondary bacteremias/1000 ICU days	4.69	2.05	<0.001	0.438 (0.313 - 0.613)
Multiresistant germs/1000 ICU days	9.59	2.53	<0.001	0.263 (0.205 - 0.339)

VAP: ventilator associated pneumonia; MV: mechanical ventilation; CRB: Catheter related bacteremia;

There were no statistical significant differences between both groups in type of admission or demographic data. Patients with SDD had significantly less Extended Spectrum Beta-lactamase (ESBL), Gram Negative Bacteria Multiresistant (GNB-MR) and *Acinetobacter spp* infections. We had also a significant reduction in ventilator associated pneumonias (VAP), urinary infections and other secondary bacteremias and antibiotic resistant bacteria infection (ARB) rates, in SDD group versus non SDD. There was no infection by *Clostridium difficile*. Colistin-resistant colonization was 16,5% and tobramycin-resistant colonization was 25,7% of samples. There was a decrease on the DDD/100 ICU stays after SDD.

Conclusion: After 8 years applying SDD a significant reduction of infections by ESBL, GNB-MR and *Acinetobacter*, was observed. A significant decrease of VAP, secondary bacteremias, urinary and ARB infections rates was also shown. An antibiotic consumption reduction was found after SDD. Low rates of colistin- and tobramycin-resistant colonization bacteria were observed

What influences duration of antibiotic therapy?

Results from a systematic literature review

R. Janssen¹; A. Oerlemans²; H. Van Der Hoeven¹; M. Hulscher²; J. Schouten¹

¹Intensive care, Radboud University Medical Center, Nijmegen, Netherlands; ²iq healthcare, Radboud University Medical Center, Nijmegen, Netherlands

Intensive Care Medicine Experimental 2020, 8(2): 000409

Introduction: Antibiotic use in hospitals, also in intensive care units (ICUs), is often inappropriate or unnecessary. Overuse of antibiotics drives antibiotic resistance. There are merely two ways to reduce the quantity of antibiotic use: not to start or early withdrawal. In ICUs the latter is far more acceptable. Even though emerging evidence suggests that reducing the duration of antibiotic therapy is safe for various types of infections, antibiotic therapy is commonly prescribed longer than recommended in daily practice. Professional performance of recommended care may be influenced by a large variety of factors. It is unclear, however, which factors influence the chosen duration of antibiotic therapy.

Objectives: The objective of this systematic literature review was to identify factors of antibiotic therapy duration in hospitals, with a special focus on ICUs.

Methods: A systematic literature search was conducted using PubMed, Embase, PsycINFO and Web of Science from 2000 onwards. All qualitative, quantitative and mixed-method studies in any language, concerning adults, and performed in an in-hospital setting were

eligible for inclusion. Studies were included if they reported original data on determinants of antibiotic therapy duration. The identified factors were categorized using the comprehensive, integrated checklist of determinants of practice as developed by Flottorp *et al.* (2013).

Results: Seventeen articles were included in this review, of which one specifically focussed on the ICU. Several determinants influencing duration of antibiotic therapy were found (see Table 1 for some examples). Most of these were factors related to individual health professionals (e.g. knowledge and skills, cognitions and attitudes, professional behaviour), followed by professional interactions (e.g. team processes, communications and peer influences), patient factors (e.g. patients' perceived needs), and guideline factors (e.g. (in)consistency with other guidelines, feasibility of the recommendations, quality of the recommendation).

Table 1. Factors influencing duration of antibiotic treatment, classified according to the framework of Flottorp *et al.* (2013)

Category	Determinants
1. Guideline factors	Conflicting guidelines Lack of evidence base for length of treatment
2. Individual health professional factors	<u>Knowledge and skills</u> Doctors don't know how to re-evaluate/stop antibiotics
	<u>Cognitions (including attitudes and emotions)</u> Feeling of personal responsibility for an infectious complication
	<u>Professional behaviour</u> Personal longstanding preferences of the surgeons
	(Older) age of patient Severity of infection
3. Patients factors	<u>Team process (Etiquette, Group culture)</u> Type of surgical (sub)specialty Type of medical specialty (surgical vs. general medical)
	<u>Communication and influence</u> Lack of supervision leaving junior staff to make complex medical decision Input from a specialist in infectious diseases
	(Shortage of) human resources (Lack of) system that facilitates stopping of antibiotics
4. Professional interactions	No formal encouragement to conduct review and revise to stop antibiotics
5. Incentives and resources	Safety from litigation for a complication
6. Capacity for organizational change	
7. Social, political and legal factors	

Conclusion: Only a few original studies have been performed investigating determinants of antibiotic therapy duration, with a remarkable lack of ICU studies. To design the most appropriate and effective improvement intervention, interventions need to be informed by clear information on determinants of behaviour. This review provides the first step for the development of effective behavioural interventions to optimize duration of antibiotic therapy. Further studies need to be conducted, specifically at ICUs, to gain more insight into factors that influence professional behaviour regarding the duration of antibiotic therapy.

Intensive Care Medicine Experimental 2020, **8(2)**: 000413

Introduction: Faecal peritonitis is a common cause of sepsis and ICU admission leading to up to 29% hospital mortality, prolonged ICU and hospital length-of-stays and increased costs. Risk factors associated with prognosis vary in different published studies.

Objectives: To analyse clinical, analytical, surgical, microbiological and physiological factors associated with poor prognosis (defined by ICU and hospital mortality, need for ICU readmission and prolonged ICU and hospital length-of-stay), within a cohort of ICU patients with the diagnosis of secondary peritonitis.

Methods: Retrospective single-centre observational cohort study from January 2015 to June 2018. Patients included suffered secondary peritonitis due to hollow viscera perforation, both as a reason for admission and/or during ICU stay. Quantitative variables are shown as mean and standard deviation, or as median with the interquartile range in case of failure to comply with normality. Qualitative variables are expressed as percentages. Multivariate analysis with binary backward stepwise logistic regression was performed. Odds ratio of the predictor variables of ICU mortality and bad prognosis are shown.

Results: 130 patients were recruited. Median age of 65 years (55-74), 45% were women. SAPS 3 median of 53.5 (43 - 65), ICU median stay 7 days (4 - 12) and ICU hospital stay 14 days (8 - 21). Readmission rate of 6.2%. ICU mortality 5.4% and hospital mortality 9.2%. In the multivariate analysis, endocrine comorbidity showed an OR 3.611 (CI 95%: 1.217-10.715; p=0.021), need for mechanical ventilation OR 12.275 (CI 95%: 1.974-76.327; p=0.007), need for parenteral nutrition OR 5.747 (CI 95%: 1.565-21,101; p=0.008), faecal peritonitis OR 2,908 (CI 95%: 1,176- 7,192; p=0.021), need for new surgery after peritonitis OR 79,746 (CI 95%: 6,718- 946,643; p=0.001) and SOFA at day 1 above 7 OR 6,939 (CI 95%: 2,208-21,814; p=0.001). Microbiological variables showed no correlation with bad prognosis.

Conclusion: Clinical, physiological and surgical characteristics showed a relationship with poor prognosis of patients with secondary peritonitis. Microbiological variables did not.

Correspondence: R. Muñoz-Bermúdez

Intensive Care Medicine Experimental 2020, **8(2)**: 000494

Introduction: Anidulafungin is commonly used for the treatment of abdominal diseases caused by *Candida* spp. in critically ill patients.

Objectives: To analyze the variability in the pharmacokinetics (PK) of anidulafungin and its diffusion in ascitic fluid in patients admitted to an Intensive Care Unit (ICU).

Methods: A prospective, observational, and descriptive pharmacokinetic study in a single ICU. Included were all patients, who received intravenous anidulafungin from October 2014 to June 2019 with a loading dose of 200 mg followed by 100 mg/day as maintenance dose and for whom the extraction was possible. Extraction of plasma samples and ascites fluid was performed at the second day of treatment [valley or predose (C_{min}) and/ or peak (C_{max}) at the end of the infusion] simultaneously whenever possible. Demographic variables, pathological, analytical history and PK data were included. Quantitative variables are described as means (standard deviation) or medians (interquartile range) and qualitative variables as relative frequencies. This project was approved by the PSMar Committee for Clinical Research Ethics (No. 2016/6987/1)

Results: A total of 10 patients aged 65 (10.6) years, 6 (60%) men, Body Mass Index (BMI) 26.2 (3.6) kg/m². 6 (60%) of them had surgical pathology. A total of 14 plasma and ascites fluid extractions were performed. The analytical values corresponding to the day of extraction were: mean serum creatinine of 1.09 (0.53) mg/dL, albumin 3.17 (0.96) mg/dL and a median bilirubin 4.9 [2, 3-17.8] mg/dL. PK data: Mean C_{min} 3.4 (1.5) mg/dL and C_{max} 5.4 (3.2) mg/dL in plasma; mean concentration in ascitic fluid 1.11 (0.8) mg/dL. Ratio C_{ascitic}/C_{min} plasma was calculated in 5 patients with a median of 0.23 [0.17-0.29]. In one case, ascites fluid levels could be extracted at C_{min}, C_{max}, 4 h and 6 h after one administration. Anidulafungin concentrations were 0.52 mg / dL, 0.51 mg / dL, 0.59 mg / dL and 0.68 mg / dL, respectively. The concentrations of anidulafungin observed in ascites fluid were higher than the epidemiological cut-off points (ECOFF value) of this echinocandin for the different *Candida* spp species, which ranged from 0.015 mg/L for *C. albicans* to 0.25 mg/L for *C. krusei*.

Conclusion: The mean anidulafungin penetration in ascitic fluid was low, 23%. However, the concentrations reached in ascites fluid could be sufficient to treat *Candida* spp since they exceed the epidemiological cut-off points.

Intensive Care Medicine Experimental 2020, **8(2)**: 000504

Introduction: Infections represent at least half of the clinically relevant complications in critically ill burn patients, and are one of the most frequent causes of death in this population. Selective Digestive Decontamination (SDD) is an infection prevention and control strategy conceived to minimize infections and, thus, it may have potential benefits in burn patients.

Objectives: We aim to assess the trend in the incidence of infections, type of microorganisms and use of antimicrobial agents before and after the implementation of SDD in a Burns Unit (BU).

Methods: We conducted a retrospective observational study in a 5-bed BU of a University Hospital. We collected data from all the patients admitted to the BU within a baseline period without SDD (2 years) and an SDD period (8 months). Chi-square, Student's T and Mann-Whitney U tests were applied for comparisons, as appropriate.

Results: A total of 48 patients were included, of which 35% received SDD (n=17). We did not find any statistically significant differences between baseline and SDD periods in terms of age (62 vs 61 years-old, p=0.86), gender (71% vs 65% male, p=0.65), BSA (23 vs 20%, p=0.52), smoke inhalation injury (32% vs 24%, p=0.53), APACHE-II (19 vs 16,

p=0.08), ABSI (7 vs 6, p=0.50) or mortality (26% vs 12%, p=0.25). Our findings are depicted in the Tables.

Table 1. Incidence of infections, before and after the implementation of SDD.

	Baseline period	SDD period	p-value
All infections			
Incidence	58%	47%	0.46
N° episodes/patient	1.94	0.88	0.20
Days to event	11 (5–15)	21 (6–30)	0.05
Bacteraemia			
Incidence	16%	6%	0.31
N° episodes/patient	0.23	0.06	0.25
Days to event	22 (20–27)	54 (54–54)	0.38
Respiratory infections			
Incidence	36%	29%	0.67
N° episodes/patient	0.81	0.35	0.25
Days to event	6 (5–11)	7 (5–17)	0.69
Skin and soft tissue infections			
Incidence	32%	24%	0.53
N° episodes/patient	0.90	0.47	0.38
Days to event	16 (12–31)	30 (27–32)	0.26

Table 2. Type of microorganisms before and after the implementation of SDD.

	Baseline period	SDD period	p-value
Staphylococcus aureus infections	3%	12%	0.24
Streptococcus pneumoniae infections	10%	0%	0.19
Other Gram-Positive infections	32%	6%	0.04
NF Gram-Negative bacilli infections	23%	18%	0.69
Enterobacteriaceae infections	29%	6%	0.05
Enterobacteriaceae infections	29%	6%	0.05

Table 3. Use of antimicrobial agents before and after the implementation of SDD.

	Exposed patients, %			Days of treatment, P50 (P25–P75)		
	Baseline period	SDD period	P	Baseline period	SDD period	P
NAP penicillins	40	29	0.48	4 (2–8)	8 (6–9)	0.29
AP penicillins	36	21	0.34	6 (4–10)	13 (4–14)	0.35
Cephalosporins	48	93	0.01	7 (17–21)	4 (4–6)	0.27
Carbapenems	44	50	0.72	11 (3–15)	18 (3–23)	0.52
Glycopeptides	16	0	0.11	12 (5–19)		
Quinolones	28	14	0.33	9 (4–7)	5 (3–7)	0.24
Aminoglycosides	8	0	0.28	10 (9–11)		
Nitroimidazoles	8	0	0.28	7 (5–8)		
Oxazolidinones	48	43	0.76	8 (4–12)	5 (3–10)	0.51
Macrolides	8	0	0.28	8 (7–9)		

Conclusion: SDD was significantly associated with a later onset of all types of infection, a lower incidence of Enterobacteriaceae and other Gram-Positive infections, and a higher exposure to cephalosporins. A nonsignificant downtrend was observed in the incidence of all types of infection, use of antimicrobial agents (except cephalosporins) and mortality.

000505**Implementation of an Antimicrobial Stewardship Program reduces antimicrobial agents use and exhibits a broad acceptance in the Intensive Care Unit**

Intensive Care Medicine Experimental 2020, **8(2)**: 000505

Introduction: Use of antimicrobial agents is a common intervention in the management of the critically-ill patient admitted to the intensive care unit (ICU). Optimizing antimicrobial use is imperative to reduce infection-related morbidity and to limit the emergence of multidrug-resistant microorganisms (MDRMs).

Objectives: To describe the results of the implementation of an antimicrobial stewardship program (ASP) in the ICU of a University Hospital in Spain, after a year of operation (from mid-2018 to mid-2019).

Methods: A multidisciplinary ASP working group was created (intensivist, microbiologist, pharmacist, preventivist and nurse). Theoretical need for antimicrobial agents use was assessed in daily meetings of the group, whenever a result of a microbiological test was available, taking into account the clinical setting, infectious syndrome, isolated organism and antimicrobial pharmacology. Non-mandatory recommendations concerning optimization of antimicrobial treatment were proposed to the attending physician after each meeting, including de-escalation (switch to narrower spectrum or discontinuation of treatment), adequacy (change to same spectrum or start a new treatment), optimization (duration, dose or route of administration) and escalation (switch to broader spectrum). We report antimicrobial utilization expressed as daily defined dose (DDD) per 100 bed-days (BD) in the ASP period and in previous periods.

Results: We held 260 meetings during the study period, where 230 recommendations were proposed over 110 patients (64% male, aged 63±15), with a 96% of adherence. Intervention proposal was more frequently triggered by blood cultures (47%) and respiratory samples (30%), with Gram-negative bacteria being the most frequent isolated type of microorganism (41%). Most interventions were advised over respiratory infections (46%), followed by abdominal organs (17%) and urinary tract infections (15%).

Antimicrobial stewardship use was fundamentally proposed as de-escalation (67%), but also as adequacy (15%), optimization (13%) and escalation (5%). Most interventions were advised over linezolid (22%) and the groups of carbapenems (21%) and penicillins (13%). Antibiotic utilization, expressed as DDD/100 BD, decreased from 175 in 2017 (no ASP), to 154 in 2018 (ASP implemented) and to 136 in 2019 (ASP fully operational).

Conclusion: We found a broad adherence rate to the ASP-group proposed recommendations. De-escalation was the most common intervention, specially in clinically relevant groups of antibiotics. We observed a downtrend in antibiotic use after the implementation of the ASP.

000506**Retrospective comparison of admission versus critical care acquired methicillin-resistant staphylococcus aureus, vancomycin-resistant Enterococci and Clostridium difficile on patient mortality and critical care length of stay at one London hospital**

S. HELYAR¹; C. Bell²; E. Cole²; I. Salako³; P. Hopkins⁴

Intensive Care Medicine Experimental 2020, **8(2)**: 000506

Introduction: Critical care patients are at particular risk of contracting a nosocomial infection within the critical care unit¹. Nosocomial infection is a major cause of mortality and morbidity for critical care patients and a leading factor in increased treatment costs². However, many patients are at risk of hospital acquired infection pre admission to the critical care unit which adversely impacts on patient outcomes³. Methicillin-Resistant Staphylococcus Aureus (MRSA) Bacteraemia⁴, Vancomycin-Resistant Enterococci (VRE)⁵ and Clostridium Difficile (CDiff)⁶ are leading hospital and critical care acquired nosocomial infections, Limited data exist on the impact of hospital versus critical care unit acquired infection on patients critical care length of stay (LOS) and critical care mortality.

Objectives: To compare impact of admission versus critical care unit acquired MRSA, VRE and C. Diff on critical care patient mortality and critical care LOS.

Methods: A retrospective analysis of all patients (critical care stay 48 hours or more) admitted to one of four critical care units (54 beds in total) at one central London hospital between March 2011 and December 2018. Patients with MRSA, VRE or C. Diff status reported to United Kingdom's Intensive Care National Audit and Research Centre (ICNARC) were included in the analysis. Admission NI was defined as an infection diagnosed within 48 hours of admission. Critical care NI was defined as any new infection diagnosed 48 hours or more post admission.

Results: There were 22,320 critical care patient admissions during the study period with an average age of 56.3 years and mortality rate of 12.7%. 21,909 (98.1%), 3041 (15.2%) and 4791 (21.4%) of patients were screened for MRSA, VRE and C. Diff respectively. 411 patients tested positive for MRSA (40% female, mean 55.9 years), with 40 (9.73%) unit acquired. Unit versus admission MRSA mortality rate was 12.1% (N=5) versus 13.5% (N=5) respectively (p = 0.81). 632 patients tested positive for VRE (35.1% female, average age 55.5 years), with 90 (9.1%) unit acquired. Unit versus admission VRE mortality rate was 39.2% (N=44) and 23.9% (N=126) respectively (p = 0.008). 310 patients tested positive for C. Diff (44.5% female, average age 58.9 years), with 147 (47%) unit acquired. Unit versus admission C. Diff mortality rate was 13.2% (N=20) and 20.7% (N=126) respectively (p = 0.078). Mean and median LOS for admission MRSA, VRE and C. Diff were 9.5/5 days, 11.2/6 days and 10.9/6days respectively. Mean and median LOS for unit MRSA bacteraemia, VRE and C. Diff were 29.5/22 days, 43.8/25 days and 25.5/6 days respectively.

Conclusion: This study highlights that there is no significant impact on mortality rates if patients contract admission versus unit MRSA bacteraemia. Patients who contract unit VRE bacteraemia are at a significantly higher risk of mortality compared to patients infected pre admission. In contrast, patients who are infected with C. Diff pre admission are at a significantly higher risk of mortality as compared to unit patients. Despite variance in mortality, patients with unit MRSA, VRE and C. Diff had increased LOS. Sub-categorisation of C. Diff and VRE mortality risk should include admission/unit infection and differences in LOS and patient mortality rates highlight the need for heightened surveillance of VRE and C. Diff within the critical care, parallel with MRSA surveillance levels.

Intensive Care Medicine Experimental 2020, **8(2)**: 000533

Introduction: Although tracheobronchitis (VAT) and ventilator-associated pneumonia (VAP) are two different clinical entities, they have some factors in common in terms of clinical and microbiological diagnosis, treatment and prognosis. The result of the evaluation of patients with these type of ventilator-associated respiratory infections can be interpreted differently if clinical and epidemiological factors are considered.

Objectives: To describe the concordance between clinical and epidemiological diagnosis, and, as a secondary objective, to know the clinical and epidemiological characteristics as well as the rates of VAT and VAP.

Methods: Retrospective and descriptive study carried out between 1st May 2015 and 31st October 2017 of patients admitted to our Intensive Care Unit (ICU). Sources: ENVIN-UCI study, Department of Preventive Medicine, electronic medical record and retrospective review of imaging studies by radiology specialist. Parameters analyzed: age, gender, date of admission, intubation and discharge, comorbidities, microorganisms, antibiotics, associated infections and mortality. Statistical analysis: qualitative values (presented as absolute and percentages), quantitative values (presented as mean and standard deviation). Concordance between clinical diagnosis (data from ENVIN-UCI) and epidemiological diagnosis (data from Department of Preventive Medicine) was measured using kappa coefficient.

Results: 290 patients needed mechanical ventilation (MV) with 4523 stays (patients x mean days under MV). VAP rate: 3,98 and VAT rate: 10,39. ICU infections: 65 (18 VAP, 47 VAT) and according to Preventive Medicine: 43 (19 VAP and 24 VAT). In imaging studies reviewed by radiology specialist, coincidence with ICU diagnosis was found in 70% of the infections and in 60% of diagnosis made by Preventive Medicine. The concordance observed between clinical and epidemiological diagnosis in VAT and VAP according to Landis and Koch was: moderate in VAP (kappa value: 0,56; CI 95%: 0,35-0,78) and fair in VAT (kappa value: 0,32; CI 95%: 0,13-0,51). In the bivariate analysis, relationship was only found between concordance and length of stay.

Conclusion: Moderate agreement was observed in VAP and fair in VAT. None of the parameters studied were associated with no concordance, except for the length of stay

Infectious complications in ICU patients with SARS COV 2 respiratory infection

B. Díez Del Corral¹; M. Pérez Ruiz¹; B. Gimenez Beltrán¹; A. Brevale Flores¹; S. Moreno Cano¹; A. Estella¹

¹University Hospital of Jerez, Intensive care unit, Jerez, Spain

Correspondence: B. Díez Del Corral
Intensive Care Medicine Experimental 2020, **8(2)**: 000546

Introduction: Many critically ill patients infected with SARS COV 2 have worse clinical course or die in ICU due to secondary infections.

Objectives: The aim of the present study is to describe the infectious complications in patients admitted in ICU with confirmed respiratory infection by Sars-Cov-2, and to assess factors related with these complications

Methods: Retrospective case series of consecutive critically ill patients admitted in ICU of a community hospital with severe pneumonia caused by SARS COV 2. Microbiological analysis of bronchoscopic bronchoalveolar lavage (BAL), urine antigen, PCR for Influenza and blood cultures were performed at ICU admission. We categorized infections as coinfections, within the first 72 hours in ICU, and those with a later onset. We analyzed if the use of corticoid therapy was related with developing infectious complications. Medical history, microbiological cultures, ICU length of stay and mortality were collected. Statistical analysis: Data was analyzed by SPSS 18 and quantitative variables were expressed as a mean ± standard deviation.

Results: Twenty patients were included. Mean age was 61,7±8 years old. 80% required mechanical ventilation. Mortality was 30%. Positive PCR SARS COV 2 resulted in 100% of BAL samples. Pneumococcal urine antigen test and Influenza resulted negative in all cases.

ICU length of stay was significantly longer in patients who developed bacterial infections; 20,11±11.4 days vs 10.5 ± 7.29 days in the non-infected group (p<0,05). Regarding fungal infections, ICU length of stay was longer in infected 23.5 ± 10.36 days vs 11.27 ± 8.3 (p<0,05).

In seven patients, 35%, BAL performed at ICU admission resulted positive: 2 patients with *Staphylococcus*, 3 with *Candida spp.* and 2 cases with bacterial/fungal co-infection. *Candida* isolation was associated with previous corticosteroid treatment.

During the ICU stay, 56,25%, developed ventilator associated pneumonia caused by *Candida spp*, *Pseudomona aeruginosa*, *Klebsiella aerogenes*. 30% developed urinary tract infection, half of these cases due to *Candida spp*. In 30% it was described as bacteremia and 10% presented catheter-related bloodstream infection.

	Previous corticosteroid n: 10	No corticosteroid n:10
Fungal infection	1	1
Fungal + Bacterial infection	5	3
Bacterial infection	1	2
No infection	3	4

Dividing the described infections by previous corticosteroids use: The most frequent isolation were *Candida spp* 10 (*C albicans* 7+*C parapsilosis* 2+*C guilliermondii* 1), *Pseudomona aeruginosa* 7, *Enterococcus faecalis* 5, *Klebsiella spp* 4 and *Staphylococcus aureus* 4.

Conclusion: Fungal infections were frequent in critically ill patients with SARS COV2 infection, probably related with corticosteroid therapy.

ICU length of stay was associated with more incidence of infections. Gram positive predominate first days of ICU admission and gram-negative infections in the later phase of ICU stay.

Health care associated infections were more frequent than co-infection.

000547**Using VAC-therapy in skin plastic in patients with necrotic form of erysipelas**J. Fuss¹; A. Voloboyeva²¹Regional hospital of Pustomyty, Lviv, Ukraine; ²Icu, Regional hospital of Pustomyty, Lviv, Ukraine**Correspondence:** J. Fuss*Intensive Care Medicine Experimental* 2020, **8(2)**: 000547

Introduction: Extensive purulent-necrotic wounds are one of the urgent and unresolved problems in purulent surgery [1,2,3]. However, along with this, adequate surgical treatment often leads to the formation of extensive post-necrectomy wounds, the independent healing of which is impossible due to their significant size [4,5]. One of the effective treatment methods in this category of patients is the use of local vacuum aspiration [6,7]. Extensive purulent-necrotic wounds are one of the urgent and unresolved problems in purulent surgery [1,2,3]. However, along with this, adequate surgical treatment often leads to the formation of extensive post-necrectomy wounds, the independent healing of which is impossible due to their significant size [4,5]. One of the effective treatment methods in this category of patients is the use of local vacuum aspiration [6,7].

Objectives: Improve the treatment results of patients with extensive purulent-necrotic wounds caused by erysipelas.

Methods: In this work, we present data on the results of treatment of 89 patients with necrotic complications of erysipelas with the use of vacuum therapy in combination with autodermoplasty. The defect sizes varied from 20 to 152 cm². The effectiveness of vacuum therapy was evaluated based on the dynamics of clinical manifestations, determining the degree of microbial contamination in the wound, analysis of the cellular composition of wound prints, phagocytic number, phagocytic activity of neutrophils, determination of the index of completion of phagocytosis.

Results: Patient wound cleansing during preparation of a wound for transplantation in the control and main groups occurred after 5.1 ± 0.5 days from the start of treatment, the appearance of granulation tissue after 8.1 ± 0.6 days, and granulation tissue covered the entire surface of the wound after 11.0 ± 0.4 days. Upon admission to the clinic, patients underwent surgical treatment, consisting in opening a purulent focus, necrectomy. Purulent discharge was observed from the wound, there was redness of the skin around the wound, edema, local temperature increase, fibrinous-purulent plaque and pain on palpation of the wound edges. After installing a vacuum aspirator, the general condition and general well-being of patients improved markedly, by the 5th day, wound cleansing and the appearance of granulation were noted. In parallel with cleansing the wound surface from necrosis and filling them with granulation tissue, local regional signs of inflammation disappeared. The degree of microbial contamination ranged from $1.9 \pm 0.7 \times 10^4$ to $2.6 \pm 0.5 \times 10^4$ / g of tissue.

It should be noted that patients of both groups needed autodermoplasty to close skin defects.

Skin transplantation was performed in the second phase of the wound process with bacterial contamination of the wound less than 102 CFU per 1 g of tissue and upon receipt of a regenerative type of wound exudate cytograms.

The use of a vacuum apparatus contributed to the metered pressing of the skin flap to the wound surface, reliable fixation of the skin flap and, to a certain extent, improved local microcirculation. Carried out autodermoplasty was effective in all cases. When using vacuum in the postoperative period in the main group, the engraftment of the skin flap accounted for 82% of the wound surface, and in patients of the control group, without vacuum therapy in the postoperative period, the engraftment amounted to 75% of the surface.

Conclusion: The use of vacuum therapy for 4–5 days in a continuous aspiration mode (–125 mm Hg) helps to purify a purulent wound, shortens the first phase of the wound process and potentiates the filling of the wound surface with mature granulation tissue ($p < 0.005$).

It is advisable to use an isolated vacuum in skin plastic in clinical practice in patients with purulent-necrotic wounds and with a necrotic form of erysipelas to heal extensive skin defects.

000549**Using ointments Argosulfan in treatment of purulent wounds**J. Fuss¹; A. Voloboyeva²; V. Polovyj³¹Regional hospital of Pustomyty, Lviv, Ukraine; ²Icu, Regional hospital of Pustomyty, Lviv, Ukraine; ³General surgery, Bukovinian State Medical University, Chernivtsi, Ukraine**Correspondence:** J. Fuss*Intensive Care Medicine Experimental* 2020, **8(2)**: 000549

Introduction: In the structure of surgical pathology, the leading place is occupied by purulent-inflammatory diseases of soft tissues [1], which are associated with the infectious process in the skin and cellular spaces caused by pathogenic or opportunistic flora [2]. Patients with this pathology make up 20–45% of all surgical patients [3,4]. The rapid development of the resistance of microorganisms to the antibacterial drugs used requires the selection of the most effective method for the local treatment of wound infections. To solve this problem, antibacterial preparations containing silver are actively used in modern practice [5,6].

Objectives: Evaluation of the effectiveness of the treatment of purulent wounds with Argosulfan ointment in a surgical hospital.

Methods: 264 patients who were admitted to the hospital in 2018–2020 with purulent wounds of various etiologies were treated. All patients were divided into 2 groups: group I ($n = 156$) included patients in whom, in the postoperative period, ointment dressings with silver sulfathiazole were used for local treatment of wounds; group II ($n = 108$) included patients who in the postoperative period for topical wound treatment used ointment dressings with antibacterial ointments - bactroban.

Upon admission to everyone, a wound was opened and a purulent cavity was drained, or primary surgical treatment of an infected wound in the first day after admission. Wounds were washed with an antiseptic solution, an aseptic dressing was applied. Patients in both study groups received the same broad-spectrum antibacterial therapy. Local treatment of purulent wounds began the next day after surgery. The following indicators were studied in dynamics: the nature of the wound discharge, the presence of edema and hyperemia of the tissues around the wound, the timing of the cleansing of the wound defect, the results of microflora culture and sensitivity to antibacterial therapy on the 1st, 5th, 10th day after the operation.

Results: Absence of hyperemia of the skin around the wound and soft tissue edema in group I averaged 4.3 ± 1.7 days, in group II - 5.5 ± 2.5 days ($t = 0.379$; $p < 0.05$).

Sterile inoculation from the wound on the 5th day was observed in 42.3% of patients in group I, and only 5.9% in group II. Statistically significant differences between the groups were obtained: $\chi^2 = 33.68$; $p < 0.05$.

In group I, a decrease in bacterial contamination by 50% was noted in 57.3% of patients, in group II - in 47.4%. There were no statistically significant differences between the groups: $\chi^2 = 2.47$; $p < 0.05$.

In group I, sterile discharge on the 10th day was observed in 100% of patients, in group II - only in 88.5%. Statistically significant differences between the groups were found: $\chi^2 = 12.2$; $p < 0.05$.

In group I, wound cleansing from pus and fibrin and the appearance of granulations on the 5th day were noted in 87.8% of patients, in group II - only in 35.9%. Statistically significant differences between the groups were revealed: $\chi^2 = 57.07$; $p < 0.05$.

In group I, wound cleansing from pus and fibrin and the appearance of granulations on the 10th day were noted in 100% of patients, in group II - only in 88.5%. Statistically significant differences between the groups were obtained: $\chi^2 = 12.2$; $p < 0.05$.

Conclusion: Use of Argosulfan ointment can improve the results of treatment of patients with purulent pathology of soft tissues and reduce the risk of secondary infection in comparison with the use of traditional antibacterial ointments - by reducing bacterial contamination, faster cleaning of the postoperative wound from pus and fibrin.

A Case series on Macrophage activation syndrome with infections. More common than we think??

J. Nikhilesh¹; V. Bohara²; A. Gupta³; V. Joshi⁴

¹Dept of critical care medicine, CHL Hospital, Indore, India; ²Dept of hematology, CHL CBCC hospital, Indore, Madhya Pradesh, India, India; ³Dept of internal medicine, CHL hospital, Indore, Madhya Pradesh, India, India; ⁴Dept of critical care services, Shalby Hospitals, Indore, Madhya Pradesh, India, India

Correspondence: J. Nikhilesh

Intensive Care Medicine Experimental 2020, **8(2)**: 000560

Introduction: Association of Macrophage activation syndrome (MAS) and infections has been documented earlier in literature however, there have been case reports and isolated cases and we did not come across a big series on above in association with infections. This communication delineates a case cohort of macrophage activation syndrome secondary to infectious diseases.

Objectives: To study the epidemiology and pattern of common variables in a cohort of Macrophage activation syndrome associated with an infectious etiology.

Methods: Setting: Sixty bedded multidisciplinary ICUs of tertiary care units.

Methodology: Consecutive patients suspected of macrophage activation syndrome fulfilling diagnostic criteria as per HLH 2004 trial were included for a duration dated first January 2017-till date with an infectious disease etiology were included. They were evaluated with a focus on demographics, SOFA scores, ALT levels, AST levels, Hemoglobin, platelet counts, serum creatinine levels, bone marrow findings, incidence of AKI, LDH levels, splenomegaly, length of stay and mortality. Death/discharge from ICU were considered as end points. Statistical analysis was done using SPSS version 23.

Results: Total of thirty-seven patients with high grade fever were included (n=37, M: F=24:13) with age distribution of 44.8±14.3 years (Range=21-70). SOFA scores were 14.8±2.2 (Range=10-18) and length of stay (LOS) was 10.4±3.31 days (Range=5-17). Hemoglobin levels were 11.7±2.8(Range 7.9-17.5) gm/dl and platelet counts were 60324.32± 25075.50 (Range12,000 -90,000). AST and ALT levels were 164± 54 (Range=61-263) and 164.9 ± 48.7 (Range=82-247) respectively [Ref <30]. Serum triglycerides, Serum ferritin levels, D-Dimer and LDH levels were 326± 34.6 mg/dl (Range=290-410), 1530.4±909.7 (Range 740-4500) ngm/ml,4000±1640 ng/ml (Range 3260-5900) and 295±15.7 (Range- 190-384) units/l respectively. The incidence of AKI for the entire cohort was n=17(45.9%) with serum creatinine levels 1.44± 1.08 (Range=0.5-5.8) mg/dl. Bone marrow was consistent with hemophagocytosis in n=22(59.5%). In hospital mortality was n=6 (16.2%) and splenomegaly was noted in n=19(51.4%). The etiology included Dengue n=7 (18.9%), Typhoid n=10(27%), HIV n=4(14.8%), Malaria n=5 (18.5%), COVID 19 n=3(8.1%) and gram-negative infections n=8(29%). On statistical analysis only Platelet levels and Ferritin levels had an association with mortality (p value 0.00035 and 0.000015).

Conclusion: MAS remains a suspect cause in any new onset fever in ICU. Its associations with infectious diseases and ability to alter outcomes should prompt an early recognition for the same. This communication documents a bad prognosis with thrombocytopenia and elevated ferritin levels in these cohorts.

Intensive Care Medicine Experimental 2020, **8(2)**: 000561

Introduction: Colonizations and infections by multi-drug-resistant (MDR) bacteria are a common occurrence in patients treated in the Intensive Care Units. Most donors have previously been treated in these intensive care units and may therefore have colonizations or infections from these pathogens. In this study, we analyze whether the organ recipients of donors who were colonized or infected with an MDR bacteria develop an infection with the treatment challenges that this would entail.

Methods: Consecutive deceased organ donors in a critical care unit from a tertiary hospital with high donation activity were registered for 72 months (January-14 to December-19). We included in the study organ donors with MDR bacteria isolates and traced the transplanted organs and the MDR isolates in their corresponding recipients. Methods consisted in an active detection of any colonization by MDR bacteria through screening with swabs twice a week. As for the diagnosis of infection is made according to clinical, analytical and imaging criteria (as in the case of pneumonia) . For each case of nosocomial infection, further variables were documented, such as confirmed pathogens, date of infection, and temporal association of the infection with devices (tracheal tube, central venous catheter, urinary catheter).

Results: From 385 deceased organ donors, we detected 31 patients colonized or infected by MDR bacteria. In average, they were 67 years old with an ICU stay of 9 days. From these 31 organ donors, we followed the 59 patients who received a graft from a donor with a positive culture for MDR bacteria. Transmission of the MDR pathogen was detected in two receptors: a Methicillin-resistant Staphylococcus aureus (MRSA)bacteremia whose donor was treated 36 hours before

the donation and a urinary tract infection for Klebsiella pneumoniae BLEE from an untreated donor due to the fact that isolates identification results were obtained after donor death and transplantation.

Conclusion: The transmission of MDR bacteria from organ donors to organ recipients is a rare occurrence. In our series, the use of organs from MDR bacteria-colonized donors is safe for recipients of these organs in terms of MDR pathogen transmission.

Intensive Care Medicine Experimental 2020, **8(2)**: 000566

Introduction: COVID 19 pneumonia is exceeding the intensive care units capacity worldwide. It is important to analyse the results to tackle the disease successfully.

Objectives: To analyse the characteristics of the patients admitted to the ICU during the COVID 19 pandemic.

Methods: Retrospective observational study conducted in an intensive care unit of a university Hospital. During the pandemic, ICU beds went from 14 to 39. We analysed patients admitted to the ICU with the diagnosis of respiratory failure due to COVID 19 pneumonia between 6/3 and 21/4 2020. Patients who are still in the ICU at the time of data collection were excluded. Demographic data (age, sex), APACHE II, comorbidities (hypertension, previous pulmonary pathology, dyslipidaemia, diabetes mellitus, obesity), laboratory data (creatinine, ferritin, total bilirubin), length of stay and treatments administered (mechanical ventilation, muscular blockers, vasoactive drugs, prone positioning) were collected.

Results: 90 patients were analysed. Male 67.8% (61/90). Average age 60.6 ± 9.6 years. APACHE II 14.3 ± 5.1. 48.9% (44/90) had cardiovascular history of which AHT 46.6% (42/90). Chronic lung disease 20% (18/90) (asthma 5.5% (5), OSAHS 5.5% (5), COPD 4.4% (4), OSAHS + asthma 3.3% (3)). 65.5% (59/90) had other comorbidities (Diabetes mellitus 23.3% (21), dyslipidaemia 35.5% (32)). 26.6% (24/90) had no previous pathology. Length of stay (days): 12 ± 10.1. The average of the maximum creatinine, ferritin and total bilirubin values were: creatinine 1.45 ± 1.23 mg / dl, ferritin 2244 ± 3193 ng / ml and total bilirubin 1.8 ± 2 mg / dl. 100% of the patients required mechanical ventilation. Prone positioning was performed in 57.8% (52/90), infusion of muscular blocker 77.7% (70/90) and vasoactive drugs 96.7% (87/90). Microbiological isolation was observed in 45.6% (41/90) of the patients. 40% (36/90) were discharged and 25.1% (23/90) were transferred to another centre due to lack of beds. Mortality rate was 34.4% (31/90).

Conclusion: As in other series, males predominate in the group of critically ill patients. Among the most frequent comorbidities correlated to COVID 19 pneumonia, we find arterial hypertension, dyslipidaemia and diabetes mellitus. Mortality is high despite the low average age and the absence of severe comorbidities. 25% of hospitalized patients were transferred so their evolution is unknown, mortality and length of stay may be underestimated.

Intensive Care Medicine Experimental 2020, **8(2)**: 000580

Introduction: Bacterial or fungal coinfection and secondary infections have an important role in comorbidity and mortality in COVID 19 critically ill patients. The typical COVID-19 clinical manifestations and laboratory findings make it quite challenging for the clinician to suspect and actively look for a different microbiological agent.

Objectives: To describe and analyse the microbiological isolations in the COVID-19 patients treated in our ICU (Príncipe de Asturias hospital).

Methods: A retrospective observational study was performed. All the critically ill COVID-19 positive patients who received treatment in our ICU (a polivalent, level II hospital ICU) were reviewed (from march 6, 2020 to april 21, 2020). Demographical, main laboratory findings, type of microbiological samples and isolated agents were collected. Chi-square tests, T Student or ANOVA were used. Signification level was established as p<0.05.

Results: A total of 67 patients were enrolled in our study. Microbiological isolations were positive in 45.6% of patients, all of them were secondary infections. In 18 patients >1 isolation was found. The microorganisms isolated were: S. Aureus 11 cases, *Coagulase-Negative Staphylococcus* 12 (8 Epidermidis, 1 Hominis), E. Faecium(8), E. Faecalis(7), Pseudomonas(9), E. coli(4), Klebsiella(2), Serratia(3), Haemophilus (1). Strenotrophomonas (2). Acinetobacter(1), Corynebacterium(1). Candida was the fungus most frequently isolated (12); it is remarkable that it was isolated in endotraqueal aspirates (ETA) in 6 cases. There was one case of aspergillosis. The most frequently positive sample was ETA (28); followed by blood cultures (19). The most frequently isolated agent in ETA was Pseudomonas (10) and S. Aureus (10), 2 were SAMR. In blood cultures, the most frequently isolated agents were S. Epidermidis, E. Faecalis and E. Faecium (6 each), followed by S. Aureus (4). We found 5 catheter related bacteriemias (S. Epidermidis 3, SAMR 1, Pseudomonas 1) and 7 bacteriemic pneumonia (SAMS 3, Pseudomonas 2, E. Coli 1 and SAMR 1).

We didn't find statistically significant the association between microbiological isolation and any of the patients' underlying diseases (p=0.528), nor with vasoactive support (p=0.43), nor with need of neuromuscular blockers (p=0.25), nor with mortality (p=0.5).

Need for prone position, traqueostomy and media hospital stay were associated with microbiological isolations with statistical significance (p value in table).

Comparative analysis between positive microbiological isolations' group and negative is shown in the table below.

Microbiological isolation			
	Yes	No	P
Sex (masculine)	55%	59%	0.49
APACHE II	14	14.6	0.73
Ferritin (ng/ml)	218	2479	0.7
Creatinine (mg/dl)	1.6	1.3	0.29
Bilirubin (mg/dl)	2.1	1.9	0.7
Prone	65%	39%	0.03
Traqueostomy	79%	37%	0.00
			1
Microbiological isolation			
	Yes	No	P
Mortality rate	55%	58%	0.5
Length of stay (days)	18.6	8.3	0.00
			5

Conclusion: Secondary infections in COVID-19 patients are a frequent finding in our group (48%), being more frequent than in other published series of cases. In our study microbiological isolations were associated to longer hospital stay, prone position and traqueostomy with with statistical significance.

Intensive Care Medicine Experimental 2020, **8(2)**: 000586

Introduction: Coronavirus disease 2019 (COVID-19) is a respiratory infection caused by a newly emergent coronavirus, SARS-CoV-2, that was first recognized in Wuhan, China, in December 2019. There is currently no approved treatment for COVID-19. Convalescent plasma has been used as a treatment in other recent epidemics, including SARS-CoV-1, Ebola, and MERS.

Objectives: We have designed a study with the main objectives to evaluate the safety and efficacy of the administration of anti-SARS-CoV-2 plasma from recovered COVID-19 donors to critically ill COVID-19 patients.

Methods: The study design is a prospective, multi-center, randomized, open-label trial comparing convalescent, ABO-compatible, anti-SARS-CoV-2 methylene blue-treated (MBT) plasma plus standard medical treatment (SMT) to SMT alone in a 2:1 ratio. Eligible patients are those hospitalized for COVID-19 (tested positive for SARS-CoV-2) and admitted to the ICU for respiratory support due to severe pneumonia (lung infiltrates). Patients will be eligible for inclusion within 48 hours of ICU admission. Exclusion criteria are prior anaphylactic reactions to blood products or methylene blue, severe acute renal or heart failure, and refractory shock. The study has been approved by the applicable regulatory authorities (<https://clinicaltrials.gov/ct2/show/NCT04280705>).

Results: Enrollment target is approximately 100 symptomatic COVID-19 adults. Interim analyses will be performed every 30 patients. Study variables will be collected daily during hospitalization from day 2 through 29±1. All patients (independent of hospitalization status) will

be monitored daily until day 10. Study visits for discharged patients have been scheduled on days 15±1 and 29±1. The primary assessment is all-cause mortality through day 29. Secondary assessments are: change in National Early Warning Score [NEWS] from baseline, time to clinical response [NEWS ≤ 2 for 24 h], time to ICU discharge and hospital discharge, duration of mechanical ventilation and oxygen therapy and absolute value and change from baseline in the Ordinal Scale. Change from baseline in quantitative SARS-CoV-2 viral load and in quantitative anti-SARS-CoV-2 IgM and IgG antibodies will be measured. In addition, patients will be monitored for treatment-emergent adverse events for the entire study period.

Conclusion: The contribution of the study results to COVID-19 therapy would be the validation of the efficacy and safety of convalescent anti-SARS-CoV-2 MBT plasma in critically ill patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000609

Introduction: The current SARS COV 2 pandemic has led to a global crisis in the health system. In ICUs we have the recent past of a decade ago with the H1N1v Influenza pandemic, since this time annually admissions in ICU of several cases of Influenza A infections have been described.

Objectives: The aim of the study were to describe clinical features of patients admitted in ICU with SARS COV 2 infections occurred during this epidemic time and to compare clinical characteristics and outcome with severe 2009 pandemic Influenza A (H1N1)v infections and 2010-2011 Influenza season infections.

Methods: Comparative study that included a prospective cohort of patients with SARS COV 2 severe infections and an historical group of patients with 2009 pandemic and 2010-2011 seasonal Influenza A H1N1v pneumonia. Setting: ICU of a community hospital. We included patients with confirmed SARS COV 2 respiratory infection. Variables analyzed were clinical characteristics, APACHE II at admission, respiratory support requirements, ICU length of stay, radiological pattern, serum reactive C protein (PCR) and procalcitonin (PCT) levels, leukocyte count (WBC) and mortality. Statistical analysis: Data were analyzed by SPSS 18 and quantitative variables were expressed as a mean ± standard deviation.

Results: Forty five patients were included, 18 with pandemic 2009 Influenza A H1N1v pneumonia, 7 with Seasonal Influenza A 2010-11 pneumonia and twenty consecutive patients with SARS COV2 pneumonia. At present, 14th may 2020, three patients are currently admitted to ICU. Comparative table shows clinical characteristics and outcome.

	Pandemic 2009 Influenza A n:18	Seasonal Influenza A 2010-11 n:7	SARS COV 2 n:20
Age	42,6± 12,7	38,4± 19,3	61,7±8,2
Apache II at admission	12,8± 6,5	10 ± 2,9	10,30±4,2
Mechanical ventilation (%)	66,7%	57%	80%
Time of mechanical ventilation (days)	8,7±8,8	15,2 ± 9,8	12,25±10,3
ICU length of stay (days)	13,9±11	11,9 ± 10,2	16,13±10,7
Prone ventilation (MV patients)	54,54 %	25%	93,75%
Non invasive ventilation	27,8%	57,1%	5%
High flow oxygen therapy	N/A	N/A	45%
Bilateral radiological infiltrate	77,8%	42,9%	80%
Reactive C protein PCR mg/l	200± 150,3	139 ±170,6	163,21±177,15
Procalcitonin PCT ng/ml	4,94± 15,8	1,17 ± 2,1	0,47±0,55
PCT>0,8	46,4%	28,6%	15%
Leukocyte count (WBC)	8588±6852	8702 ± 6256	9595±3924
Confirmed coinfection	22,2%	14,3%	10%
Confirmed NAVM	16,7%	14,3%	30%
Mortality	16,7%	28,6%	30%

Conclusion: The clinical profile and outcome of SARS COV2 pneumonia differs considerably from those caused by Influenza in critically ill patients.

Despite no differences in the scales of severity at ICU admission were observed, severity of respiratory failure and the need for mechanical ventilation is greater in SARS COV2 infections.

Increased hospital length of stay and more healthcare-related infections could justify the worst patient prognosis in SARS COV 2 pneumonia.

Intensive Care Medicine Experimental 2020, **8(2)**: 000646

Introduction: According to published epidemiological data, critical care is needed by 5% of COVID-19 patients [1]. An impressive effort from ICU teams allowed to multiply their capacity by two or three-fold, trying to cover the continuous need [2,3].

Objectives: To report ICU admissions related to COVID-19 at a polyvalent ICU of a second-level hospital, with eight beds available in summer, and 10 in winter (0.47-0,59 ICU beds/10,000 inhabitants).

Methods: Retrospective study of ICU patients (>18 years old) with nasal/throat swabs or bronchial aspirate positive for SARS-CoV-2 by PCR, between March 5th and May 7th, 2020. Patients transferred to other centres and those still in ICU were excluded. The local IRB approved the study. Patients were treated according to current national protocols. After analysis of clinical characteristics, we performed a multivariate analysis to check the causes and associated factors of ICU mortality. Statistical analyses performed using SPSS 20.0.

Results: 75 patients presented a positive PCR; 49 finally included. Median age 65 years (IQR: 59-72); 65.3% men. 61.2% came from hospital ward. 93.9% presented on admission respiratory failure due to pneumonia. 73.5% suffered from some comorbidity (44.9% cardiovascular, 42.9% endocrine, 12.2% malignancy, 10.2% respiratory, 6.1% chronic liver disease, 6.1% neurologic and 4.1% chronic renal disease). Table 1 shows relevant clinical data. Median ICU length-of-stay 12 days (IQR 9-19.5). Survival upon ICU discharge was 77.1%.

Regarding multivariate analysis, no statistically significant association was noted between mortality and comorbidities ($p=0.126$) except cardiovascular comorbidity (OR 4.8, CI95%: 1.2-26.4; $p=0.028$) when performing a multivariate backward stepwise regression model. Albeit no organic failure (OF) presented individual association with mortality, we did find an association with the number: a threshold value of 4 OF was associated with ICU mortality ($p<0.001$). We also observed a statistical trend between mortality and number of days on MV: 19.88 days in non-survivors vs 14 among survivors ($p=0.056$). Finally, we did not find any relationship between severity scores (SAPS3, Clinical Frailty Scale, SOFA on admission) and mortality.

Table 1. Relevant clinical data

Variable	All adults (N=49)	
Organ failure (number, percentage)	Cardiovascular	40 (81.6)
	Respiratory failure	45 (91.8)
	Kidney failure	22 (44.9)
	Hepatic failure	8 (16.3)
	Hematologic	10 (20.4)
	Neurological	12 (24.5)
Number of organ failures per patient (median, IQR)	3 (2-4)	
Respiratory failure management (number, percentage)	Invasive MV	44 (89.8)
	ARDS diagnosis	43 (87.8)
	Need for reintubation	4 (8.2)
	Days on MV (median, IQR)	11 (9.3-19.8)
	Percutaneous tracheostomy	2 (4.1)
	Prone positioning	25 (51)
	Neuromuscular blockade	36 (73.5)

Conclusion: In our cohort, mortality was significantly associated with cardiovascular comorbidities (OR 4.8) and a higher number of associated organ failures. The present study tries to highlight the importance of inclusive strategy based on multidisciplinary collaboration and maintenance of well-established protocols despite adversities [4].

000649**Investigating hospital acquired pneumonia in critical care**P. Beddoes¹; D. Melia²

¹Anaesthetics Department, Whipps Cross University Hospital, London, United Kingdom; ²Critical care, Whipps Cross University Hospital, London, United Kingdom

Correspondence: P. Beddoes*Intensive Care Medicine Experimental* 2020, **8(2)**: 000649

Introduction: Responsible for 5.9% of all UK critical care admissions (M Woodhead, 2006), community acquired pneumonia (CAP) is a common cause of critical care admission. Antibiotics are vital in the treatment of CAP but their use is associated with morbidity such as colitis, infection with resistant organisms and kidney injury. The use of investigations to identify a causative organism may facilitate better antibiotic stewardship (I Johnson, 2017).

The 2009 British Thoracic Society (BTS) guideline recommends that patients admitted to critical care with severe CAP should have blood cultures, sputum or other respiratory samples for microscopy, culture and sensitivity (MC&S), urine pneumococcal and legionella antigen testing performed (Lim WS, 2009).

In this audit cycle, on finding adherence to BTS guidelines at our institution to be low, we used a simple aide-memoire for nursing staff and doctors requesting investigations for patients with CAP and demonstrated improved adherence with an increase in identification of causative pathogens in severe CAP. Our intervention was simple, inexpensive and resulted in significant improvement in the investigation of severe CAP, adherence to guidelines and more precise microbiological diagnosis in patients with severe pneumonia.

Methods: 20 consecutive adult patients with a diagnosis of CAP admitted to a London ICU December 2018 - February 2019 were identified. We excluded patients <18 years and those with hospital acquired pneumonia. Using the electronic patient record (EPR), we noted investigations performed and results.

On discussion with nurses and junior doctors responsible for ordering investigations, it became clear that while an 'atypical screen' was commonly requested, there was poor understanding of what tests were then required. We made a laminated card listing required investigations for patients with severe CAP and attached this at eye line to computer monitors where tests are requested on the unit to serve as a visual prompt to staff requesting investigations. We listed investigations as they appear on our electronic requesting system to ensure that the correct search terms were used.

The following winter, the audit was repeated to re-assess compliance with guidelines.

Results: There was improvement in testing across all investigations. There was significant increase in legionella and pneumococcal antigen testing, respiratory virus PCR, blood cultures and mycoplasma DNA. The proportion fully investigated as per BTS guidelines rose by 40% (11.5930% to 61.3271% $P=0.006$). The commonest missing test was sputum culture. The percentage of patients with a causative organism identified for their CAP rose by 30% (-0.1759% to 53.6369% $p=0.05$)

Conclusion: CAP is a common cause of admission to intensive care. If investigated thoroughly, most patients will have an underlying organism identified, allowing for a narrower spectrum of antibiotic, which should not be forgotten in the context of COVID-19.

Simple aide memoires can bring clarity to poorly understood terms such as 'Atypical screen'.

Introduction: Circulating antibody-producing B cells secrete antibody following context-dependent stimulation by pathogen antigens. Secreted antibody from lymphocytes harvested and *ex vivo* cultured from patients with infection (antibodies-in-lymphocyte supernatant, ALS, assay) could be used as a diagnostic test that, unlike conventional serology, removes the requirement for convalescent sampling.

Objectives: We compared the diagnostic accuracy of ALS assay with standard molecular tests for respiratory syncytial virus (RSV), globally the most prevalent cause of childhood pneumonia.

Methods: We enrolled children admitted to Patan Hospital, Nepal, with a clinical diagnosis of pneumonia from October 2016 to June 2017. Peripheral blood mononuclear cells (PBMCs) were separated from whole blood and cultured for 48 h using standard methods. We used a IgG ELISA to RSV F protein (Fitzgerald) to calculate antibody concentrations in ALS. We compared ALS to RSV F protein to the results of the NxTAG Luminex Respiratory Pathogen Multiplex PCR panel (Luminex Corp, USA) on nasopharyngeal (NP) swab specimens from the same patients.

Results: Of 280 children admitted to hospital, 83 (30%) had primary endpoint pneumonia on chest radiographs (PEP). RSV was detected from NP specimens by PCR in 29/280 (10%) children, of whom 5/29 (17%) had PEP. Blood samples were taken a median of 4 days following onset of symptoms. There were significantly *decreased* concentrations of IgG to RSV in ALS samples from patients in whom RSV was detected in comparison with others (Figure 1).

Figure 1: Comparison between ALS and PCR for RSV diagnosis for the study cohort. Log₁₀ versus RSV PCR result from nasopharyngeal swabs (x-axis; $p = 0.015$, Wilcoxon)

Conclusion: Children with RSV pneumonia (by PCR of NP specimens) had lower ALS to RSV F protein than children with other pneumonia etiologies. This result supports the lack of protective humoral immunity induced by either RSV infection, or previous RSV vaccines.

000705**Covid-19: clinical outcome of younger people admitted to ICU. A retrospective single-center cohort study**L. Oyaert¹; A. Vandebroek¹; D. Helsloot¹; C. Missant¹; W. De Corte¹; S. Lamote¹¹Anesthesia, intensive care & emergency medicine, AZ Groeninge, Kortrijk, Belgium**Correspondence:** S. Lamote*Intensive Care Medicine Experimental* 2020, **8(2)**: 000705

Introduction: The Coronavirus disease 2019 (COVID-19) pandemic, caused by the Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2), led in spring 2020 to a worldwide crisis. In the majority there is a mild course, however in up to respectively 20% and 5% there is a severe and even critical presentation. Initial reports from China and Italy showed poor outcome for patients admitted to Intensive Care Unit (ICU), particularly for the elderly. We focused in our analysis on the outcome of younger patients admitted to ICU.

Methods: In this retrospective, single-center cohort study, we assessed clinical outcome of younger patients by comparing those aged below 66 years with those aged 66 years and above. We further divided the former group in 2 cohorts, namely patients with (young+RF (risk factor)) and without (young-RF) any comorbidity including obesity (BMI > 30). Between March 13 and May 15, patients admitted with confirmed COVID-19 to ICU were consecutively screened. Exclusion criteria were COVID-19 cases without respiratory failure and Do Not Resuscitate (DNR) order at admission. Primary outcome was mortality, secondary outcome were need for mechanical ventilation (MV), duration of MV, proportion successfully weaned off ventilator, length of ICU stay (ICU-LOS), incidence of associated organ failure and rate of recovery. The latter was assessed at day 10, 14, 21 and 28 by using an ordinal clinical scale: 1. no hospitalization; 2. at hospital; 3. at ICU; 4. ICU with high flow oxygen therapy (HFOT) or non-invasive ventilation (NIV); 5. MV; 6. dead. Mann-Whitney U, χ^2 or Fisher's exact tests were used as appropriate and analyses were performed using SPSS.

Results: Of the 61 patients screened, 55 were eligible (6 patients excluded: 5 with DNR-code, 1 patient who didn't suffer from respiratory failure). Median age overall was 66 years (IQR 57-78) and males (M) were predominant, especially in the younger group (overall 65% M, young 80% M vs old 53% M, $p=0.038$). The younger cohort accounted for 45% ($n=25$), one-third of them had no comorbidities at all ($n=9/55$, 16%). Most frequently reported concomitant pathology was obesity (overall 27%, median BMI 27.5; young 32% vs old 23%, $p=0.303$), hypertension (overall 49%, young 40% vs old 57%, $p=0.218$), cardiovascular disease (overall 33%, young 16% vs old 47%, $p=0.016$) and diabetes (overall 29%, young 12% vs old 43%, $p=0.11$). There was a significantly higher incidence of obesity and hypertension in the young+RF cohort (50%, $p=0.0088$ and 63%, $p=0.003$) compared to the young-RF cohort.

Overall ICU mortality was 32%. Even though the fatality rate for younger people was lower (young 22% vs old 40%, $p=0.158$), this was not statistically significant due to high mortality in the young+RF group (36% for young+RF vs 40% old, $p=0.786$), while none of the young-RF group died (vs 36% for young+RF, $p=0.0465$). More than half of the patients ($n=31/55$, 56%) required MV, without significant differences between young and older patients (52% vs 60%, $p=0.551$), although only 11% ($n=1/9$) of the young-RF group ended up with MV versus three-quarters of the young+RF group ($p=0.002$). Prone ventilation was applied in 16 cases ($n=16/31$, 52%). Forty-five percent of the ventilated patients were successfully weaned off the ventilator (46% young vs 44% old, p NS; 100% young-RF vs 42% young+RF, $p=0.154$). Duration of MV for survivors was shorter for the younger vs the elderly (11.73 vs 18.76 days, $p=0.66$) and for younger-RF vs younger+RF (8.38 vs 15.07 days), but none of these differences were significant. ICU-LOS didn't differ among the different cohorts

with a median duration of 10 days overall (young 11.5 vs old 9, $p=0.59$; young-RF 9 vs young+RF 13, $p=0.26$). Incidence of severe associated organ failure was slightly lower in the younger population (24% vs old 33%, $p=0.448$), with kidneys as most vulnerable organ. None of the young-RF patients experienced any severe associated organ failure while young+RF patients had even higher incidence of such an extrapulmonary manifestation than the elderly (38% vs 33%, $p=0.777$). Younger people tended to recover faster than the elderly, particularly the young-RF group outperformed the other cohorts with significantly higher proportions of patients clinically improving on the ordinal clinical scale by 1 point as evaluated at day 10 (89%, $p=0.06$), 14 (89%, $p=0.013$) and 21 (100%, $p=0.005$) as well as by 2 points at day 28 (100%, $p=0.01$).

Conclusion: This study demonstrates that younger people can be severely hit by COVID-19 as well. Only those without any comorbidities at all have better clinical outcome in terms of mortality, MV requirement, associated organ failure and rate of recovery. As functional outcome after surviving remains unclear, caution and prevention remain mandatory for patients in all age groups, irrespective of their comorbidity.

000728**The association between d-dimer, mortality and ITU admission in COVID-19-is there a connection? A retrospective study**L. Fakes¹; H. Said²¹West Middlesex University Hospital, Isleworth, United Kingdom; ²Intensive care, West Middlesex University Hospital, Isleworth, United Kingdom**Correspondence:** L. Fakes*Intensive Care Medicine Experimental* 2020, **8(2)**: 000728

Introduction: Coronavirus disease 2019 (COVID-19) was first reported in Wuhan, China in December 2019. Many studies have since focused on identifying parameters by which to risk stratify patients. Elevated d-dimer levels have been reported in up to 46% of patients (1), with higher levels noted in patients requiring intensive care unit (ICU) admission (2). A recent systematic review including six retrospective cohort studies conducted in China, found raised admission d-dimer levels are significantly associated with increased mortality in COVID-19 (3). Given patients present at different time points in their illness, measuring d-dimer at admission may not accurately represent the potential severity of infection. We therefore sought to evaluate whether this association was maintained in a United Kingdom patient cohort when maximal d-dimer was measured.

Objectives: The aim of this study was to investigate the association between maximum d-dimer and both ITU admission and mortality in patients with COVID-19.

Methods: This retrospective single-centre study included patients presenting to West Middlesex University Hospital (London, United Kingdom) with a laboratory confirmed diagnosis of COVID-19. We selected a sample of 150 consecutive survivor and non-survivors. Patients in which no d-dimer sample was taken were excluded, giving a total

sample analysed of 99 survivors and 118 non-survivors. In all cases, electronic medical records were used to obtain the highest d-dimer value during admission, survivor status, and whether ITU admission occurred. Median and mean d-dimer values were calculated, and confidence intervals (CI) used to assess statistical significance.

Results: D-dimers were elevated in 74.7% of survivors and 94.9% of non-survivors with mean d-dimers of 2683 µg/mL (Standard deviation [SD] 4350, CI 857) and 3588 µg/mL (SD 3790, CI 683) respectively, and median d-dimers 1070 µg/mL and 2200 µg/mL respectively. In patient admitted to ITU the mean and median d-dimer was 5597 µg/mL (SD 5272, CI 1654) and 3377 µg/mL respectively. In patients with ward-based care the mean d-dimer was 2635 µg/mL and median d-dimer 1600 µg/mL (SD 3184, CI 456). No differences were statistically significant ($p < 0.05$).

Conclusion: This study supports previous studies in China showing d-dimer levels are commonly raised in COVID-19 positive patients (1, 4, 5). However, in contrast, we found no significant difference between d-dimers in survivors and non-survivors. Similarly, we found patients admitted to ITU had higher d-dimers than ward-based patients supporting the findings of Wang et al. (2) but this was not statistically significant. This may reflect differences in the studied patient populations, or more likely could be attributable to the different approach adopted in this study of measuring maximal rather than admission d-dimer. Overall, these findings suggest parameters other than d-dimer may be more useful clinically in risk stratifying COVID-19 patients and predicting need for ITU admission or mortality.

Intensive Care Medicine Experimental 2020, **8(2)**: 000747

Introduction: Acute kidney injury (AKI) is a frequent complication seen in patients with COVID-19 infection admitted to intensive care. National UK data indicates 26% of patients admitted to critical care with COVID-19 infection require renal replacement therapy (RRT), 61% of whom died (1). This has significant implications for resource utilisation. Better understanding of this disease and requirement for renal support will not only help plan local services but may also give insights into improved treatment and preventative strategies.

Objectives: We aimed to assess the incidence of AKI and need for RRT in critically ill patients with COVID-19 in a single large UK tertiary centre. The association between need for RRT and the presence of several co-morbidities as well as overall mortality was also examined. These local findings were also compared with national data.

Methods: Contemporaneous electronic medical records were retrospectively reviewed for all patients admitted to ICU for 10 weeks from March 2020 in a single large UK tertiary centre. Data extracted included demographics, co-morbidities, fluid balance, creatinine, eGFR, RRT, APACHE II score and outcome. AKI was defined as per the KDIGO criteria (2) and renal recovery defined as free from RRT for over 48 hrs.

Results: A total of 93 patients with COVID-19 were admitted to ICU during this period. The median age was 62 and 28 (30%) were female. 51 (56%) developed AKI and RRT was provided in 33 (36%). The overall ICU mortality was 35%, excluding 2 patients who remained in ICU at the time of reporting. Factors associated with the development of AKI are shown in Table 1. Multiple regression analysis retained APACHE II and requirement for mechanical ventilation as significant associations with the development of AKI (Table 2), with similar results for requirement for RRT.

	AKI (51)	No AKI (42)	P value
Median age (range)	64 (17-82)	57 (28-77)	0.05
Female sex (n/%)	14 (27%)	14 (33%)	0.53
Hypertension	19 (37%)	14 (33%)	0.69
Diabetes	10 (20%)	10 (24%)	0.62
Obesity (BMI >30)	21 (41%)	15 (36%)	0.59
Chronic Kidney disease	10 (20%)	2 (5%)	0.034
Pre-existing nephrotoxic therapy	20 (39%)	14 (33%)	0.558
Admission APACHE II (median, IQR)	17 (14-19)	12 (9-16)	<0.0001
Diuretic use in ICU	36 (72%)	29 (69%)	0.76
Total Furosemide dose (mg) (median, IQR)	165 (60-260)	260 (89-510)	0.65
Mechanical ventilation	48 (94%)	30 (73%)	0.005
Median (IQR) ICU Length of stay	19 (9-29)	15 (7-24)	0.03
ICU Survival	25 (50%)	34 (83%)	0.001

Table 1 : Clinical and demographic factors associated with AKI

	Odds ratio (95% CI)	P value
Age (per year increase)	1.0 (0.9-1.03)	0.45
CKD (presence)	2.7 (0.4-19.2)	0.32
APACHE II (per 1 point increase)	1.2 (1.1-1.4)	0.002
Mechanical ventilation	11.2 (1.6-80.7)	0.016

Table 2 : Binary logistic regression for Independent association with the development of AKI

Conclusion: COVID-19 patients in our cohort experienced a high rate of AKI and need for RRT, although rates were in keeping with those seen in other causes of acute respiratory distress syndrome (3). Although AKI was associated with a higher risk of death, this is mostly explained by the severity of presenting illness. We found no evidence that diuretic therapy was independently associated with the development of AKI or need for RRT.

Introduction: Studying the characteristics of infections acquired within the ICU during the last 5 years.

Methods: Descriptive study, based on the data collected in the ENVIN - ICU base of our medical-surgical unit, collected during the months of the official participation period. To do this, we have selected infections acquired within the ICU from 2015 to 2019. We will describe the location of the infection, the most frequently isolated microorganisms, the number of infections that received antibiotic treatment, appropriate antibiotic treatment

Results: During the official ENVIN-ICU registration periods from 2015 to 2019, there are 132 records of infections acquired intra ICU. Of these 132, the most frequent locations in decreasing order are: pneumonia related to mechanical ventilation or intubation (27), tracheobronchitis associated with mechanical ventilation (21), bacteremia of unknown focus (18), non-surgical infection of the digestive system (10), bacteremia secondary to abdominal infection (9), bacteremia secondary to catheter infection (9), bacteremia secondary to respiratory infection (8), urinary tract-related urinary infection (6), other infection (6). The most frequently isolated microorganisms in these records of intra-ICU infection are: *Pseudomonas aeruginosa* 13.74% (n = 18), *Enterococcus faecium* 12.21% (n = 16), *Klebsiella pneumoniae* 9.16% (n = 12), *Staphylococcus epidermidis* 8.40% (n = 11), *Stenotrophomonas maltophilia* 5.34% (n = 7), *Escherichia coli* 5.34% (n = 7). Of the 132 registered intra-ICU infections, 87.88% (n = 116) received antibiotic treatment. Of those treated with antibiotherapy (n = 116), 79.17% (n = 24) of pneumonias associated with mechanical ventilation received the appropriate antibiotic treatment, 100% (n = 5) of urinary tract-related urinary tract infections, 71.43% (n = 21) of bacteremia primary and secondary to catheter infection, 75% (n = 20) of bacteremia secondary to infection of another focus, and 78.26% (n = 46) of those classified as other intra-ICU infections.

Conclusion: In the period 2015-2019 of ENVIN-ICU registration in our unit, the most frequent intra-ICU infections acquired were pneumonia and tracheobronchitis associated with mechanical ventilation and bacteremia of unknown focus. The most frequently isolated microorganisms are *Pseudomonas aeruginosa*, *Enterococcus faecium*, and *Klebsiella pneumoniae*. Receiving antibiotic treatment in 87.88% of these infections, being correct in a very high percentage.

000795**Attitudes and beliefs of Spanish healthcare professionals during the COVID-19 pandemic**

B. N. Santana-Lopez¹; Y. G. Santana-Padilla¹; J. M. González-Martín¹; L. Santana-Cabrera¹

¹Intensive care unit, Maternal and child Hospital, Las Palmas de Gran Canaria, Spain

Correspondence: B.N. Santana-Lopez
Intensive Care Medicine Experimental 2020, **8(2)**: 000795

Introduction: During the COVID-19 pandemic, healthcare professionals are taking the risk of becoming infected or infecting their families. Spain is the country with the highest number of infected healthcare professionals worldwide.

Objectives: Our aim was to study the attitudes and beliefs of these professionals during the current pandemic.

Methods: Descriptive study conducted by using an online questionnaire – based on an earlier one – which was sent to healthcare professionals at the national level, during the week March 20-27, 2020.

Results: Healthcare professionals returned 971 completed questionnaires. A total of 803 (82.7%) participants thought that they did not have suitable PPEs to protect them from infection with COVID-19. In spite of this, 606 (62.4%) of them were ready to work, even with a higher-than-usual risk of becoming infected at work and getting ill. Furthermore, 815 (83.93%) participants were ready to work more hours than usual and 697 (71.78%) were ready to work in a different workplace. Finally, 669 (68.9%) of them put their duties towards their families before their responsibility at work.

Conclusion: Remarkably high professional commitment has been observed among Spanish healthcare workers in the current pandemic. They were ready to work even when many of them considered that they did not have suitable PPEs, and were thus taking a higher than usual infection risk. However, they put the health of their relatives before their duties at work.

000811**Bacteraemia and VV-ECMO Cannulation: A single centre audit**

J. Medhora¹; S. Williams¹; I. Scott¹

¹Intensive Care Department, NHS Grampian, Aberdeen, United Kingdom

Correspondence: J. Medhora
Intensive Care Medicine Experimental 2020, **8(2)**: 000811

Introduction: Veno-Venous Extra Corporeal Membrane Oxygenation (VV-ECMO) requires central access with either bifemoral cannulae (FF), a bicaval dual lumen cannula in the internal jugular vein (JJ) or femoral access with jugular return (FJ) (1). Bacteraemia secondary to cannula site infection in patients supported by VV-ECMO poses an increased risk in this group. Currently there is little published work on ECMO cannula site infections however, evidence based on central venous catheter infections is considered to be, in part, transferable.

The relevance of the site of central venous catheters to incidence of bacteraemia in critically unwell patients is controversial. Some studies suggest that the femoral site poses a higher risk of catheter infection (2) whilst others suggest there is no significantly increased risk in using the femoral vein compared to the jugular vein (3). Work on central lines for dialysis may be more valid than other types of central access as dialysis lines are not used for drug delivery, whilst also being exposed to a continuous flow (4).

Objectives: To assess whether the incidence of bacteraemia in patients cannulated for VV-ECMO varies based on cannulation site.

Methods: Data was collected for patients admitted to the Intensive Care Unit at Aberdeen Royal Infirmary, a centre for VV-ECMO, between February 2014-February 2020. We carried out a retrospective audit of the cannulation site in each patient and the number that developed a bacteraemia. Bacteraemia was defined as a positive blood culture result in the time period between cannulation date up until 48 hours after decannulation (2,4). Data on duration of cannulation, cannulation to bacteraemia time and location of patient at time of cannulation was also collected.

Results: Sixty patients were identified. Of these, 35 had a bicaval dual lumen cannula in the internal jugular vein, 24 had bifemoral cannulation and 1 patient had femoral access with jugular return. Ten bacteraemias were identified overall. A larger proportion of patients with bifemoral cannulation developed bacteraemias and mean time to infection in these patients was shorter. Sixty percent of the bacteraemias identified were due to a staphylococcal organism.

Conclusion: Our results suggest that VV-ECMO patients with femoral cannulae placed are more at risk of bacteraemia. This is in keeping with previous work on central venous catheter infections showing that femoral lines increased infection risk despite a shorter duration of insertion.

One patient developed two separate bacteraemias, one of which was caused by *Streptococcus mitis*, an organism found in the oropharynx and therefore a bacteraemia which is unlikely to have originated from the ECMO cannulae. This highlights the difficulty in discerning if a bacteraemia is truly secondary to ECMO cannulation, especially in the absence of line tip culture.

The impact of ECMO cannula related bacteraemia on mortality cannot be accurately assessed. Whilst it is important to consider infection risk when selecting cannulation insertion site, other factors will affect decision making such as ease of transfer, risk of thrombosis, risk of mechanical complications at time of insertion, ease of proning and the patient's Body Mass Index.

Intensive Care Medicine Experimental 2020, **8(2)**: 000817

Introduction: There is scare information of bacterial and/or fungal infections (coinfections or superinfections) in critical ill patients with COVID-19 pneumonia.

Objectives: The objctive of the study is evaluate bacterial and/or fungal infections in respiratory viral infections and discuss antibiotic empirical management.

Methods: This is a multicentre, observational and retrospective study. Patients with confirmed COVID-19 and other respiratory virus infection which required ICU admission were recruited from October 2018 to April 30th 2020. We described the population and distribution of infections.

Results: We evaluated 112 critical patients with respiratory virus infections. 58 critical care patients with COVI-19 and a further 54 patients with other respiratory infections. COVID-19 patients had significantly less respiratory co-infection (3 vs 29; $p < 0.001$). 96% of patients were treated with antibiotics at admission. In comparison with those with other respiratory infection, superinfection was not significantly higher (46 vs 31; $p = 0.1$). Probable/possible ventilator associated pneumonia was the most frequent source of infection (29%) in COVID-19 patients while in other respiratory virus infection were bacteraemia and urinary tract infection (25%). In COVID-19 patients the most frequent bacteria involved was *Pseudomonas aeruginosa* (24%) while the most frequent in other respiratory virus were Coagulase-negative Staphylococcus (29%)

Conclusion: In COVID-19 patients the incidence of coinfection is low (3%). Because of this fact, empirical antibiotic at admission should be closely evaluated. In this group, the incidence of superinfection was

46%; ventilator associated pneumonia and *pseudomonas aureginosa* were the most frecuent source and etiology.

Intensive Care Medicine Experimental 2020, **8(2)**: 000819

Introduction: When the Coronavirus Disease 19 (COVID-19) pandemic emerged in spring 2020, there was no effective treatment available. In a recent randomized clinical trial dexamethasone (DXM), a pure glucocorticoid agonist, was shown to have a beneficial impact on outcome of patients with Acute Respiratory Distress Syndrome (ARDS). As severe COVID-19 is characterized by an excessive systemic inflammation, we gradually implemented DXM in our therapeutic strategy, although initial guidelines didn't support systematic use of steroids, based on former data with viral infections and ARDS. This study evaluates the impact of DXM on the outcome of patients with COVID-19 admitted to our Intensive Care Unit (ICU).

Methods: In this retrospective, single-center cohort study, we consecutively screened all confirmed COVID-19 patients admitted to ICU between March 13 and May 15 and compared patients who received DXM (DXM group) to those who didn't (no-DXM group). Exclusion criteria were length of ICU stay less than or equal to 5 days, COVID-19 positive case without respiratory failure and Do Not Resuscitate (DNR) order at admission. Subgroups we analyzed were mechanically ventilated patients and patients getting DXM prior to initiation of mechanical ventilation (MV). Primary outcome was mortality, secondary outcomes were need for MV, duration of MV, proportion successfully weaned off ventilator, ICU-length of stay (ICU-LOS), rate of recovery, incidence of associated organ failure and incidence of infections. Rate of recovery was assessed at day 10, 14, 21 and 28 by using an ordinal clinical scale: 1. nohospitalization; 2. at hospital; 3. at ICU; 4. ICU with high flow oxygen therapy (HFOT) or non-invasive ventilation (NIV); 5. MV; 6. dead. Mann-Whitney U, χ^2 or Fisher's exact tests were used as appropriate and analyses were performed using SPSS.

Results: Of the 61 patients screened, 47 were eligible (14 patients excluded: 8 with ICU-LOS \leq 5 days, 5 with DNR-code, 1 patient who

didn't suffer from respiratory failure). Eighteen cases (38%) received dexamethasone, 6 of them before intubation. Baseline characteristics and severity of disease scores (APACHE II, SAPS II and worst SOFA score day 1 to 5) were similar in both groups. Median age was 67 years (IQR 57-78) overall, patients in the DXM group tended to be younger (63, IQR 54-71) than those in the no-DXM group (70, 62-78), although statistically not significant ($p=0.203$). Up to two-thirds were male (DXM 72% vs no-DXM 62%, $p=0.475$). Nearly all our patients received hydroxychloroquine, frequently in combination with azithromycin. Rarely tocilizumab (DXM 17%, no-DXM 3%, $p=0.54$) or remdesivir (only one patient, in the DXM group) was associated.

Overall ICU mortality was 31% (DXM 33% vs no-DXM 28%, $p=0.67$). Up to almost three quarters of the DXM group were ventilated, compared to 55% of the no-DXM group ($p=0.96$). This higher proportion is rather due to selection bias than caused by DXM, as the drug was frequently started after initiation of MV. In both groups, a similar proportion of patients has been successfully weaned off the ventilator (DXM 54% vs no-DXM 56%, $p=0.87$). MV duration (26.2 (IQR 18.9-32.1) vs 10.0 days (IQR 7.5-18.6, $p=0.05$)) and ICU-LOS (21 (IQR 14-40) vs 9 days (IQR 8-14), $p=0.019$) were both significantly longer in the DXM group. Proportion of patients clinically improving as assessed by an ordinal scale at several points in time was lower in the DXM group compared to those of the no-DXM group, although not statistically significant. Moreover, incidence of severe associated organ failure in the DXM group was twice as high as in the no-DXM group (44% vs 21%, $p=0.75$) with kidneys as the most affected extrapulmonary organs, with respectively up to 40% and 10% requiring Renal Replacement Therapy ($p=0.75$). There were more nosocomial infections reported in the DXM-group than in the no-DXM group (56% vs 17%, $p=0.04$).

Similar findings were observed in the MV-subgroup (total of 29 patients with 13 getting DXM) with comparable mortality (46% vs 44%, $p=0.581$) for both groups but longer duration of MV (26.2 vs 10.0 days, $p=0.05$), trend to longer ICU-LOS (40 vs 26 days, $p=0.11$) and slower recovery (8% clinically improved with 2 points at day 28 for DXM vs 56% for no-DXM patients, $p=0.006$) in the DXM group. Incidence of severe associated organ failure (62% vs 38%, $p=0.198$) and nosocomial infections (69% vs 25%, $p=0.017$) was higher as well in this group.

Finally, 5 out of 6 patients (83%) getting DXM prior to intubation responded well, while only one patient further deteriorated ending up on the ventilator and deceased eventually.

Conclusion: On the one hand, we couldn't demonstrate a beneficial impact of DXM on the outcome of patients for COVID-19 with even a higher incidence of ICU-acquired infections in the DXM group. On the other hand, the vast majority of patients getting the drug prior to intubation didn't further deteriorate suggesting a possible positive effect of prompt administration. Due to the small size and the study design with a presumably sicker DXM cohort, it is difficult to draw any firm conclusions. Further research is warranted to establish the role and the perfect timing of administration of DXM to treat COVID-19.

Interactive online tutorials for knowledge-sharing during a pandemic: Experience of the OxPal Partnership

R. Conway-Jones¹; R. Jurdon¹; T. Ali²

¹Medical sciences division, University of Oxford, Oxford, United Kingdom;

²Intensive care medicine, Buckinghamshire Healthcare NHS Trust, Aylesbury, United Kingdom

Correspondence: R. Conway-Jones

Intensive Care Medicine Experimental 2020, **8(2)**: 000828

Introduction: Web-based distance-learning is increasingly used during the COVID-19 pandemic. OxPal is a pre-established medical education partnership between University of Oxford medical students and their counterparts in Palestine. Our work has shown online learning to be feasible and effective for knowledge sharing to the occupied Palestinian territories (oPt). In response to the COVID-19 pandemic, OxPal rapidly organised and conducted a lecture on the virology and epidemiology of COVID-19. In feedback, the most common request was for further teaching on COVID-19 management (13/36 requests), which was supported by focus group discussion. Conducting teaching internationally raises unique challenges in understanding and responding rapidly to local needs.

Objectives: We seek to evaluate the feasibility and efficacy of interactive, real-time online tutorials on the management of COVID-19 as a method for knowledge sharing to the oPt during the pandemic.

Methods: Our established network was used to advertise tutorials to medical students and clinicians in the oPt (>800 unique emails and 2 social media platforms). Tutorials were conducted by a critical care consultant via Zoom. A systematic approach to management of severe COVID-19 was provided. The lecturer's local guidance was shared and its evidence base discussed. Feedback was elicited via an online survey. The primary outcomes were attendance and learner-reported change in confidence in COVID-19 management. As of June 2020, 3 such sessions have been conducted and placed on Youtube2.

Results: Primary outcome data is shown in Table 1. Feedback came from students at all medical schools in the oPt, from levels spanning Year 4 Medical Student to Resident doctor.

Table 1.	Attendance	Questionnaire respondents (n)	"BEFORE the lecture, how confident were you in your knowledge of how to manage a COVID-19 patient? On a scale of 1-10." Mean (Range)	"AFTER the lecture, how confident are you in your knowledge of how to manage a covid-19 patient? On a scale of 1-10." Mean (Range)
Lecture 1: Assessment & Imaging	24	8	4.1 (1-7)	7.1 (4-9)
Lecture 2: Sepsis & ARDS	15	9	3.9 (1-6)	7.2 (4-9)
Lecture 3: Ventilation & Proning	5	N/A		

When asked to rate tutorial quality on a 1-5 scale, 7/8 respondents for Lecture 1 rated tutorial quality as 4 (Good); for Lecture 2 4/9 respondents rated the tutorial quality as 4 (Good) and 2 rated it as 5 (Excellent).

7/8 and 7/9 described the difficulty of Lectures 1 and 2 respectively as '3- About right' on a 1-5 scale.

Conclusion: Online distance-learning is feasible and effective for knowledge sharing to the oPt during the COVID-19 pandemic. We saw a drop in attendance over 3 sessions. This could be due to a reduction in new cases in the oPt in that time (May to mid-June 2020)³, reducing perceived need. There were also medical school examinations in June. Therefore, lecture plans must be made in response to immediate need and be systematically adaptable as the target population's situation changes.

Intensive Care Medicine Experimental 2020, **8(2)**: 000830

Introduction: Throughout 2016 to 2018 our centre enrolled in a national programme that aimed to study the good practices in infectious diseases prevention and to implement a national bundle. This project was conducted due to Portugal's high rates of nosocomial infections, reaching almost twice the European numbers in 2013, with substantially high expenses on health [1].

Methods: Two different types of infections were studied in our intensive care unit (ICU): central venous-catheter (CVC) related bacteremia and intubation-associated pneumonia. Collaborative Breakthrough was implemented and results were analysed.

Results: Our ICU represents 2,2% of the national patients studied (in 19 hospitals), with an average age difference of 3 years older than the national mean. Despite a high variability, the mean duration period in the ICU was similar to the other hospitals studied, with an average 10,6 days stay. Our mortality was slightly higher than the studied (18% mortality), but with no high variability throughout the years analysed, in oppose to our higher SAPS II scores values, that averaged 49, in comparison with a national SAPS II score mean of 44. Our patients mostly diverged on the necessity for antibiotics, with only 16% need, compared with 51% nationally. Also showing smaller values were the need for intubation (58 vs 75%) and the average intubation period (5,7 vs 6,6 days).

The results of the infectious outcomes were consistent and improving throughout the years [2]. Both CVC placement and intubation numbers per patient were lower in our ICU than expected. In 2015 there were 0,7 blood infections per 1000 days of CVC, with a reduction to 0,6 in 2019, one year after the national program (representing a 14% reduction). Nationally there was a significant reduction of 23%, but rarely reaching values lower than one blood infections per 1000 days of central venous access. On the other hand, the number of intubation-associated pneumonia reported was reduced by 68% in our ICU for the past 10 years, in comparison to a 30% national reduction, with only 1% of patients admitted to our ICU in 2019 suffering intubation-associated pneumonia.

Conclusion: Hospital-acquired infections are a significant health issue [3]. Several guidelines and protocols have been implemented worldwide, aiming for its reductions. A lot has been accomplished the past decade, but there is still a lot that can be done, as this national program has come to show us.

Intensive Care Medicine Experimental 2020, **8(2)**: 000844

Introduction: The pandemic caused by SARS-CoV-2 is an epidemiological emergency that has led to the rapid search for effective treatments to reduce the complications and improve the survival rate of the population affected by this virus.

One of the main complications that can result from SARS-CoV-2 is the cytokine storm or hypercytokinemia: a syndrome characterised by the elevation of inflammatory markers, such as D-dimer, interleukin-6, ferritin and C-reactive protein, which, in addition, leads to clinical and radiological deterioration. In light of this inflammatory response, some therapies have been considered, such as corticosteroids in high doses or monoclonal antibodies like Tocilizumab (anti-IL-6) or Bevacizumab (anti-IL-2).

Although scientific associations have not endorsed the use of immunoglobulins as immunomodulators, this therapy could be considered for those patients with refractory acute respiratory distress syndrome (ARDS) and contraindications to previous treatments (due to suspected superinfection, among other causes).

Objectives: To describe our experience in the use of immunoglobulins in CoVid-19 patients with refractory ARDS with inflammatory response criteria and contraindications to the immunomodulatory therapy.

To describe radiological evolution, changes in the inflammatory markers, mortality and complications after the administration of immunoglobulins.

Methods: Retrospective, descriptive, observational study conducted in the Intensive Care Unit of the Hospital Universitario Reina Sofia in Córdoba, Spain.

Epidemiological variables, complications, mortality, radiological controls and inflammatory markers (interleukin-6, D-dimer, ferritin, C-reactive protein, lymphocytes) were collected in three different stages: immediately before, during and after administering a course of immunoglobulins in doses of 2 g per kg of the patient's body weight over a period of 3 to 6 days.

At the time of writing, some of the patients involved are still in the Intensive Care Unit.

Results: Of the total number of patients admitted to our ICU due to CoVid-19 (n=41), 8 received treatment with immunoglobulins. 3 of the patients were women; one of them died. One of the patients is still in ICU and the rest were discharged. The average age was 59.8 years old. The time elapsed between the admission to the ICU and the initial treatment with immunoglobulins ranges from 3 to 8 days.

After analysing the data, we noticed the average of all inflammation reactants had decreased, while lymphocytes had increased after the immunoglobulins treatment:

	Before	During	After
C-reactive protein	257	151	85
D-dimer	13,631	13,604	6,293
Interleukin-6	1,263	296	295
Ferritin	5,248	5,614	1,520
Lymphocytosis	0.78	1.16	1.39

(Mean values)

There was a significant response in the decrease of the interleukin-6 (n=7). D-dimer dropped over 50% in 3 patients. Ferritin decreased over 50% in 3 of the cases. One of the patients showed elevation of the interleukin-6, ferritin and D-dimer, probably due to superinfection. The CRP also fell by half in other 3 cases. Only one patient suffered from thrombotic events (thrombophlebitis in inferior vena cava).

While monitoring the affected pulmonary fields in the serial chest x-rays, we noticed a drop in the average of affected fields: 3.12 before the treatment, 3.8 during and 2.5 after the treatment.

We also observed an improvement in the lymphopenia of our patients. However, it should be noted that in 3 of the 5 patients who developed an increase of absolute lymphocytes and of their white blood cell percentage, this was due to a general increase of the leukocytosis.

Conclusion: In cases of refractory ARDS and increase of the inflammatory response in CoVid-19 patients admitted to ICU with contraindications to monoclonal antibody therapy or to corticosteroid therapy in high doses, we could consider administering 1 g of immunoglobulin per kg of the patient's body weight for a time period between 3 and 6 days.

Studies with a larger sample size are required to confirm the effectiveness of immunoglobulins in this group of CoVid-19 positive patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000889

Introduction: COVID-19 has challenged our health system and our standard practices. Mechanically ventilated (MV) COVID-19 patients have long intensive care unit (ICU) stays [1] increasing their exposure to nosocomial infections (NI).

Objectives: In a perspective of quality improvement, we studied the incidence of NI and use of broad-spectrum antibiotics (BSA) in MV COVID-19 patients.

Methods: We collected data retrospectively for every MV COVID-19 patient admitted to our 18- to 38-bed expanded ICU between 01.03. and 30.04.2020. ICU days, ventilation days (VD), catheter days (CD), use of BSA, fever days (> 38°C) and c-reactive protein (CRP) were recorded. Each suspected NI, defined by the introduction of BSA ≥ 48h after admission or repeated administration of BSA after an antibiotic free period ≥ 48h, was reviewed by an infectiologist. NI were confirmed using CDC criteria [2] for ventilator associated pneumonia (VAP), central line associated blood stream infections (CLABSI), urinary tract infections (UTI), or clinical evidence for septic shock (SS) and bacteraemia (BE) from another origin.

Results: Of 54 COVID-19 patients, 37 MV patients (69%) spent a total of 672 ICU days, with 504 VD and 545 CD. They had fever during 26.5% of ICU days. Median peak CRP was 309 mg/l (IQR, 264-365) after a median stay of 3 days (IQR, 2-5). Among 31 suspected NI, 21 (68%) NI were confirmed: 4 VAP, 6 CLABSI, 1 UTI, 8 SS and 2 BE from another origin. The incidence of VAP and CLABSI was respectively 7.9/1000 VD and 11/1000 CD. Our 2019 annual incidence for VAP and CLABSI was 3.9/1000 VD and 1.7/1000 CD. Global incidence of confirmed NI was 31.3/1000 ICU days.

Conclusion: The incidence of confirmed VAP and CLABSI was higher in MV COVID-19 patients than in our standard ICU population of 2019. COVID-19 patients might have a greater risk of NI due to anatomical barrier disruption and maladaptive immune response, but other factors such as cohorting of several patients in the same room, using gloves for self-protection with insufficient replacement and temporary deviation from standardized procedures could have contributed to the incidence of NI. BSA were often prescribed early during ICU stay, reflecting physician's anxiety facing this new disease and the difficulty to diagnose NI. Severe COVID-19 pneumonia induces a prolonged fever, high inflammatory state, diffuse lung infiltrates and protracted respiratory failure, which makes classical criteria for VAP less specific. In that setting, NI definitions should be refined to find an optimized set point for BSA introduction, avoiding under- and overuse.

Intensive Care Medicine Experimental 2020, **8(2)**: 000897

Introduction: COVID-19 pandemic has been a challenge for health-care professionals. This is a virus that seemed to follow a clinical pattern with an intense inflammatory response and thrombogenic load, for which we don't have a specific treatment.

Objectives: Different therapeutic strategies for COVID-19 have been used to target the viral replication, to limit the inflammatory response and to avoid thrombotic complications. We describe the prescribed treatment of COVID-19 patients (COVp) admitted in our ICU during the pandemic. This treatment was based on the protocol of our center, the availability of drugs and the published literature at the time.

Methods: A retrospective descriptive observational analysis about treatment of COVp admitted in our ICU during the pandemic, from March 13 to May 4, 2020, along with the ICU clinical evolution of the same patients under these treatment guidelines.

Results: From March 13th to May 4th 2020, 48 COVp were admitted in our ICU: 31 males (64.6%), with an average age of 57,7 y.o. (CI 95% 54,6-60,9) and APACHE II score 17,25 (CI 95% 15,6-18,7). The time lapse from the onset of symptoms until admission in ICU was 8,8 days (CI 95% 7,6-10,1). The average white bloodcells when entering was $9,8 \times 10^9/L$ (CI 95% 8,3-11,3), PCR 169 ng/L (CI 95% 141-197), D dimer 5841 ng/ml (CI 95% 1737-9945), ferritin 1807 ng/ml (CI 95% 1726-1888) and 37 patients (77,1%) had a lymphocyte count $< 1,0 \times 10^9/L$. Upon admission to the ICU, all patients were treated with hydroxychloroquine, 33 patients (68,8%) with azithromycin associated and 47 patients (97,9%) with lopinavir/ritonavir. Methylprednisolone was administrated to 44 patients (91,7%), of which 13/44 (29,5%) 40 mg/8h with variable duration (discretion of the responsible physician), and 31/44 (70,4%) 500 mg/24h for five days. Interferon beta-1b was administered to 38 patients (79,2%), tocilizumab to 10 patients (20,8%), and anakinra to 4 patients (8,3%). Enoxaparin was given to 44 patients (91,7%): 18/44 (37,5%) with antithrombotic prophylaxis dose, 20/44 (45,4%) with 1 mg/kg/24h and 6/44 (13,6%) with 1 mg/kg/12h. Forty patients (83,3%) needed invasive mechanical ventilation with an average duration of 22,2 days (IC 95% 17,3-27); 35 patients (72,9%) needed vasopressors and 6 patients (12,5%) renal replacement therapy. Our patients showed: tetraparesis that increased the mechanical ventilation and the UCI stay days, 22 patients (45,8%); delirium, 21 patients (43,8%); nosocomial infection, 17 patients (35,4%); arrhythmias, 11 patients (22,9%) (9/11 atrial fibrillation and supraventricular tachycardia); and vascular thrombosis, 2 patients (4,2%). The average ICU stay was 23,1 days (CI 95% 18,4-27,8). 13 patients died (27%).

Conclusion: All our patients were treated with hydroxychloroquine and most of them with lopinavir/ritonavir, methylprednisolone and interferon beta-b1. Half of them received higher heparin doses than those used for antithrombotic prophylaxis.

Combination Therapy with Meropenem and Ciprofloxacin Shows a Synergistic Benefit against Intermediate and Resistant *Pseudomonas aeruginosa* Isolates from Critically Ill Patients in the Hollow-Fiber Infection Model

N. Karabasevic¹; J. Roberts²; L. Stronach²; S. Naicker²; F. Sjövall³; F. Sime²

Intensive Care Medicine Experimental 2020, **8(2)**: 000898

Introduction: Patients with sepsis and septic shock have altered antimicrobial pharmacokinetics, which often results in suboptimal drug concentrations. Septic patients are also at risk for infections with resistant organisms such as *Pseudomonas aeruginosa*. Combination therapy against *P. aeruginosa* infections is still debatable.

Objectives: This study aims to investigate whether there is any synergistic benefit, in terms of bacterial killing and suppression of emergence of resistance, of a meropenem-ciprofloxacin combination therapy in comparison to monotherapy with the same antibiotics

against *P. aeruginosa* in septic patients with altered pharmacokinetics, using a dynamic Hollow-Fiber Infection Model (HFIM).

Methods: Two intermediate to resistant *P. aeruginosa* isolates code numbered 27 (MICmeropenem of 4 mg/L and MICciprofloxacin of 1 mg/L) and 40 (MICmeropenem of 16 mg/L and MICciprofloxacin of 1 mg/L) were evaluated in a 5-day HFIM investigation. Changes of the total and resistant bacterial populations were evaluated using quantitative cultures. The studied regimens were equivalent to 2 g of meropenem every 8 h (30 min infusion), 600 mg of ciprofloxacin every 8 h (45 min infusion) and the combination of the same antibiotics. The doses and pharmacokinetic simulations were based on recommendations and data from previous studies on critically ill patients (1, 2).

Results: In both HFIM investigations, combination therapy achieved considerably greater bacterial killing and resistance suppression compared to the monotherapies. The monotherapies started to fail after 24 h, with increased bacterial concentrations of 3-6 log₁₀ CFU/ml. From there, strain 40 plateaued at 8-9 log₁₀ CFU/ml after 48 h. Strain 27 continued increasing from 3-6 log₁₀ CFU/ml at 48 h until reaching 9-10 log₁₀ CFU/ml at 120 h. In contrast, the combination therapies suppressed bacterial growth from 6 h and onward. Additionally, the monotherapies had accelerated growth of resistant subpopulations reaching 8-9 log₁₀ CFU/ml, while no resistance was detected in the combination therapies.

Conclusion: This study suggests a synergistic benefit of combination therapy with meropenem and ciprofloxacin against *P. aeruginosa* in critically ill patients with altered pharmacokinetics. Our findings support empirical combination therapy against *P. aeruginosa*, especially for resistant isolates.

Antimicrobial consumption during SARS-CoV2 outbreak

A. Knapen¹; LP. Moulart¹; R. Courcelle¹; P. Henin¹; JB. Mesland¹
¹Icu, CH Jolimont, La Louvière, Belgium

Correspondence: J.B. Mesland
Intensive Care Medicine Experimental 2020, **8(2)**: 000911

Introduction: Since the beginning of SARS-CoV2 outbreak, paucity of data has been published regarding rate of co-infection and super infection. Most guidelines have recommended empirical antimicrobial for mechanically ventilated patients admitted in ICU (1). In the meantime, the differentiation between bacterial super infection and bacterial colonization of the respiratory tract has been challenging especially with the hyperinflammatory state of critical cases admitted in ICU.

Consequently, high prescription rate of antibiotics has been described in the literature for SARS-CoV2 patients but no data has been published on antibiotic consumption specifically in ICU patients.

Objectives: Our main objective is to evaluate the antibiotic consumption (Days Of Therapy, antibiotic prescribed, timing within ICU

hospitalization) in our critical SARS-CoV2 patients and evaluate the potential effect on antimicrobial resistance.

Methods: In an observational, retrospective and monocentric study, we reviewed antibiotic prescription (name, duration, indication) of all SARS-CoV2 patients admitted in our ICU between march 2020 and may 2020. β -Lactams were then stratified by their tendency to drive antimicrobial resistance based on classification developed by Weiss and al. (class 1 to 6) (2).

Results: Between march 2020 and may 2020, 44 critical SARS-CoV2 have been admitted to our ICU (22 beds). We have been able to collect data from 41/44 patients. Mean age at admission was 63 years. 83% received mechanical ventilation (34/41 patients), for a total of 505 days, and 24% (10/41 patients) received ECMO therapy, for a total of 172 days. Mortality in our unit was 50%. All but one patient received hydroxychloroquine and 38/41 patients received azithromycin as it was recommended by our national Belgian guidelines. Both medications were given during 5 days.

92% received an antibiotic at some point during their ICU stay. Based on recommendations, 46% (19/41 patients) received empirical therapy at admission despite the fact that none of our patients were in shock. Considering co-infections positive microbiology within the first 48 hours after admission, then 17% were in that case. First antibiotic prescription for the rest of the cohort occurred for 9/41 patients within the first week and for 6/41 patients within the second week.

From 682 patient ICU days, 396 Days Of Therapy (DOT) of antibiotics were documented, representing 581 DOT/1000 patient-days. Prescription was distributed as follows: 26% for amoxicillin-clavulanate, 23% for piperacillin/tazobactam, 12% for cefuroxime, 7% for ceftriaxone, ceftazidime, and vancomycin, 6% for meropenem, 5% for amikacin, 2% for amoxicillin, flucloxacillin, temocillin, ciprofloxacin, and 1% for cefepime.

37% of all antibiotics were at least classified as class 4 (2), and 44% of prescription had an anti-pseudomonal coverage. Non effective prescription (pathogen with documented resistance to the antibiotic prescribed) in 8% of cases (33/396 DOT).

Conclusion: Antibiotic consumption was in the range of previously described consumption from general ICU outside of SARS-CoV2 pandemic: De Bus and al. reported 1232 DOT/1000 patient-days (3). Consumption decrease would have been possible by avoiding empirical administration at admission (absence of shock in all patients), and use of newly available technique like RT-PCR.

Concern about antimicrobial resistance need to be emphasized, resulting from increased patient exposure to antimicrobials, often suboptimally or inappropriately used (4). Indeed, on the one hand hyperinflammatory state might have increased the likelihood of antibiotic prescription in case of bacterial superinfection. And on the other

hand long duration of ventilation and previous antimicrobial exposure might have prompted the clinician to prescribe a broad spectrum antibiotherapy.

Tigecycline reduces blood glucose in the critically ill patients with severe infection

W. Huang¹; B. Li²; Y. Lu²; Y. Li¹

¹Department of intensive care medicine, The Sixth People's Hospital, Shanghai Jiao Tong University, Shanghai, China; ²Department of epidemiology, Fudan University School of Public Health, Shanghai, China

Correspondence: W. Huang

Intensive Care Medicine Experimental 2020, **8(2)**: 000922

Introduction: Tigecycline is a last-resort antibiotic to treat severe infection caused by multidrug-resistant bacteria. It may induce decreased blood glucose, as described elsewhere [1-3]. In the drug inserts, incidence of decrease in blood glucose is labeled as <2%. In the critically ill patients, severe infection is common; however, the impact of Tigecycline reducing blood glucose remains to be assessed.

Objectives: This study is to determine if Tigecycline reduces blood glucose in critically ill patients with severe infection and further identify the factors associated with decreased blood glucose.

Methods: We retrospectively studied critically ill patients who received Tigecycline in the ICU department of the Sixth's People Hospital in Shanghai, China from January, 2018, through July, 2019. Mixed-model repeated measure was utilized to compare the mean blood glucose before and after Tigecycline administration. The two phases (before and after Tigecycline administration) and daily blood glucose (measured at 6am, 2pm and 10pm) were presented as two repeated factors. Other factors were considered covariates or between-subjects factors in the model, including sex, age, comorbidity, prognosis, duration and dosage of Tigecycline administration, and intravenous glucose infusion. Multivariate linear regression model was employed to determine the association of above-mentioned factors with decrease in blood glucose. Moreover, binary logistic regression was utilized to determine the factor associated with hypoglycemia that was defined as a decrease ≥ 2.8 mmol/L in the study. Receiver operating characteristic (ROC) and its area under curve (AUC) were then employed to evaluate the factor in predicting hypoglycemia. All analyses were performed using SPSS Statistics, version 23.0 (IBM Corporation, Armonk, NY). A *P* value <0.05 was considered statistically significant.

Results: A total of 168 patients were studied, including 105 male and 63 female, with an average age of 64.2 ± 15.8 yrs. After Tigecycline administration, daily blood glucose at three points of time significantly decreased ($P < 0.001$), regardless of other factors. The decrease in blood glucose, defined as the difference between the minimum blood glucose before and after Tigecycline administration, was positively correlated with death ($\beta = 0.78$, $P = 0.016$), maximum decrease

in blood glucose within 24 hrs ($\beta=0.67$, $P=0.032$), and duration of administration (hrs) ($\beta=0.004$, $P<0.001$). Hypoglycemia was identified in 19 patients (11.3%), which was determined to be associated with death (OR=3.71, $P=0.014$) and maximum decrease in blood glucose within 24 hrs (OR=1.18, $P=0.002$). The AUC for the maximum decrease in blood glucose within 24 hrs was determined to be 0.76 (95%CI, 0.66-0.86) and best cutoff value was 4.35 mmol/L (sensitivity, 0.90; specificity, 0.53).

Conclusion: Tigecycline significantly reduces blood glucose in the critically ill patients with severe infection. In addition, decrease in blood glucose is associated with risk of death, duration of Tigecycline administration, and maximum decrease in blood glucose within 24 hrs, further suggesting usage with extreme caution. A decrease ≥ 4.35 mmol/L in blood glucose may predict hypoglycemia, which would facilitate early warning in the critically ill patients.

Differences between survivors and no survivors in ICU patients with severe influenza infection, according to nursing and severity indexes

A. Vakalos¹; N. Tsikliras¹; S. Patsatzakis¹

¹Icu, Xanthi General Hospital, Xanthi, Greece

Correspondence: A. Vakalos

Intensive Care Medicine Experimental 2020, **8(2)**: 000039

Introduction: Influenza virus infection is an important cause of mortality worldwide, leading to 250000 to 500000 deaths each year in the developed world. Mortality is caused by the primary viral infection, but also by influenza-associated pulmonary co-infections.

Objectives: Our retrospective observational study aimed to evaluate the difference in the outcome of patients with influenza infection requiring admission to both Medical and Surgical Intensive Care Unit (ICU) served to a community hospital, according to nursing and severity indexes.

Methods: From January 2006 to October 2019, 1332 patients admitted to our ICU. From these, 25 (1.87%), were indicated with the diagnosis of severe influenza infection. The patients separated into two groups. Group A involved all patients who survived ICU and group B all patients who died in ICU. We looked for statistically significant difference (p-value two-tailed) between the medians values of two groups, using the unpaired Mann-Whitney test or the unpaired t-test Welch corrected according to the normality test, according to nursing (Age, sex, LOS, MVD) and severity (Simplified Acute Physiology Score: SAPS II, predicted mortality by SAPS II, Acute Physiology and Chronic Health Evaluation: APACHE II, predicted mortality by APACHE II, Glasgow Coma Scale: GCS) indexes.

Results: We detected no statistical difference between the two groups according: age ($p=0.6314$), sex ($p=1.000$), GCS ($p=0.3830$), LOS ($p=0.9979$), MVD ($p=0.4342$), predicted mortality by SAPS II score ($p=0.2001$)

We detected statistical significant higher group B value according to APACHE II score ($p=0.0281$), predicted mortality by APACHE II score ($p=0.0276$), SAPS II score ($p=0.0356$)

Conclusion: According to our data, demographic data and nursing indexes were about the same among the two groups. On the other

hand, severity scores like APACHE II score and SAPS II score were both statistically significantly higher in group B, assuming that patients who died in ICU admitted to ICU in more severe illness. But, only predicted mortality by APACHE II score achieved to be statistically significantly higher in group B. Our data suggest that we can use the APACHE II severity score as an accurate severity score in these patients.

000930

Implementation of an Antibiotic Stewardship Program in an ICU

S. Carvalho Brugger¹; B. Balsera Garrido¹; M. Miralbés Torner¹; A. Bellés Bellés²; J. Caballero López¹; M. Vallverdú Vidal¹

¹Intensive care unit, University Hospital Arnau de Vilanova, Lleida, Spain;

Intensive Care Medicine Experimental 2020, **8(2)**: 000930

Introduction: Antibiotic Stewardship Programs, in Spain known as PROA, are becoming increasingly important in both hospital and primary care. These programs work on optimizing antibiotic (ATB) prescribing to improve patient prognosis, minimize adverse effects, monitor the onset of resistance, and ensure the use of cost-effective treatments.

Objectives: In this work we review the performance of a PROA team in an ICU.

Methods: The authors present a descriptive analysis of the daily performance of a team of intensivists dedicated to infections, with the application of PROA in a polyvalent UCI, during the year 2019, comparing to the previous year. The interventions carried out by the PROA team were: general recommendations, initiate, de-escalate, shift or stop ATB, sampling for cultures, pk/pd optimization, and consults directly made by other doctors to the PROA team.

Results: During 2019, 632 interventions have been made. The recommendation was initiating ATB treatment in 38.1% of them, and discontinue it in 63.45%, with an adherence of 91.1%, higher than the previous year (87.9%). Non-adherence was observed in interventions about days of ATB treatment (35.71%), discontinuation of antibiotic therapy by negative cultures (17.85%) and general recommendations made to the responsible physician (16%). Adherence was observed mainly in interventions about days of treatment, general recommendations, de-escalation of ATB and culture-directed ATB treatment. The interventions that most often motivated the onset of ATB were: culture-directing ATB treatment (28.63%), de-escalating (22.82%), expanding spectrum (15.76%) and initiate empirical treatment in cases of suspected infection (12.45%). The most frequently used ATBs on interventions were 3rd generation cephalosporins (cefotaxime 15.35%), ureidopenicillines (piperacillin-tazobactam 9.5%), and aminoglycosides and linezolid (8.2%). 63.44% of interventions recommended the suspension of ATB treatment, the most common reasons were: days of ATB treatment (37.65%), de-escalate (21%), negative cultures (10.22%) and a few times the suspension because a limitation of therapeutic effort. The most frequently discontinued ATBs were ureidopenicillines (piperacillin-tazobactam 21.7%), aminoglycosides (amikacin 9.23%), 3rd generation cephalosporins (cefotaxime 9%), linezolid (6.5%) and azoles (6.23%). Regarding inquiries made to the PROA team by the UCI team, the advices given were not initiate ATB, not changing antimicrobial therapy and extending the spectrum, with an adherence of the doctors of 100%. In addition, a total of 100 recommendations have been made (15.8%) with 91% adherence relative to contact isolations (22%), microbiological sampling (20%), initiation of ATB therapy (13%) and not starting ATB or non-indicated ATB treatment (9%). Overall mortality in 2018 was 10.95%, and 10.67% in 2019 (not significant). It has been observed a trend for the reduction of multi-resistance since the implementation of the PROA. The rates of BMR infection during ICU stay have been 1.55/100 patients and 2.9/1000 days of stay in 2018, and 1.22/100 patients and 2.47/1000 days of stay in 2019.

Conclusion: The interventions carried out have had a high adherence, which reflects the trust placed by the doctors responsible towards the PROA UCI team. These interventions have resulted in a decrease

in multidrug-resistant bacteria in the ICU, antimicrobial consumption and a better ATB policy, with no implications for mortality. It is important to give out the results obtained to positively strengthen its good work and to be able to identify areas of improvement.

Intensive Care Medicine Experimental 2020, **8(2)**: 000944

Introduction: The full spectrum of COVID-19 infection ranges from an asymptomatic disease, through mild respiratory tract illness to a severe pneumonia and acute respiratory distress syndrome (ARDS), including multiorgan failure and death. This novel coronavirus induces the release of inflammatory cytokines, and it is the disruption of the immune response that can lead to multiorgan dysfunction and ARDS (1). Coagulopathy in COVID-19 infection is correlated with mortality, with D-dimer levels being of particular importance as biomarker (2).

Objectives: To describe the pathological findings of post-mortem lung biopsies in patients who died of SARS-CoV-2 infection.

Methods: A prospective observational study of post-mortem lung biopsies in patients who died of COVID-19 was conducted. Biopsies were obtained by 14G tru-cut from March 31 to May 25, 2020 in the ICU of the Fundación Jiménez Díaz in Madrid. Morphological studies were performed using immunohistochemical techniques (IHC). On the last day of admission, data regarding the epidemiology, respiratory mechanics and severity of disease was collected.

Results: In total, 16 patients were studied (100% H). The median age was 63 years (IQ 56-66 years). The most frequent previous medical history included: ETS 31%, LD 31%, DM 18% and OM 31%. Median of previous admission day was 28 (IQ 14-39). Median APACHE II 14. Days of admission to ICU were 27 (range 1-44). The median number of days on MV was 24. Tracheotomy was performed in 63%. The ventilatory mode was volume control in 100%, with an average tidal volume of 6.21 ml/kg of predicted body weight. This resulted in a plateau pressure of 31 cmH₂O, a driving pressure of 21 cmH₂O and a static compliance of 17.5 ml/cmH₂O. Regarding arterial gases: pH of 7.29 (IQ of 7.17-7.38), pCO₂ of 74 (IQ 53-87) and a PaO₂/FiO₂ ratio of 64 (IQ 58-108). The average laboratory values were: D-dimer (DD) 3860 µg/L, lymphocytes 850 (abs), platelets 138000 µl, Hb 8.5 g/L, creatinine 1 mg/dl, PCR 13.6 mg/dl, ferritin 892 ng/mL. All patients received prophylaxis with LMWH. If the DD was higher than 3000 µg/L, the LMWH was administered at therapeutic dose (1 mg/kg/24h). Diffuse alveolar damage and frequent formation of hyaline membranes were observed in 100% (Fig. b), 44% presented pneumonia in cryptogenic organization. It should be noted that 78% of the patients had frequent capillary microthrombosis (Fig. a). In addition, the IHC showed intense expression of CD163+ macrophages as well as CD8.

The results showed diffuse alveolar damage and hyaline membrane formation in all patients, and capillary microthrombosis in more than

75% of them. In the pre-mortem analysis the DD was higher than 3,000 µg/L in more than half of cases. The frequent finding of CD163+ macrophages represents the histopathological substrate for the macrophage activation syndrome seen in these patients.

Conclusion: Our results confirm the hypothesis that SARS-Cov-2 may trigger a macrophage activation syndrome, as well as a state of hypercoagulability, which would support the implementation of immunosuppressive and anticoagulant treatment, beside supportive therapy.

Intensive Care Medicine Experimental 2020, **8(2)**: 000985

Introduction: Analyzing which antibiotics have been used more frequently as empirical treatment in our unit over almost two decades and the duration of their use

Methods: Descriptive study based on the data collected in the ENVIN - ICU base of our medical-surgical unit, collected during the months of the official participation period. We describe the most frequently used antibiotics (meropenem, piperacillin-tazobactam, levofloxacin, azithromycin and linezolid), their percentage of use and average duration of treatment, analyzing two time periods, 2002-2009 and 2010-2019

Results: During the period 2002-2009, there were 916 records of antibiotics, the most used was levofloxacin 13.32%, with an average duration of 6.71 ± 4.99 days, piperacillin-tazobactam 12.77% and an average of 7.37 ± 4.41 days, meropenem 4.91% and an average of 8.40 ± 6.07 days, linezolid 2.07% and 7.74 ± 68.48 days on average, azithromycin 0.22% with an average of 4'00 ± 0'00 days.

During the period 2010-2019 there were 1570 records of antibiotics, the most used was meropenem 17.26% with an average duration of 6.22 ± 4.92 days, piperacillin-tazobactam 15.16% and 5.81 ± 4.17 days, linezolid 12.23% and 5.38 ± 3.60 days, levofloxacin 7.45% and 4.84 ± 4.02 days, azithromycin 3.444% with an average of 3.96 ± 1.38 days. Extracting only the data for the year 2019, there are 204 records, the most used antibiotic is piperazillin tazobactam 20.59% and 5.52 ± 3.41 days, meropenem 19.12% and 5.87 ± 3.11 days, linezolid 14'71% and 5'17 ± 3'27 days, azithromycin 4'90% and 4'40 ± 1'78 days, levofloxacin 1'47% and 5'67 ± 2'31 days.

Conclusion: We observe that the most used antibiotics have been modified, shortening their time of use, during the study period. Highlight the decrease in the use of levofloxacin and the increase in azithromycin, in addition to the frequent use of piperacillin-tazobactam maintained over time for almost two decades.

Intensive Care Medicine Experimental 2020, **8(2)**: 000986

Introduction: Descriptive analysis of the population admitted to our medical-surgical ICU in the last two decades.

Methods: Descriptive study based on the data collected in the ENVIN - ICU base of our medical-surgical unit, collected during the months of the official participation period. We divided the total number of patients into two periods: 2002-2009 and 2010-2019, and studied characteristics such as: age, sex, APACHE, SAPS II, underlying disease (medical, surgical, trauma, coronary), deaths, days of ICU stay, origin of the patients (hospitalization unit, another ICU, their home, long-stay center).

Results: During the period 2002-2009, 1114 patients were registered. The average age was 61.44 ± 14.67 years old, 62.48% male. The average score on the SAPS II scale was 29.77 ± 12.63 points, and APACHE was 16.61 ± 8.53 points. The base disease registered was medical 79.44%, surgical 11.22%, trauma 1.53%, coronary 7.81%. The origin of the patients (n=466) prior to ICU admission was a 25.99% hospitalization unit, another ICU 2.07%, home address 12.95%, long-stay center 0.90%. Regarding mortality (n=1109) 176 deaths occurred (15.87%). During the period 2010-2019, 2533 patients were registered. The average age was 63.12 ± 14.80 years, with 67.11% males. The average SAPS II score was 30.64 ± 16.35 points and in APACHE 15.19 ± 8.70 points. The registered base disease was medical 48.72%, coronary 40.43%, surgical 9.87% trauma 0.99%. Its origin prior to income (n=2531) was his home 61.39%, one hospitalization unit 31.35%, another ICU 6.20%, long stay center 0.99%. Regarding mortality (n=2513) 322 were recorded death (12.81%).

Conclusion: Throughout these two decades, there are an increasing number of registered patients, whose most frequent origin was their home, with the medical reason persisting as the most frequent, and finding a decrease in mortality. Coronary patients go from 7 to 40% in the second decade, which could partially explain the decrease in mortality, without affecting the severity of the patients.

Correspondence: Á. Vidal González
Intensive Care Medicine Experimental 2020, **8(2)**: 000988

Introduction: The full spectrum of COVID-19 infection ranges from an asymptomatic disease, through mild respiratory tract illness to a severe pneumonia and acute respiratory distress syndrome (ARDS), including multiorgan failure and death. This novel coronavirus induces the release of inflammatory cytokines, and it is the disruption of the immune response that can lead to multiorgan dysfunction and ARDS (1). Growing evidence suggests that a subgroup of patients with severe disease might experience a deregulated systemic inflammation in conjunction with cytokine storm syndrome, leading to death (1, 2). There is an increasing interest in describing the histopathology of COVID-19 infection in different organs, through the study of samples obtained by means of core needle biopsies or full necropsies. Extending our knowledge will allow a better understanding of the disease and the development of new therapeutic targets.

Objectives: To describe the histopathological changes of the bone marrow in patients who died in ICU due to SARS-CoV-2 infection

Methods: A prospective observational study of bone marrow biopsy (BMB) in patients who died of COVID-19 was carried out in the ICU of

the Fundación Jiménez Díaz in Madrid from March 31 to May 25, 2020. Morphological and immunohistochemical (IHQ) studies were performed on the samples. Epidemiological, severity and analytical data were also collected.

Results: 4 BMBs were performed. 100% of patients were male. The median age was 60 years (IQR 56-65). The most frequent past medical history were: LD and morbid obesity in 50%, ATH in 25%. The APACHE II at 24h of admission was 13.5. The mean number of days of admission to the ICU was 14.5 days (IQR 3.5-25) with 23 days of MV. Prone ventilation was performed in 75% and tracheostomy in 50%. The median of values in the pre-death analysis was: D-dimer 4209 µg/L, fibrinogen 816 g/dl, lymphocytes 400 abs, platelets 83,000/µl, Hb 10.35 g/L, creatinine 1.15 mg/dl, PCR 37.8 mg/dl, ferritin 892 ng/mL, LDH 332 u/L, total bilirubin 1.3 mg/dl and lactic 2.4 mmol/L. They were treated in 75% of cases with LPV/RTV, hydroxychloroquine and 250 mg methylprednisolone pulses, in 50% of them with interferon alpha-2b and only one patient received tocilizumab. Histiocytic hyperplasia with hemophagocytosis (Fig. a) was observed in 75% of patients and non-specific inflammatory myelopathy in one patient.

The BMB results show findings consistent with the diagnosis of hemophagocytic histiocytosis (HH). HH is a common finding associated with severe viral problems and represents the histological counterpart of the macrophage activation (MAS) suffered by these patients. Macrophage activation syndrome (MAS), also known as hemophagocytic lymphohistiocytosis (SHLH), is characterized by the overactivation of cytotoxic T cells with hemophagocytosis by macrophages and a massive release of inflammatory cytokines. For these reasons it is classified within the cytokine storm syndromes.

Conclusion: In our series, not all cases met the diagnostic criteria of HLH, but we do consider that it represents the histological substrate for MAS in these patients, supporting the indication of immunomodulatory treatment.

Use of antibiotics in a medical surgical ICU. Descriptive study of the last 20 years

CM. Rodríguez Mejías¹; A. López Fernández¹; J.P. Valencia Quintero²; J.C. Luque Moscoso¹; J. Machado Casas¹

¹Medicina Intensiva, Hospital Universitario Virgen de las Nieves, Granada, Spain; ²Medicina intensiva, Regional Hospital Santa Ana de Motril, Motril, Spain

Correspondence: A. López Fernández
Intensive Care Medicine Experimental 2020, **8(2)**: 000989

Introduction: To know how the general use of antibiotics in an ICU has evolved over two decades.

Methods: Descriptive study, based on the data collected in the ENVIN - ICU base of our medical-surgical unit, collected during the months of the official participation period. To do this, we have divided the total number of patients collected into two periods: 2002-2009 and 2010-2019. To study the evolution, we are going to describe the number of

antibiotics per patient with antibiotics, relationship days without antibiotics / patient stays with antibiotics, most frequent causes of antibiotic indication, description of the use of antibiotics used (empirical or specific, change of treatment, Reason for change). The qualitative variables will be expressed in percentages.

Results: During the first period, the number of antibiotics per patient with antibiotics was 2.21, while in the second period it was 2.53. The ratio of days without antibiotics / patient stays with antibiotics was 0.19 in the first period and 0.21 in the second period. In the first period, the use of 1760 antibiotics was recorded, the most frequent indication was other prophylaxis with 34.20%, hospital infection extra ICU 25.06%, community infection 21.59%, hospital infection intra ICU 18.01%. In the second period, the use of 2624 antibiotics was recorded, the most frequent indication was community infection 33.16%, extra-ICU hospital infection 25.76%, intra-ICU hospital infection 19.36%, another prophylaxis 10.75%. Regarding the reason for antibiotherapy, in the first period the empirical treatment was 82.12% and in the second 76.74%. Antibiotic treatment (empirical or specific) produced a change of 25.73% in the first period, and 21.79% in the second period. The reasons for the change in antibiotherapy during the first period were a poor clinical evolution 38.26%, unknown 33.56%, microorganisms not covered 21.48%, others 4.03%, toxicity (Adverse effects) 2.01%, spectrum reduction 0.67%, resistance during treatment 0%. The reasons for the change in antibiotherapy during the second period were the reduction of the spectrum 41.91%, poor clinical evolution 28.68%, microorganisms not covered 13.73%, others 7.60%, toxicity (adverse effects) 6.37%, resistance during treatment 1.47%, unknown 0.25%.

Conclusion: In this descriptive study, it is observed how over two decades (coinciding with the implementation of the Zero projects), more antibiotics have been used, having more days free of antibiotherapy, changing the most frequent cause of antibiotic indication, and highlighting the largest use of de-escalated antibiotics today.

Intensive Care Medicine Experimental 2020, **8(2)**: 001024

Introduction: Rapid spread of SARS-CoV-2 pandemic (COVID-19) has taken traditional ICU capacity to the limit worldwide. A demand overcoming availability has forced intensivists to select the patients who can benefit the most from admission. Predictive models based on routine clinical data may be valuable in the decision-making process.

Objectives: We aim to assess whether chronic comorbidities and laboratory tests drawn at presentation are good predictors of mortality in patients with severe SARS-CoV-2 infection (COVID-19) admitted to the Intensive Care Unit (ICU).

Methods: We conducted a retrospective observational single-centre study in the ICU of a University Hospital in Spain, over 3 months. All the patients who were admitted to the ICU with PCR-confirmed severe SARS-CoV-2 infection were included. Past medical history, laboratory tests drawn at presentation and clinical outcomes were obtained from

the electronic medical record. Association among each variable and mortality was evaluated by bivariate analysis (Chi-square, Student's T and Mann-Whitney U tests, as appropriate). Potential explanatory variables from bivariate analysis were used to build a multivariate logistic regression model to predict mortality.

Results: We included 87 patients, 77% male, age 60±12 years-old [survivors 56±12 vs non-survivors 67±10, p<0.01], BMI 27 (25–32) kg/m² [survivors 27 (26–32) vs non-survivors 27 (24–32), p=0.94], APACHE-II 17±6 [survivors 14 vs non-survivors 20, p<0.01], mechanical ventilation 93% [survivors 59 vs non-survivors 41, p=0.73], hospital mortality 38%. Our findings are depicted in Tables 1 and 2. Our model (Table 3) showed 76.2% sensitivity and 89.7% specificity to predict mortality (area under the ROC curve 0.91).

Table 1. Association of chronic comorbidities with mortality.

	Overall frequency, %	Survivors, %	Non-survivors, %	p-value
Hypertension	30	20	45	0.01
Asthma	8	9	6	0.59
COPD	3	0	9	0.02
Hypothyroidism	11	9	15	0.40
Ischemic heart disease	5	0	12	0.01
Diabetes	14	7	24	0.03
Neoplasia	13	9	18	0.22

Table 2. Association of laboratory values at presentation with mortality.

	Survivors, median (IQR)	Non-survivors, median (IQR)	p-value
Leukocytes, ×10 ³ /μl	7.1 (5.4–9.5)	7.7 (5.8–14.7)	0.69
Lymphocytes, ×10 ³ /μl	0.8 (0.5–1.1)	0.6 (0.3–0.8)	0.01
D-dimer, ng/ml	685 (399–1041)	641 (531–2070)	0.65
High sensitivity troponin I, ng/l	9 (5–17)	35 (13–225)	<0.01
Creatinine, mg/dl	0.9 (0.7–1.1)	1 (0.7–1.3)	0.15
C-reactive protein, mg/l	123 (61–216)	108 (59–179)	0.39
Procalcitonin, ng/ml	0.2 (0.1–0.3)	0.3 (0.1–0.7)	0.11
Lactate, mmol/l	1.6 (1.3–2.2)	1.8 (1.4–2.3)	0.43

Table 3. Multivariate logistic regression model to predict mortality.

	Coefficient	Standard error	Odds ratio (95% CI)	p-value
Age, per year	0.112	0.05	1.12 (1.01–1.23)	0.02
Gender, female	0.915	1.01	2.45 (0.35–17.99)	0.36
Hypertension, yes	0.996	0.87	2.71 (0.49–14.88)	0.25
Diabetes, yes	0.586	1.24	1.80 (0.16–20.32)	0.64
Lymphocytes, per 1×10 ³ /μl	-3.944	1.53	0.02 (0.01–0.39)	0.01
Creatinine, per mg/dl	-0.045	0.13	0.96 (0.74–1.23)	0.72
Troponin, per ng/L	0.006	0.01	1.01 (0.01–1.02)	0.18
Intercept	-6.274	3.099		0.04

Conclusion: In our series, mortality in severe SARS-CoV-2 infections requiring admission to the ICU was significantly associated with age and APACHE-II.

A prediction model based upon basic demographic data (age and gender), chronic comorbidities (hypertension and diabetes) and

laboratory values at presentation (lymphocytes, creatinine and troponin) is able to reliably predict mortality in this patient population.

Intensive Care Medicine Experimental 2020, **8(2)**: 001073

Introduction: Infections caused by *A. baumannii* are associated with high mortality and healthcare costs. In critical care settings, the incidence of acquired resistance of *A. baumannii* to commonly prescribed antibiotics is increasing, rendering the treatment of the relevant infections rather challenging and compromising patients' outcomes.

Objectives: To prospectively record the incidence, clinical characteristics, treatment and outcome of infections caused by pandrug – resistant (PDR) *A.baumannii* in critically ill patients.

Methods: The study was performed at a 19-bed polyvalent intensive care unit (ICU). All the mechanically ventilated patients with documented infection caused by PDR *A. baumannii*, from November 2018 until February 2020 were enrolled in the study. Concentrations (MICs) were determined by the broth microdilution method, as indicated by the CLSI. Disease severity was evaluated by APACHE-II and SOFA score on ICU admission. Patients' demographics, clinical characteristics, treatment and outcomes in 7 and 30 days were recorded. Clinical success was defined by a lessening of the signs and symptoms of infection, while microbiologic success was considered, as the eradication of the pathogen from cultures.

Results: Ten patients (mean age \pm SD= 58 \pm 17 yrs, 8 males/2 females) with documented infection due to *A. baumannii* were enrolled in the study. Regarding comorbidities, diabetes mellitus was present in 3 (30%) pts, arterial hypertension in 5 (50%) pts, and coronary artery disease in 3 (30%) pts. APACHE-II score in ICU admission was 18 \pm 7, while SOFA score was 8 \pm 3. Bloodstream infection was present in 6 (60%) pt. Among them, central line associated bloodstream infection (CLABSI) was observed in 5 (83%) pts, and primary bacteremia in 1 (17%) pt. Ventilator associated pneumonia (VAP) was diagnosed in 4 (40%) pts. Mean length of stay of enrolled patients in the ICU, prior to infection, was 18.5 \pm 10 days. Regarding prior colonization, PDR-*A.baumannii* was isolated in stool and bronchial secretion surveillance cultures of 8 (80%) pts. 7 (70%) pts had received broad spectrum antibiotics prior to infection due to *A.baumannii*, while 5 among them had also received intravenous and nebulised colistin. All patients were empirically treated with combinations of colistin, high dose ampicillin/sulbactam (A/S), rifampicin or tigecycline with broad spectrum antibiotics (meropenem or ceftazidim/avibactam), for 14 \pm 4 days. Clinical

and microbiological success was observed in 7 (70%) of patients. In two patients (20%), blood cultures remained positive, while in another patient, *A.baumannii* infection was complicated with meningitis. ICU mortality in 10 days of infection was 30%. ICU mortality was significantly associated with SOFA score ($p < 0.05$). Mean length of stay in ICU after infection was 39 \pm 17 days.

Conclusion: Broad use of antibiotics has increased the isolation rate of PDR-*A.baumannii* in critical care settings. Antibiotic combinations might offer a therapeutic benefit, as a result of possible synergistic effect. Further studies are required in order to elucidate the therapeutic options and clinical outcomes of infections caused by PDR pathogens.

Nosocomial Gram-Negative Rod Monobacteremia in ICU: A 10-Year Study

D. Adukauskienė¹; A. Dambrauskienė²; D. Valanciūnė³; V. Micpovilytė¹
¹Intensive care unit, Hospital of Lithuanian University of Health Sciences Kaunas Clinics, Kaunas, Lithuania; ²Infection control service, Hospital of Lithuanian University of Health Sciences Kaunas Clinics, Kaunas, Lithuania; ³Anesthesiology and intensive care department, Klaipėda Seamen's Hospital, Klaipėda, Lithuania

Correspondence: V. Micpovilytė

Intensive Care Medicine Experimental 2020, **8(2)**: 001092

Introduction: Antibiotics resistant Gram-negative rod (GNR) bacteremia is increasing worldwide every year. Diagnosis of nosocomial Gram-negative rod monobacteremia (N-GNRM) in critically ill patients has been associated with prolonged hospitalization in intensive care units (ICUs) and a higher rate of mortality. The identification of pathogens, the pervasiveness of multiple antibiotic resistance, and risk factors for resistant strains are helpful in selecting appropriate empirical antibiotic therapy to reduce hospitalization time and mortality. The aim of this study was to identify the risk factors for the development of nosocomial multiple antibiotic resistance strains and mortality.

Methods: A retrospective cohort study was performed, analyzing the data of patients treated in ICU after 72 hours of hospitalization, with positive gram-negative rod monobacteremia over a period of 10 years.

Results: Over the year 2009-2018, 261 cases of N-GNRM were identified. The detected pathogens include: 31.8% (n=83) *Acinetobacter* spp., 19.9% (n=52) *Klebsiella* spp., 18% (n=47) *Escherichia coli* and etc. Monobacteremia caused by *P. aeruginosa* was detected only in the last three years of the researched period, from 4 (8.5%) cases in 2016 to 7 (28%) cases in 2018 ($p < 0.05$). The sensitivity to Imipenem was 88.8% (n = 206), to Meropenem 85.4% (n = 199), to Amikacin 65.1% (n = 142), to Cefoperazone / Sulbactam 61.6% (n = 141) and to Piperacillin / Tazobactam 48% (n = 120). 61.6% (n=161) of all the cases studied, had multiple antibiotic resistance, out of which 39.8% (n=104) was extensively drug-resistant (XDR) ($p < 0.001$). Of all *Acinetobacter* spp., XDR made up 69.9% (n=58) ($p < 0.001$). The identified risk factors for bacteremia in resistant strains include male gender ($p = 0.012$), age ≥ 65 year old ($p = 0.010$), hospitalization in ICU ≥ 16 days ($p = 0.012$), and the duration of mechanical lung ventilation (IMV) ≥ 14 days ($p < 0.001$). In a multivariate analysis, 69.3% (n=181) of mortality was associated with male gender ($p = 0.001$), acute kidney injury with the need for hemodialysis (AKI-HD) ($p = 0.001$) and shock ($p < 0.001$).

Conclusion: Over a ten-year period, the most common cause of N-GNRM in ICU was *Acinetobacter* spp., dominated by XDR strains. Male gender, older age, prolonged stay in ICU and longer duration of IMV were identified as risk factors for multiple antibiotic resistance strains. Furthermore, male gender, acute kidney injury with the need for hemodialysis and shock, were related to almost 70% rate of mortality.

Intensive Care Medicine Experimental 2020, **8(2)**: 001122

Introduction: Analysis of the STRIVE Phase 2 Trial of Once-Weekly Rezafungin for Treatment of Candidemia and Invasive Candidiasis Compared with Caspofungin: Outcomes by ICU Status and APACHE II Score

Authors Patrick M. Honoré¹, Anastasia Kotanidou², Massimo Girardis³, Shawn Flanagan⁴, Taylor Sandison⁴

¹CHU Brugmann University Hospital, Brussels, Belgium; ²General Hospital of Athens “Evangelismos”, Athens, Greece; ³University Polyclinic Hospital of Modena, Modena, Italy; ⁴Cidara Therapeutics, Inc. San Diego, CA, USA

Objectives: INTRODUCTION

Invasive fungal disease (IFD) caused by *Candida* spp. is associated with longer hospital duration and higher mortality rates for the critically ill.1-3 For such patients, treatment with an echinocandin is recommended first-line therapy.4 Rezafungin (RZF) is a novel, next-generation echinocandin in Phase 3 development for treatment of candidemia and invasive candidiasis (IC) and for prevention of IFD caused by *Candida*, *Aspergillus*, and *Pneumocystis* in blood and marrow transplant recipients.

Objectives: To evaluate outcomes of the Phase 2 STRIVE trial of RZF QWk for the treatment of candidemia and/or IC compared with caspofungin (CAS) once-daily (NCT02734862)5, based on ICU status and APACHE II scores.

Methods: Patients in STRIVE were randomized to 1 of 2 doses of RZF (400 mg QWk or 400 mg in Week 1, then 200 mg QWk [400 mg/200 mg], the latter being studied in Phase 3) or CAS (70 mg on Day 1, then 50 mg QD) for ≥ 14 days. For this ad-hoc subanalysis, data were stratified by ICU status (no ICU or ICU admission within Days 1–4) and by APACHE II score category (<10, 10–19, and ≥20). Efficacy (overall success [resolution of clinical signs of infection + mycological eradication], mycological success, and investigator assessment of clinical cure at Day 14; and 30-day all-cause mortality) and safety (treatment-emergent adverse events [TEAEs]) endpoints were evaluated.

Table 2. Outcomes by Treatment Group and APACHE II Score – STRIVE mITT Population

Number of Patients (%)^a

APACHE II Score		10–19		≥20	
<10					
RZF PooledN=36	CAS N=16	RZF PooledN=58	CAS N=33	RZF PooledN=25	CAS N=9
21 (58.3)	12 (75.0)	43 (74.1)	20 (60.6)	16 (64.0)	6 (66.7)
22 (61.1)	13 (81.3)	45 (77.6)	20 (60.6)	17 (68.0)	6 (66.7)
24 (66.7)	13 (81.3)	47 (81.0)	21 (63.6)	18 (72.0)	6 (66.7)
2 (5.6)	0	4 (6.9)	5 (15.2)	8 (32.0)	3 (33.3)

^aAPACHE II data not available for efficacy outcomes from 6 patients (N=3 each, RZF Pooled and CAS) and for safety outcomes in 7 patients (N=3, RZF Pooled; N=4, CAS).

APACHE II=Acute Physiology and Chronic Health Evaluation.

Results: Efficacy rates among RZF-treated patients admitted to the ICU were similar to or higher than those with no ICU admission (Table 1). On the primary efficacy endpoint of overall response, 75% of the RZF-treated ICU cohort and 60.7% of the non-ICU cohort achieved overall success. In CAS-treated patients, efficacy rates were lower among the ICU cohort than in the non-ICU cohort (Table 1). In general,

response rates with RZF were comparable across APACHE II scores and response rates with CAS were lower in patients with higher APACHE II scores (Table 2). Analysis of TEAEs by ICU status and by APACHE II scores showed no concerning trends or differences between RZF and CAS; not surprisingly, higher numbers of SAEs were seen in patients with ICU admission (vs no admission) and with APACHE II scores ≥20 (vs scores <20) (data not shown).

Conclusion: This Phase 2 subanalysis demonstrated RZF efficacy in patients admitted to the ICU and across APACHE II scores, and the safety of rezafungin in these subpopulations was comparable to that of caspofungin. While RZF outcomes appeared worse in the lower acuity patients, this was primarily due to the high numbers of indeterminate outcomes (i.e., missing data and lost to follow-up) among these patients. These findings contribute to the evidence of RZF safety and efficacy in a broad range of patients and support the ongoing Phase 3 development of RZF for the treatment of candidemia and IC (ReSTORE; NCT03667690).

Rolando Viani (Cidara Therapeutics, Inc., San Diego, CA, USA)

Taylor Sandison (Cidara Therapeutics, Inc., San Diego, CA, USA)

Objectives: Rezafungin is a novel echinocandin in Phase 3 development. STRIVE (NCT02734862)1 is the global, Phase 2 trial of rezafungin once-weekly for treatment of candidemia and/or IC versus standard of care. Results of STRIVE were evaluated by geographic region to assess for differences in the complete trial population

Methods: Data were stratified by region of enrollment (EU vs North America [NA]) and analysed for differences in patient demographics and baseline characteristics, treatment patterns, and efficacy outcomes.

Results: Patients enrolled in EU (N=131) were older than in NA (N=76) (mean, 64 vs 52 years, respectively) and were predominantly male (61.1%) and White (93.1%). The NA population was 50% male

and comprised 23.7% Black or African-American patients. On average, NA patients weighed more and had higher BMI (+2.3 kg/m²). The same leading *Candida* species were isolated at baseline in both regions but with differing distribution. *Candida albicans* comprised 44% of EU isolates, and proportions of *Candida parapsilosis*, *Candida glabrata*, and *Candida tropicalis* were similar (13-18%). In NA, *C. albicans* accounted for 52% of isolates, followed by 25% *C. glabrata* and 7% each for *C. parapsilosis* and *C. tropicalis*. In both regions, 55% of patients received 8-14 days of IV treatment; 27% of EU patients received >14 days versus 18% in NA. Fewer patients in EU were switched to oral step-down (24.4% vs 42.7% NA). The NA population had a higher proportion of patients with IC (26.3% vs 17.6% EU).

Outcomes were comparable between regions except for higher rates of overall success in EU patients treated with rezafungin 400 mg in Week 1 followed by 200 mg once weekly, compared with the NA cohort.

Conclusion: The Phase 2 STRIVE trial demonstrated few differences by region in demographic and baseline characteristics. The EU population was slightly older, and NA patients were generally heavier. Non-*albicans* species were predominant in the EU and comprised almost half of the NA isolates. Efficacy by region showed no consistent trends, although interpretation of efficacy-related differences are limited by group size. Results of this analysis may inform future evaluation of data from the rezafungin clinical trial program.

Intensive Care Medicine Experimental 2020, **8(2)**: 001129

Introduction: During the months of March to May we have experienced in Spain the consequences of the COVID 19 pandemic. Different factors can be related to the evolution of a pathology, both those of the pathology and the patient, as well as those derived from the high number of cases in a short period of time. Below we intend to analyze the different factors that are related to the evolution of COVID-19 pneumonia in our area.

Objectives: Describe the related factors to mortality in patients admitted to the ICU due to COVID-19 pneumonia during the pandemic period.

Methods: Descriptive study conducted in a polyvalent ICU with 12 critical care beds and 21 semi-critical beds. All patients admitted for COVID-19 pneumonia during the pandemic period were included.

The qualitative variables are expressed as percentages and were compared using the X²-test, the quantitative variables are expressed as means and standard deviations (SD) and were compared using the student's t test. A logistic regression model was constructed with ICU mortality as a dependent variable.

Results: 95 patients were admitted, Table 1 describes the main characteristics of the patients.

RESULTS. 95 patients were admitted, Table 1 describes the main characteristics of the patients.

Variables	
Age (years, mean (SD))	58.6 (10)
Sex (male%)	71
SOFA at admission ≤ 5 (%)	76
Rockwood frailty scale at income ≤ 3(%)	100
Multi-organ failure (%)	16

ICU long of stay (days, mean (SD))	13.1 (12.9)
Hospital stay (days, mean (SD))	25.4 (16.7)
ICU mortality (%)	19
Hospital mortality (%)	20

100% of the patients received Kaletra, hydroxychloroquine and Azithromycin as treatment, 40% in addition, Tozilucimab, 34% interferon. On March 31th, the corticosteroid treatment protocol was implemented in the institution, 62% of patients were admitted before this date (first 2 weeks) and 58% of patients were treated with corticosteroids. Table 2 show the factors related to ICU mortality.

Variable	Dead	Live	p
Age (years, median (DE))	64.83 (6.492)	57.19 (10.159)	0.007
Patients before corticosteroid protocol

Hospital floor's discharge with delirium(%)			
No	14.7	85.3	0.043
Si	18.5	81.5	

Table 3 shows the logistic regression analysis for mortality in the ICU after adjusting for possible confounding factors.

Variable	95% confidence interval		p
	Lower limit	Upper limit	
Cardiovascular comorbidities	-0.327	-0.003	0.046
Acute kidney failure	-0.489	-0.004	0.046
Hospital-acquired pneumoniae	-0.458	-0.22	0.031

Conclusion: Only a relationship between mortality in the ICU and previous cardiovascular comorbidity is observed, as well as with the development of acute renal failure and nosocomial pneumonia. However, other aspects that should be considered in the face of a possible new outbreak are the use of corticosteroids, the doses of sedation and muscle relaxants and the appearance of delirium.

Introduction: During the months of March to May we have experienced in Spain the consequences of the COVID 19 pandemic. Different factors can be related to the evolution of a pathology, both those of the pathology and the patient, as well as those derived from the high number of cases in a short period of time. Below we intend to analyze the different factors that are related to the evolution of COVID19 pneumonia in our area.

Objectives: Describe the corticosteroids use related factors in the treatment of covid-19 pneumonia in patients admitted in ICU during the pandemic period.

Methods: Descriptive study carried out in a polyvalent ICU. All patients admitted because of COVID-19 pneumonia during the coronavirus outbreak were included.

A corticosteroid treatment protocol was established for patients with severe covid-19 pneumonia whose institutional implementation was on 03/31/2020.

Statistics: Qualitative variables are expressed as percentages and were compared using the X2-test.

The quantitative ones are expressed as means and standard deviations (SD) and were compared using the t-Student test.

A logistic regression model was constructed with treatment with corticosteroids as a dependent variable.

Results: Table 1 describes their main features.

Table 1	Variables	
	Age (years, mean (SD))	58.6 (10)
	Sex (male%)	71
	SOFA at admission ≤ 5 (%)	76
	Rockwood frailty scale at income ≤ 3(%)	100
	Multi-organ failure (%)	16
	Shock (%)	6
	Acute kidney failure (%)	11.6
	ICU long of stay (days, mean (SD))	13.1 (12.9)
	Hospital stay (days, mean (SD))	25.4 (16.7)
	ICU mortality (%)	19
	Hospital mortality (%)	20

100% of patients received all Kaletra, Hydroxychloroquine and Azithromycin treatment.

40% of them, in addition, received Tozilucimab and 34% of them received interferon too.

55 patients (58%) were treated with corticosteroids and 52 of them followed the institutional protocol started on March 31.

Table 2 shows corticosteroids use related factors.

Variable	Corticosteroids	No Corticosteroids	p
Ventilation's days (days, median (DE))	10.7 (8.2)	13.4 (10.3)	0.037
ICU's mortality (%)	No	57.1	42.9

Hospital's mortality (%)	No	66.2	33.8
	Si	42.1	57.9
Tracheal intubation (%)	No	65.6	34.4
	Si	54	46
Propofol infusion's days (days, median (DE))	8.6 (9.7)	6.5 (6.7)	0.001
Remifentanyl infusion's days (days, median (DE))	6.9 (6.5)	2.2 (4.3)	0.003
Dexmedetomidine infusion's days (days, median (DE))	4.7 (6.6)	2.8 (4.3)	0.009
Maximum value of D-dimer, median (DE)	8481.8 (9214.5)	16220.8 (32114.)	0.02
Hospital-acquired pneumoniae (%)	No	60.6	39.4
	Si	61.94	38.1
Antibiotic treatment for hospital-acquired infections (%)	No	50	50
	Si	66	34
UTI %	No	58	42
	Si	72.2	27.8
SOFA < 5	No	16.7%	83.3%
	Si	40	60
Delirium %	No	62.5	37.5
	Si	58.1	41.9

Table 3 shows the logistic regression analysis with the use of corticosteroids as a dependent variable.

Variable	95% confidence interval		p
	Lower limit	Upper limit	
Propofol infusion days	0.01	0.043	0.037
Remifentanyl infusion days	-0.078	-0.024	0.001

Conclusion: After adjusting for different confounding variables, a statistically significant relation is maintained between the use of corticosteroids for treatment of patients with COVID-19 pneumonia admitted in ICU and infusion days of propofol and remifentanyl. However, its relation with other aspects (tendency to fewer days in mechanical ventilation and less ICU and hospital mortality) should be taken into account for future outbreaks and studies.

Intensive Care Medicine Experimental 2020, **8(2)**: 001131

Introduction: During the months of March to May we have experienced in Spain the consequences of the COVID 19 pandemic. Different factors can be related to the evolution of a pathology, both those of the pathology and the patient, as well as those derived from the high number of cases in a short period of time. Below we intend to analyze the different factors that are related to the evolution of COVID-19 pneumonia in our area.

Objectives: To analyze the clinical utility of measuring D-dimer and Ferritin in patients admitted to the ICU with COVID-19 pneumonia during the SARS-CoV-2 outbreak.

Methods: Descriptive study carried out in a polyvalent ICU. All the patients admitted for pneumonia-COVID-19 during the pandemic period. Analytical measurements of d-dimer and ferritin were made from admission to hospital discharge. All patients had minimum 2-3 weekly measurements of these values.

Statistics: ROC curve analysis was performed for the maximum value of D-dimer and Ferritin and the difference between the minimum and maximum value (delta) of these parameters regarding different clinical variables.

Results: 95 patients were admitted. Table 1: describes the clinical variables analyzed with ROC curve with respect to the value of D-dimer and Ferritin.

Table 1	Variables	
Age (years, mean (SD))		58.6 (10)
Sex (male%)		71
SOFA at admission ≤ 5 (%)		76
Pulmonary embolism (%)		13
Patient receives anticoagulation (%)		26
Patient receives corticosteroids (%)		58
ICU long of stay (days, mean (SD))		13.1 (12.9)
Hospital stay (days, mean (SD))		25.4 (16.7)
ICU mortality (%)		19
Hospital mortality (%)		20

13 cases of pulmonary embolism (PE) were diagnosed, 3 of them were from the main pulmonary artery, 5 of them from segmental pulmonary artery, 1 of them from small glass and 5 of them from subsegmental arteries. In the group of 22 desoagulated patients, PE was only confirmed in 5 cases. Figure 1: represents the behavior of the ROC curves for ICU mortality and corticosteroid treatment.

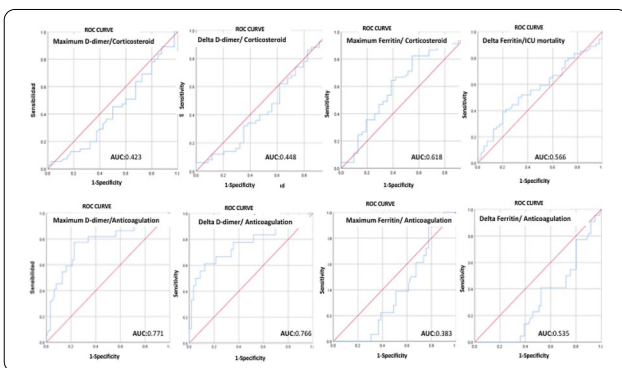

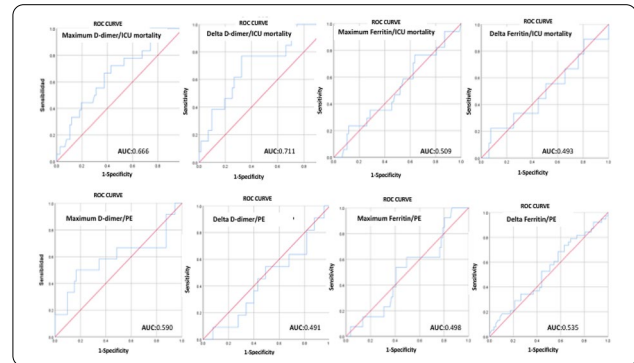

Figure 2: represents the behavior of ROC curves for diagnosis of PE and anticoagulated patient.

As the best result, we look at the area under the curve (AUC) for ICU mortality with respect to the delta of the D-dimer that shows a value of 0.711 with a 95% CI (0.561-0.861) and a significance asymptotic: 0.016. An increase in D-dimer between 5500 and 6000 ng / mL is related to ICU mortality with a sensitivity between 0.77-0.61 and specificity between 0.68 / 0.69. The AUC for anticoagulated patient and PE shows the relationship of the D-dimer value and its delta to empirically anticoagulate a patient but not to diagnose PE.

Conclusion: The behavior of the maximum values of D-Dimer and Ferritin, as well as its delta, showed no prognostic neither diagnostic utility for PE and no utility in therapeutic decision-making in ICU hospitalized patients with COVID-19 related pneumonia. The need for routine measurement of these parameters in this group of patients should be assessed.

Introduction: During the months of March to May we have experienced in Spain the consequences of the COVID 19 pandemic. Different factors can be related to the evolution of a pathology, both those of the pathology and the patient, as well as those derived from the high number of cases in a short period of time. Below we intend to analyze the different factors that are related to the evolution of COVID-19 pneumonia in our area.

Objectives: Describe the main characteristics of the patients admitted in ICU due to covid-19 related pneumonia during the coronavirus outbreak.

Methods: Descriptive study carried out in a polyvalent ICU with 12 beds for critical care and 21 for semi-critical care. All patients with covid-19 related pneumonia admitted in ICU in the outbreak were included in the study.

Statistics: Qualitative variables are expressed as percentages and quantitative variables are expressed as means and standard deviations (SD).

Results: 95 patients were entered, Table 1 described the main clinical characteristics of the patients.

Table 1	Variables	
Age (years, mean (SD))		58.6 (10)
Sex (male%)		71
SOFA at admission ≤ 5 (%)		76
Rockwood frailty scale at income ≤ 3 (%)		100
Multi-organ failure (%)		16
Patient receives anticoagulation (%)		26
Acute kidney failure (%)		11.6
ICU long of stay (days, mean (SD))		13.1 (12.9)
Hospital stay (days, mean (SD))		25.4 (16.7)
ICU mortality (%)		19
Hospital mortality (%)		20

Table 2: describes other clinic characteristics and complications.

Table 2	Variables	
Lymphopenia on admission (%)		84.2
Lymphopenia recovered at ICU's discharge (%)		73.7
Hospital-acquired pneumonia (%)		24.1
Non-catheter associated bacteraemia (%)		9.2
Catheter associated bacteraemia (%)		9.2
UTI (%)		20.7
Endocarditis (%)		2.3
Clostridium difficile infection (%)		3.3
Fungal infection (%)		4.6
CMV infection (%)		22.3
Antibiotic treatment for hospital-acquired infections (%)		56.6
Noradrenaline (%)		42.5
Midazolam infusion's days (days, median (DE))		3.9 (5.3)
Propofol infusion's days (days, median (DE))		7.8 (8.9)
Remifentanyl infusion's days (days, median (DE))		5.2 (6.5)
Morphine infusion's days (days, median (DE))		3.9 (5.6)
Patients with muscle relaxer's continuous infusion (%)		56
Dexametomidine infusion's days (days, median (DE))		3.9 (5.8)
Delirium (%)		47
Refeeding (%)		14
Hospital floor's discharge with antipsychotic treatment (%)		23
Adverse events (%)		1.1

Table 3 describes respiratory failure and mechanical ventilation characteristics

Table 3	Variables	
Non-invasive ventilation (NIV) (%)		33
NIV before tracheal intubation (%)		25.3
High flow nasal cannula oxygen therapy (HFNC) before tracheal intubation (%)		16.8
Tracheal intubation (%)		66.3
Pao2/FiO2 before tracheal intubation < 100 (%)		41
PEEP the first 24 hours of intubation (cmH2O, median (DE))		12.3 (2.4)
P/FiO2 the first 24 hours of intubation (median (DE))		0.5 (0.2)
P/Plateau the first 24 hours of intubation (cmH2O, median (DE))		25.2 (2.7)
A/PaO2 the first 24 hours of intubation (cmH2O, median (DE))		12.6 (2.4)
Compliance the first 24 hours of intubation (%)		35.5 (11.2)
Pao2/FiO2 before tracheal intubation (cmH2O, median (DE))		117.5 (56.8)
Pao2/FiO2 the first 24 hours of intubation (cmH2O, median (DE))		211 (84.5)
Vt/ideal weight the first 24 hours of intubation (ml/kg, median (DE))		6.9 (1.1)
Proneations on intubated patients (%)		45.3
ECMO (%)		3.2
Tracheostomy (%)		41.8
ICU's ventilator (%)		72
Only ICU's ventilator (%)		57.7

ICU mortality was 19% and 20% at hospital discharge.

Conclusion: Patients admitted in ICU for COVID-19 related pneumonia presented severe hypoxemia as the main organ affectation upon admission, requiring protective ventilation. Prone ventilation and tracheostomy were performed in a high percentage of patients. Infectious complications, PE and delirium were frequent.

Intensive Care Medicine Experimental 2020, **8(2)**: 001145

Introduction: During the months of March to May we have experienced in Spain the consequences of the COVID 19 pandemic. Different factors can be related to the evolution of a pathology, both those of the pathology and the patient, as well as those derived from the high number of cases in a short period of time. Below we intend to analyze the different factors that are related to the evolution of COVID-19 pneumonia in our area.

Objectives: Describe the factors related to delirium in patients admitted in ICU due to COVID-19 pneumonia.

Methods: Descriptive study carried out in a polyvalent ICU. All patients admitted because of pneumonia by COVID-19 during the pandemic period were included. It was considered that a patient presented delirium by the ICU medical teams' clinical diagnosis. Delirium treatment was confirmed and adequated together with a psychiatry team destined to ICU.

Statistics: Qualitative variables were expressed as percentages and were compared using the X2-test, quantitative were expressed as means and standard deviations (SD) and were compared using T-Student test. A logistic regression model with delirium as dependent variable was constructed.

Results: 95 patients were admitted, 35.6% presented delirium during ICU admission and 16% at discharge to hospitalization plant. 66.3% of all patients were intubated. 100% received Kaletra, Hydroxicloroquine and Azithromycin as treatment, additionally, 40% received Tocilizumab, 34% Interferon and 58% corticoids. Table 1 describes clinical characteristics.

Variables	Table 1
Age (years, mean (SD))	58.6 (10)
Sex (men, %)	71
Psychiatric history %	11.4
Antidepressant treatment %	7.4
Antipsychotic treatment %	1.1
Narcotic abuse %	0
Smoker %	9.5
Enolism %	0
Dexametomidine %	42.1
Clonidine %	22.1
Olanzapine %	19.5
Quetiapine %	23
Other antipsychotic %	21.8
Other anxiolytic %	33.7
Antipsychotic treatment at discharge to hospitalization plant %	26.8

Table 2 shows factors related to delirium.

Table 2	Variable	Delirium	No delirium	p
ICU mortality %	No	30.4	69.6	0.047
	Yes	55.6	44.4	
Hospital mortality %	No	38.2	61.8	0.337
	Yes	26.3	73.7

	Yes	14.3	85.7	
Prone Ventilation %	No	20.5	79.5	0.003
	Yes	51.2	48.8	
Midazolam perfusion (days, mean (SD))		7.5 (6.5)	1.8 (3)	0.001
Propofol perfusion (days, mean (SD))		15.6 (8.7)	3.4 (4.7)	0.001
Remifentanyl perfusion (days, mean (SD))		10.4 (7.2)	2.2 (3.4)	0.001
Dexametomidine perfusion (days, mean (SD))		9.4 (6.3)	1.4 (2.3)	0.001
Muscle relaxation perfusion %	No	20.8	79.2	0.001
	Yes	46.1	53.9	
Days at ICU (days, mean (SD))		12.9 (10.2)	14.3 (14.7)	0.038
Days at Hospital (days, mean (SD))		37.9 (17.3)	18.6 (11)	0.016
Corticoids days (days, mean (SD))		6.4 (6.5)	4.07 (3.1)	0.022
Corticoids dose (mg, mean (SD))		108.5 (113)	61.3 (77)	0.018
Nosocomial pneumonia %	No	25.8	74.2	0.001
	Yes	66.7	33.3	
Nosocomial antibiotic %	No	8.3	91.7	0.001
	Yes	59.6	40.4	
UTI %	No	21.7	78.3	0.001
	Yes	88.9	11.1	
SOFA < 5 %	No	31.9	68.1	0.116
	Yes	53.3	46.7	

Table 3 shows logistic regression analysis of delirium as dependent variable.

Table 3	Variables	95% confidence interval		p
		Inferior limit	Superior limit	
	Mortality ICU	0.013	0.841	0.044
	Prone ventilation	0.191	0.749	0.002
	Nosocomial pneumonia	-1.808	-0.225	0.014

Conclusion: The patients admitted at our ICU due to COVID-19 pneumonia presented a high delirium incidence. Different factors as intubation and mechanical ventilation were associated with its development, as well as sedation and muscle relaxants. However, it should be noted the statistically significant association after adjusting by different confusion factors between delirium with mortality in ICU, nosocomial infection appearance and prone ventilation.

Co/Super infection in critical SARS-CoV2 pneumonia

B. Rodrigues De Castro¹; A. Knappen¹; LP. Moulart¹; P. Henin¹; JB. Mesland¹ Icu, CH Jolimont, La Louvière, Belgium

Correspondence: J.B. Mesland

Intensive Care Medicine Experimental 2020, **8(2)**: 001173

Introduction: Knowledge and understanding about SARS-CoV2 pathology is still poor. Viral pneumonia are known to promote co-infection or secondary bacterial infection. Diagnosis might be difficult between colonization of the respiratory tract and real infection. We need to be aware of specific patterns of infection as it is crucial for empiric prescription when needed.

Objectives: To review microbiological data regarding our critical SARS-Cov2 patients and evaluate if there is specific patterns of bacterial co-infection and super infection.

Methods: In an observational, retrospective and monocentric study, we reviewed microbiological data (blood culture, endotracheal aspirate, bronchoalveolar lavage) of all SARS-Cov2 patients admitted in our ICU between march 2020 and may 2020. If the same bacteria grew in different sample, it was counted as a unique episode.

Results: Between march 2020 and may 2020, 44 patients have been admitted to our 22 beds ICU for critical SARS-CoV2 pneumonia. Mean age at admission was 62,44 years (range 38 years – 83 years). 37/44 patients received mechanical ventilation, for a total of 638 days, and 13/44 patients received ECMO therapy, for a total of 249 days. ICU Mortality of our cohort is 50%.

From our routine microbiology testing from tracheal aspirate, 34/44 patients had documented positive culture. 80 specimens were identified, distributed in order of prevalence as : Klebsiella species for 20% (Klebsiella pneumoniae for 8,75%, Klebsiella oxytoca for 6,25%, Klebsiella aerogenes for 3,75%, Klebsiella varicola for 1,25%), Pseudomonas aeruginosa for 13,75%, E. Coli for 8,75%, Proteus species for 7,5% (Proteus mirabilis for 3,75%, Proteus vulgaris for 2,5%, Proteus hauseri for 1,25%), Staphylococcus aureus for 7,5% (MSSA for 6,25%, MRSA for 1,25%), Enterobacter species for 6,5% (Enterobacter cloacae for 3,75%, Enterobacter asburiae and kobei for 1,25%), Citrobacter koseri for 3,75%, Hafnia alvei for 2,5%, Streptococcus pneumoniae for 2,5%, Serratia species for 2,5%, Haemophilus influenzae for 1,25%. We noted a high number of Candida albicans positive specimens (13,75%), which is not considered to be able to be an agent of pneumonia.

We performed 16 bronchoalveolar lavage (BAL). 87,5% were predominantly neutrophilic. Regarding Pneumocystis jirovecii, indirect immunofluorescence using monoclonal antibodies were negative in all patients. All but one patient had BAL galactomannan negative, and none of our patients had positive respiratory culture for Aspergillus fumigatus. Multiplex RT-PCR was requested in 6 patients. 2/6 were strongly positive for HSV, and all were negative for Pneumocystis jirovecii.

12/44 patients developed at one time during their ICU stay an episode of bacteremia. 9/12 were secondary to ventilatory associated pneumonia. From our cohort, 17% had co-infection at admission (considering co-infection as positive microbiology within the first 48 hours in our ICU).

Conclusion: To conclude, we did not find typical organism described in community acquired pneumonia as being prevalent in SARS-CoV2 pneumopathy. Most of our positive microbiology were Gram negative bacteria, typical of ventilatory associated pneumonia. Indeed patients had to be mechanically ventilated during prolonged period of time. None of our patient had documented PCP or invasive pulmonary aspergillosis (IPA), as opposed to case series who found until one-third of patients with putative IPA(1)(2).

Intensive Care Medicine Experimental 2020, **8(2)**: 001180

Introduction: The incidence of infection with severe acute respiratory syndrome coronavirus 2 (SARS-CoV 2) worldwide is still on the rise and the prevention and treatment of coronavirus disease - 2019 (COVID-19) still a major challenge. Among those existing medications used for COVID-19 are intravenous immunoglobulins (IVIG) which are known for their anti-inflammatory effects and approved in several immune mediated disorders, including Kawasaki syndrome. Several case reports showing beneficial effects of IVIG administration in COVID-19 patients have been reported recently (1-5)

Objectives: To compare clinical outcomes and biomarkers in patients with severe COVID-19 treated with standard of care (SoC) alone or with SoC and IVIG.

Methods: Data from a cohort of severely ill COVID-19 patients requiring intensive care at a center of excellence in Turkey was analysed retrospectively. A subgroup of patients received high-dose IVIG (Octagam 5%) treatment at 0.4 g/day for 5 consecutive days in addition to SoC according to a site-specific treatment algorithm and was compared to those patients receiving SoC alone. Clinical outcome measures included duration of specific treatment modalities, time to start of mechanical ventilation, change in ventilation mode, ICU and hospital discharge, and overall survival. Plasma biomarkers of inflammation (CRP, ferritin, PCT, IL-6, D-dimer, leukocytes) were measured at baseline and 6 days after ICU admission and treatment start. Imbalance in APACHE II scores was addressed by propensity-score-matching; otherwise Kaplan-Meier and multiple regression models were used.

Results: Data from 93 patients were included into analysis. Of these, 51 had received IVIG plus SoC and 42 were treated with SoC alone. In both groups, about 75% of patients were male and patients had comparable BMI and blood group distribution as well as comparable vital signs. The IVIG group was slightly younger (mean: 65 vs. 71 years) and had slightly lower baseline disease scores (mean APACHE II: 20.6 vs. 22.4; mean SOFA: 5.0 vs. 7.0). Apart from IVIG, patients in both groups were treated with hydroxychloroquine, favipiravir, azithromycin, oseltamivir, tocilizumab/anakinra, methylprednisolone, and/or ascorbate. Analysis showed that overall survival (OS) was 61% in the IVIG and 38% in the control group. After controlling for imbalances at baseline, there remained a trend for better OS (OR: 2.2, 95%CI: 0.9-5.4, p=0.091) and a significantly longer median survival (68 vs. 18 days, p=0.014). Moreover, IVIG treatment significantly reduced CRP levels by 46% within 6 days compared to SoC alone (p=0.049), but had no relevant effect on any other inflammation marker measured.

Conclusion: Adjunct treatment with IVIG might add to the currently limited armamentarium against COVID-19, especially due to its well-known anti-inflammatory properties. However, results need to be confirmed in a randomized, controlled trial.

Microbiological profile of infections in patients admitted by COVID-19 to the intensive care unit (ICU)

S. Ramiro González¹; MDM. Molina Morales¹; CM. Rodríguez Mejías¹; J. Machado Casas¹

¹Medicina intensiva, Hospital Universitario Virgen de las Nieves, Granada, Spain

Correspondence: S. Ramiro González

Intensive Care Medicine Experimental 2020, **8(2)**: 001183

Introduction: Coronavirus infection (COVID-19) produces a severe acute respiratory syndrome that in up to 5 - 10% of cases requires admission to the ICU, with overinfection being one of the most frequent complications during a stay in this Unit.

Objectives: To describe the main intra-ICU infections according to location and microbiological germ isolated in patients admitted for COVID-19.

Methods: Retrospective descriptive study conducted with the data collected for the ENVIN registry in the period from March 13, 2020 to April 30, 2020 in the ICU of the Virgen de las Nieves Hospital in Granada.

Patients over 18 years old with a stay of more than 24 hours were included. Baseline characteristics: age, sex, degree of severity (APACHE II), mean stay, ICU mortality and extrinsic risk factors. The type of intra-ICU infections are exposed according to the isolated microorganism and the location of the infection.

Results: A total of 60 patients admitted to the ICU of our hospital are included, 80% of which are male, with a mean age of 60.03 ± 11.25 years and with APACHE II at admission of 13.76 ± 5.65 years. The average stay in the ICU was 21.11 ± 13.45 and the mortality was 38.18%. Among the extrinsic risk factors, more than 80% of these patients required an artificial airway, 98.33% carried a central venous catheter and 98% a urinary catheter and 60% had received antibiotherapy prior to admission to the ICU.

The rate of intra-ICU infections was 90 infections per 100 patients admitted, the most frequent location being bacteremias of unknown focus and secondary to catheter infection (50%), followed by pneumonias associated with mechanical ventilation (27.59%) and urinary tract infections (13.79%). In the case of bacteremias, up to 67.74% of large positive microorganisms were isolated, most frequently *E. Faecalis* and *S. epidermidis*, and up to 16.13% candida spp. *Faecalis* (50%), followed by *Candida* spp.; on the other hand, in pneumonias associated with mechanical ventilation, 57.14% of gram-negative bacilli stand out, among them *Pseudomonas aeruginosa* and *klebsiella pneumoniae*, and up to 19% of fungal isolation.

Conclusion: A high rate of intra-ICU infections is observed in patients admitted for COVID-19, the most frequent being labacteremia of unknown focus and secondary to catheter infection. This high rate of infections may be justified by the high percentage of invasive devices used as well as by the degree of complexity and severity of these patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000020

Introduction: Coenzyme Q10 (CoQ10) is a lipid-soluble vitamin-like compound present in the inner membrane of the mitochondria, where it transports electrons from complexes I and II to complex III of the mitochondrial respiratory chain (MRC). CoQ10 removes free radicals, inhibits the initiation and propagation of lipid peroxidation in cellular membranes, and aids in the regeneration of other antioxidants, such as vitamin E and C. CoQ10 levels in septic ICU patients have been investigated by a limited number of studies. The possibility that CoQ10 plasma concentrations exhibit time course changes from the initial period of critical illness to sepsis and septic shock, remains currently unexplored.

Objectives: We sought to investigate whether in a group of initially non-septic, critically ill patients, coenzyme Q10 (CoQ10) changes during progression from critical illness to sepsis and septic shock and assess its associations with inflammatory biomarkers, and intensive care unit (ICU) outcome.

Methods: This was an observational analysis on 63 initially non-septic ICU patients. CoQ10 was sequentially measured on admission in the ICU (baseline) and at sepsis and septic shock onset. Additionally, CoQ10 was measured in 25 age and sex-matched healthy controls. Inflammatory biomarkers were determined at baseline.

Results: On ICU admission and prior to sepsis development, patients had lower CoQ10 levels compared to healthy controls (0.89 vs. 1.04 µg/ml, $p < 0.01$). At sepsis onset, CoQ10 levels decreased to 0.63 µg/ml, $p < 0.001$, and at septic shock ($N = 14$) to 0.42 µg/ml, $p < 0.0001$. Baseline CoQ10 correlated with low density lipoprotein ($r = 0.409$, $p = 0.002$), and tended to negatively correlate with IL-8 and TNF- α . CoQ10 at sepsis was not associated with ICU mortality.

Conclusion: Initially non-septic, critically ill patients have lower CoQ10 on ICU admission compared to healthy controls, with a further decrease in sepsis and septic shock, suggesting that CoQ10 depletion is related to sepsis severity. CoQ10 is a component of the mitochondria, and supplementation might improve mitochondrial function in septic shock.

Intensive Care Medicine Experimental 2020, **8(2)**: 000022

Introduction: Acute renal failure has been studied extensively, mainly to try to minimize pharmacological toxicity. Early administration of appropriate and correctly dosed antibiotics is one of the cornerstones of sepsis treatment. At present, the opposite situation is also disturbing, in which there is an augmented renal clearance (ARC), because it could affect the outcome of these patients.

Objectives: The purpose was to determine the prevalence of the phenomenon of relevant augmented renal clearance ($> 170\text{ mL/min/1.73 m}^2$, rARC) and analyze the characteristics of these patients.

Methods: Multicenter, observational, prospective, epidemiological study in the critically ill patient with sepsis. 18 hospitals were recruited where 3 prevalence points were made, calculating the glomerular filtration rate (GFR) in 4-hour urine collection sample. The characteristics of these patients were compared with those with non-rARC group (GFR $90\text{--}170\text{ mL/min/1.73 m}^2$). A descriptive analysis and a univariate analysis were performed. A type I error < 0.05 was considered statistically significant. The results are given in medium and 95%CI.

Results: 561 patients of 65.5 (63.5–66.5) years were included. We focus on those 116 patients with $\text{TFG} > 90\text{ mL/min/m}^2$. Of these 116 patients, 34 (29.31%) were classified in the rARC group and 82 (70.7%) in the non-rARC group. The rARC patients were younger 59.5 (51–64) years vs. 64.5 (61–70) years, $P = 0.03$. However, the sex ratio was also: 55.9% in rARC vs. 68.3% in non-rARC, $P = 0.56$. Mortality was also similar in both groups: ICU mortality was 11.8% in rARC vs. 14.6% in non-rARC, $P = 0.94$. In-hospital mortality was the same: 17.6% in rARC vs. 17.1% in non-rARC, $P = 0.56$. And length of stay (LOS) was also similar: ICU-LOS was 15.5 (13–36) days in rARC group, vs. 20.5 (15–27) days in non-rARC, $P = 0.56$. And HOSP-LOS was 34 (15–53) days in rARC group, vs. 34 (27–43) days in non-rARC, $P = 0.3$.

Conclusion: Relevant-ARC is found in almost 30% of ICU patients. rARC patients are younger. Conversely, sex is similar, and so is mortality and length of stay.

Assessment of lipolysis activity by the composition of plasma fatty acids

S. Tachyla¹; A. Osipenko²; O. Tupitsyna³

¹Department of Anesthesiology and Intensive Care, Mogilev Regional Hospital, Mogilev, Belarus; ²Central research laboratory, Mogilev State University named after A. A. Kuleshov, Mogilev, Belarus; ³Department of anesthesiology and intensive care, Mogilev Emergency City Hospital, Mogilev, Belarus

Correspondence: S. Tachyla

Intensive Care Medicine Experimental 2020, **8(2)**: 000079

Introduction: Sepsis and multiple organ dysfunction syndrome (MODS) accompanied by an increase of catabolic reactions, which

include activation of lipolysis. Assessment of lipolysis activity allows us to judge the severity of the patient's condition and its changes during treatment. It may also be necessary to determine the amount of nutritional support.

Objectives: To develop a method for assessing lipolysis activity by the composition of blood plasma fatty acids in patients in abdominal surgery.

Methods: A prospective case-control study of the composition of blood plasma fatty acids was performed in 31 patients after abdominal operations during the first 24 h after admission in the intensive care unit (ICU). The patients were divided into two groups: group 1 (n = 15) - without sepsis and MODS, group 2 (n = 16) - the presence of sepsis and MODS. Sepsis and MODS were established by the criteria of the 2016 SCCM / ACCP conference.

Measurements of the composition of fatty acids were carried out on gas chromatographs TX-1000, LBET-800 (Russian Federation). Final identification was carried out using the method of chromatography-mass spectrometry using Thermo Scientific DSQ II (USA). The determination of the proportion of individual fatty acids was carried out by the internal normalization method using the Unichrom-97 spectrometric information recording system.

Statistical processing of the results was performed using the SPSS and Statistica 7.0 programs. Data are presented as medians and quartiles. Differences between groups were determined by the Mann-Whitney U test.

Results: Of the 31 patients, there were 19 men and 12 women, age 40 (35-46) years, height 172 (168-175) cm, body weight 80 (64-92) kg. Patients in groups with no statistical differences in sex, age, weight, height. The Apache III score was significantly higher in the group 2 of 53.0 (39.2-74.7) points vs 33.3 (9.9-53.2) points (p=0.01). The duration of treatment in the ICU was significantly higher in the group 2 of 11 (5-15) days vs 2 (2-3) days (p<0.001). Mortality in the group 1 - 0%, in the group 2 - 25%.

Patients had the following pathology: acute pancreatitis - 7, chronic pancreatitis - 11, cholelithiasis - 5, acute intestinal obstruction - 3, abdominal trauma - 4, peptic ulcer with perforation - 1. They performed laparotomy - 26, laparoscopy - 5 relaparotomy - 3.

It was found that in the composition of total plasma lipids, the total proportion of palmitoleic and oleic fatty acids increases. In patients of the group 1 this proportion is 18.2 (16.2-19.6)%, then in patients of the group 2 it is 27.9 (24.5-31.3)% (p<0.001).

The construction and analysis of the receiver operating characteristic curve for the method is performed. It was established that the area under the curve is 0.929 with a 95% confidence interval from 0.837 to 0.978 (p < 0.0001), sensitivity 87.5%, specificity 93.3%, threshold 21.7%.

Conclusion: The increase in the proportion of palmitoleic and oleic fatty acids in the composition of total blood plasma lipids reflects an increase in lipolysis activity.

Assessing the activity of lipolysis allows us to judge the intensity of catabolic processes in the body in patients.

Predictive utility cannot be inferred from associations – a systematic review of the sepsis literature to quantify the confusion in reporting

T. Varga¹; AS. Andreasen²; P. Moseley³

Intensive Care Medicine Experimental 2020, **8(2)**: 000115

Introduction: Precision medicine is considered to be the means to improve outcome of sepsis patients in the future. Statistical analyses applied to results may uncover high degrees of associations between markers or interventions and outcomes; however, even high degrees of association do not necessarily imply a predictive value of an intervention. Precision medicine requires prediction; thus attributing predictive value to associations diverges from this path and may lead to erroneous conclusions that can ultimately harm patients.

Objectives: To determine whether and to what extent published literature in sepsis with claims of prediction in their titles in fact do provide relevant measures of prediction in their abstracts. Our core premise was that abstracts, as the most informative summaries of published papers, should always confirm the claims of the title by reported statistical methodology that pertains to predictive utility.

Methods: A systematic search was performed using NCBI PubMed on Jan 27, 2020, aiming to identify articles that contain the terms sepsis and prediction in the titles using the following search term: sepsis[Title] AND (prediction[Title] OR predict[Title] OR sepsis[Title] OR predictive[Title] OR predicting[Title]) AND (hasabstract[text] AND "humans"[MeSH Terms]). General terms and defined measures of individualized prediction, as well as other reported statistical methodologies related to associations, were extracted from the abstracts of these papers. Prediction metrics were defined as measures derived from individualized predicted outcomes or probabilities, while association metrics were defined as measures pertaining to group results.

Results: In total, 518 articles, published between 1978 and 2019, were identified. Of these, 34 were excluded due to non-relevance to this systematic assessment. The remaining 484 articles, published in 227 unique journals, comprised our study sample. Of these articles, 36% (n=173) did not report metrics of predictive utility, while the remaining 64% (n=311) included at least one metric of predictive utility in their abstracts. Of the abstracts that reported measures of predictive utility, the most common reported metrics were ROC AUC (70%), sensitivity (40%) and specificity (36%). Of the abstracts without measures of predictive utility, 54% did not define their methodology, while 28% performed logistic regression and 15% performed Cox models. Full review of the 173 undefined manuscripts revealed that more than 75% (n=117) were actually describing a relationship based upon associations only, while 17% (n=31) contained some measure of prediction.

Conclusion: We demonstrate evidence that more than one-third of abstracts from papers that claim to provide insights on prediction in the sepsis literature actually provide no methodology to evaluate prediction in their abstracts. In most cases, these manuscripts offer a measure of association or no defined methodology at all. When no information was available in the abstract, more than 75% of these manuscripts did not provide measures of prediction and often claimed prediction while using only tests of association. Such confusion may ultimately harm patients, for instance by undergoing unnecessary and inappropriate treatment of abnormalities that proves not to be predictive despite statistically significant associations.

Intensive Care Medicine Experimental 2020, **8(2)**: 000116

Introduction: Endothelial cells are involved in the pathogenesis of sepsis and organ dysfunction caused by sepsis. There is no well-established method in clinical practice for evaluating endothelial injury in sepsis. Endothelial microparticles (MPs) (EMPs) are extracellular vesicles derived from the cellular membranes of injured or apoptotic endothelial cells, which suggests that EMPs may be a marker for endothelial injury in sepsis.

Objectives: To examine whether the number of EMPs is increased in patients with sepsis and reflects the severity of sepsis.

Methods: This prospective observational study was performed to examine the numbers of circulating EMPs in patients with sepsis using flow cytometry (ethics committee approval: 2018-1-353). We collected platelet-poor plasma (PPP) from patients diagnosed with Sepsis-3 on admission and on days 2, 3, 5, and 7 of hospitalisation. We also collected PPP for a non-sepsis control group from patients who were admitted to the intensive care unit after undergoing scheduled head and neck surgery on admission and on days 2, 3, and 5 of hospitalisation. EMPs were defined as CD31+/CD41- MPs [platelet endothelial cell adhesion molecule (PECAM)+ EMPs], CD144+ MPs [vascular endothelial (VE)-cadherin+ EMPs], CD62E+ MPs (E-selectin+ MPs), CD54+ MPs [intercellular adhesion molecule (ICAM)-1+ EMPs], and CD106+ MPs [vascular cell adhesion molecule (VCAM)-1+ EMPs] MPs.

Results: We examined the numbers of circulating EMPs in 72 patients with sepsis (sepsis, 29; septic shock, 43) and 30 non-sepsis patients. The numbers of all types of EMPs were significantly higher in patients with sepsis than in non-sepsis patients during the study period, except for VCAM-1+ EMPs on admission. The numbers of PECAM+ and VE-cadherin+ EMPs, the expressed endothelial antigens of which are rich in endothelial cell intercellular junctions and regulate endothelial junctional integrity and permeability, were significantly higher in patients with septic shock than in those with sepsis until day 5. On the other hand, the number of E-selectin+ EMPs, which are endothelial adhesion molecules induced by inflammatory stimuli, such as E-selectin, ICAM-1, and VCAM-1, on admission was significantly higher in patients with septic shock than in patients with sepsis. The numbers of PECAM+, VE-cadherin+, and E-selectin+ EMPs on admission, as well as PECAM+ EMPs on day 2, were significantly higher in patients who died in the hospital than those in survivors.

Conclusion: The number of EMPs significantly increased in patients with sepsis, which may suggest that an increase in the number of EMPs may reflect endothelial injury in sepsis. Furthermore, the numbers of PECAM+ and VE-cadherin+ EMPs are higher in patients with septic shock than in patients with sepsis and might be novel markers of the severity of septic endothelial injury.

Intensive Care Medicine Experimental 2020, **8(2)**: 000142

Introduction: The presence of sepsis on patients' admission to the intensive care unit (ICU) is associated with adverse outcomes [1]. It has been demonstrated that many patients suffer additional infectious and septic episodes, which might increase mortality [2].

Objectives: Our aim is to delineate the incidence and clinical characteristics of the secondary sepsis event in comparison with sepsis on admission in a setting of endemic difficult-to-treat Gram-negative microbial infections.

Methods: Secondary ICU-associated sepsis was defined as a second septic event, >48 hours after admission. Data were retrieved from the records of all patients admitted in our 16-bed mixed ICU between July 2015 and December 2017. We excluded patients with an ICU stay of <48hs. We described continuous variables as median (IQR) and categorical variables as number (percentage) and we performed comparisons with Mann-Whitney, Wilcoxon test and chi-square test, where appropriate. We used survival analysis to evaluate ICU mortality.

Results: Sixty-five septic patients (65 episodes), 42 (64.6%) male, and 35(53.4%) medical, were analyzed. Their age, Charlson comorbidity index, APACHE II, and SOFA on admission were 73 (65-79) years, 4 (3-5), 24 (18-27.5), and 10 (8-12), respectively. The most commonly encountered primary septic focus was intraabdominal (46.2%), and 42(64.6%) patients were in septic shock. A pertinent culture displayed a pathogen in 35 (53.8%) episodes, and Gram-negative isolates prevailed (26/35, 74.3%).

Sixteen (24.6%) patients presented secondary sepsis on day 9(6-15.5), an isolate was identified in 93.7% of events, and *Acinetobacter baumannii* was isolated in 8/15 events (53.3%). The presence of hypothermia on the day of both episodes was the same (20%); temperature and white blood cells did not differ between the events.

Regarding the outcome, overall ICU mortality was 46.2%. The Kaplan-Maier curve analysis of 30-day mortality did not show any difference between patients with and without secondary sepsis. However, secondary sepsis was associated with prolonged length of stay in the ICU (21 vs. ten days, p=0.001). Eventually, more patients died after their first month in the critical care department (ICU mortality of 75% vs. 37%, p=0.02).

Conclusion: In a setting of endemic difficult-to-treat Gram-negative bacteria, secondary sepsis, on top of primary sepsis, can lead to both prolonged hospital stay and late mortality.

Intensive Care Medicine Experimental 2020, **8(2)**: 000159

Introduction: Frailty increases the risk of morbidity and mortality in patients with critical illnesses. However, most previous studies evaluated a heterogeneous population. The specific characteristics of patients with sepsis according to frailty in the intensive care units (ICUs) remains unclear.

Objectives: We aimed to investigate the association between frailty and characteristics, clinical features, and outcomes among patients with suspected infection in ICUs.

Methods: This is a secondary analysis of the Japanese Association for Acute Medicine Sepsis Prognostication in Intensive Care unit and Emergency room (JAMA SPICE)-ICU study, which was a multicenter study of patients with suspected infection. We included adult patients (≥ 18 years) with suspected infection who were admitted to ICUs. Frailty was evaluated using the Canadian Study on Health and Aging Clinical Frailty Scale (CFS)[1]. As previously reported [2], baseline patient characteristics and outcomes were compared between three frailty groups: fit (scale 1–3), vulnerable (scale 4) and frail (scale 5–9). We also performed a subgroup analysis of patients with sepsis, which was defined based on sepsis-3 criteria. The Kaplan–Meier survival curve for 90 days was also drawn.

Results: We enrolled 650 patients with suspected infection, including 599 (92.2%) patients with sepsis, for this study from the SPICE-ICU database. Patients with a median rating of 3 (3–5) according to the CFS, were included: 337 (51.8%) were fit, 109 (16.8%) vulnerable, and 204 (31.4%) frail. Comorbidities were more prevalent in frail and vulnerable patients than in fit patients. The APACHE II scores for fit, vulnerable, and frail patients were 18 (12–25), 22 (17–28), and 21 (15–27), respectively ($p < 0.01$). The body temperatures of patients were as follows: fit 37.5 (36.5–38.5) $^{\circ}\text{C}$; vulnerable 37.5 (36.4–38.6) $^{\circ}\text{C}$; frail 37.0 (36.3–38.1) $^{\circ}\text{C}$ ($p < 0.01$). Regarding the laboratory data, the CRP level in fit, vulnerable and frail patients were 13.6 (4.6–24.5) mg/dl, 12.1 (3.9–24.9) mg/dl, 10.5 (3.03–21.0) mg/dl, respectively ($p < 0.01$). There was no statistically significant difference regarding organ dysfunction among the groups. In-hospital mortality did not differ statistically according to frailty: fit 55/335 (16.4%); vulnerable 23/107 (21.5%); frail 45/203 (22.2%), $p = 0.19$. Kaplan–Meier survival curves showed that there was little difference in the mortality rate among groups during the acute phase. However, vulnerable and frail patients tended to die after the acute phase while the fit did not, although the difference was not statistically significant ($p = 0.25$, Figure). Compared to fit or vulnerable patients, fewer frail patients were discharged to home: fit 125/280 (44.6%); vulnerable 36/84 (42.9%); frail 40/158 (25.3%).

Conclusion: Frailty was associated with a poor response to inflammation of infection. Frail and vulnerable patients with suspected infection including sepsis tended to have poor outcomes after the acute phase in their clinical courses.

The temporal relationship between mitochondrial- and monocyte cell functionality during sepsis

M.J. Melis¹; E. Karakike²; N. Koliakos³; E.J. Giamarellos-Bourboulis²; M. Shankar-Hari⁴; M. Singer¹

¹Bloomsbury institute of intensive care medicine, University College London, London, United Kingdom; ²4th department of internal medicine, National and Kapodistrian University of Athens, Medical School, Athens, Greece; ³3rd department of surgery, National and Kapodistrian University of Athens, Medical School, Athens, Greece; ⁴School of immunobiology and microbial sciences, King's College School, London, United Kingdom

Correspondence: M.J. Melis

Intensive Care Medicine Experimental 2020, **8(2)**: 000235

Introduction: Immune responses in sepsis involve simultaneous activation and suppression of circulating leukocytes. These immune responses are often associated with mortality [1]. Alterations in mitochondrial functionality of monocytes and lymphocytes are associated with immune suppression, severity of sepsis, and mortality [2–4]. Monocyte HLA-DR expression is an important marker for monitoring immune alterations during sepsis [5]. We postulated that immune dysfunction with decreased monocyte HLA-DR expression during sepsis may be induced by a bioenergetic shutdown.

Objectives: To assess the correlation between mitochondrial function (as measured by mitochondrial membrane potential ($\Delta\Psi\text{m}$) and ROS production), and immune cell functionality (measured by monocyte HLA-DR expression) during the time-course of sepsis.

Methods: Septic and pre-operative control patients were recruited at the ATTIKON University Hospital in Athens, Greece. Whole blood was collected at four different timepoints (days 1, 2, 4 and 7 after admission) for septic patients and at one timepoint for control patients. Whole blood was lysed and stained with anti-CD14 to identify monocytes, TMRM and MitoSox as measures of $\Delta\Psi\text{m}$ and ROS production, anti-HLA-DR for HLA-DR receptor expression, and Annexin-V and 7AAD as markers for apoptosis and cell death. Appropriate positive-, negative-, and isotype controls were used. Samples were measured

using a BD FC500 flow cytometer and analysed using FlowJo. Prism was used for statistical analysis with Kruskal-Wallis non-parametric tests comparing different groups at day 1, and a repeated measures mixed ANOVA model to analyse trends over time within groups.

Results: 16 septic patients (10 survivors), and 13 pre-operative control patients were enrolled. There were no differences in $\Delta\Psi_m$ between the three groups on day 1. A change over time was found for all septic patients ($P=0.02$), without any differences between survivors and non-survivors. Higher levels of mitochondrial ROS were found in non-survivors on day 1 compared to controls ($P=0.02$). No differences were however found over time for either survivors or non-survivors. Compared to controls, HLA-DR expression was lower in septic patients on day 1 ($P=0.05$ for survivors). HLA-DR expression recovered over time in survivors ($P=0.003$ versus non-survivors).

Conclusion: Bioenergetic alterations (mitochondrial ROS production and $\Delta\Psi_m$) do not explain the reduction in HLA-DR levels in sepsis patients.

Intensive Care Medicine Experimental 2020, **8**(2): 000236

Introduction: Diagnosing sepsis remains difficult because it is not a single disease but a syndrome with various pathogen- and host factor-associated symptoms. Sepsis-3 was established to improve risk stratification among patients suspected with infection based on organ failures but it has been still controversial compared with previous definitions.

Objectives: We aimed to investigate characteristics according to whether patients who met sepsis-2 (severe sepsis)1 and sepsis-3 definitions2 among patients with suspected infection in ICU.

Methods: This was a multicenter, prospective cohort study. It conducted by 22 intensive care units (ICUs) in Japan. Adult patients (≥ 16 years) with newly suspected infection from December 2017 to May 2018 were included. All patients were admitted to the ICUs in study hospitals. Patients were divided into four groups according to whether they met each definition or not: (both) sepsis-2 and sepsis-3; sepsis-2 and no sepsis-3; no sepsis-2 and sepsis-3; and no sepsis-2 and no sepsis-3. Characteristics and in-hospital mortality were compared according to the groups.

Results: In total, 652 patients with suspected infection were admitted to 22 ICUs during the study, of whom 558 (85.6%) met the sepsis-2 definition and 600 (92.0%) met the sepsis-3 definition. The sepsis-2 and sepsis-3 definitions comprised different individuals, and 527 (80.8%) patients met both definitions (sepsis-2 and sepsis-3). Thirty one exclusively met the sepsis-2 (sepsis-2 and no sepsis-3) and 73 exclusively met the sepsis-3 (no sepsis-2 and sepsis-3) definition. A total of 21 patients did not meet either definitions (no sepsis-2 and no sepsis-3). Systemic inflammatory response syndrome (SIRS) positive (≥ 2) among patients with sepsis-2 and sepsis-3; sepsis-2 and no sepsis-3; no sepsis-2 and sepsis-3; and no sepsis-2 and no sepsis-3 were 100%; 100%; 68.5%; and 66.7%, respectively. Quick sequential organ failure assessment (qSOFA) positive (≥ 2) among patients with sepsis-2 and sepsis-3; sepsis-2 and no sepsis-3; no sepsis-2 and sepsis-3; and no sepsis-2 and no sepsis-3 were 66.8%; 35.5%; 27.4%; and 14.3%, respectively. In-hospital mortality among suspected infection, sepsis-2, and sepsis-3 patients was comparable (19.2%, 21.7%, and 20.0%, respectively). In-hospital mortality among patients with sepsis-2 and sepsis-3; sepsis-2 and no sepsis-3; no sepsis-2 and sepsis-3; and no sepsis-2 and no sepsis-3 were 22.0%; 16.1%; 5.5%; and 0%, respectively. Patients who met sepsis-3 shock definition had higher in-hospital mortality than those who met sepsis-2 shock definition (27.4% vs 34.3%).

Conclusion: Most patients with suspected infection admitted to ICU meet sepsis-2 and sepsis-3 definitions. They were less suitable for risk stratification in this setting. However, in-hospital mortality did not occur if patients did not meet any criteria. Better criteria might

be developed by better selection and combining elements in both definitions.

Role of transesophageal echocardiography in non-cardiac medical intensive care patients with sepsis of an unknown origin without preknown heart disease

C. Ditzges¹; R. Schmid¹; W. Huber¹; T. Lahmer¹

¹Medizinische klinik und poliklinik ii, Klinikum rechts der Isar; Technische Universität München, Munich, Germany

Correspondence: C. Ditzges

Intensive Care Medicine Experimental 2020, **8(2)**: 000282

Introduction: In septic patients - besides a rapidly beginning therapy - the effective search for the inflammatory focus is imperative to reduce morbidity and mortality. Therefore the prior diagnostic steps entail laboratory and imaging investigations (i.e. computer tomography). If these do not lead to any concrete result, transesophageal echocardiography (TEE) is recommended to exclude an infective endocarditis (IE). As the lethality of infective endocarditis can be up to 30%, TEE is an important diagnostical tool in intensive care medicine. In this study we investigated the role of TEE to detect a septic focus in patients on medical intensive care units especially without underlying cardiac disease as until now it is still unclear.

Methods: We conducted a retrospective 10 years analysis of non-cardiac medical intensive care unit patients with sepsis of unknown origin but without preknown heart disease, who underwent a TEE to detect IE as the focus of the inflammation. We collected data about laboratory findings, risk-scores, TEE-results, DUKE-criteria and mortality.

Results: From 1925 septic patients 108 (6%) underwent a TEE and were included in the study (average age 60 years, 61% male). Among these patients 15 (14%) were diagnosed an IE and six (42%) of them died. APACHE II- as well as SOFA-score were lower in patients with IE compared to patients with another septic focus (23 vs 27 and 9 vs 11), but showed statistical significance. Neither leucocytes (18.1 vs 20.6 G/l), CRP (20.8 vs 13.4 mg/dl), procalcitonin (32.9 vs 17.9 ng/ml) nor body temperature (36.9 vs 37.2 °C) showed significant differences between both groups. Positive blood cultures were found in 80% of patients with IE and in 42% of the others. Comparing the results of the modified DUKE-criteria the patient with IE met in average 1.5 major criteria and 2.1 minor criteria. Patients without IE (0.2 major and 1.4 minor criteria) met significantly less criteria ($p < 0.001$). Those who left the intensive care unit alive received their TEE significantly earlier ($p = 0.001$).

Conclusion: This study demonstrates the relevance of TEE in sepsis of unknown focus and without underlying cardiac disease. Due to the high incidence of IE in septic patients in combination with an increased morbidity and mortality a transesophageal echocardiography should be carried out as soon as possible when having such patients on a medical intensive care unit. Clinical findings in patients with infective endocarditis show a high heterogeneity, so that the diagnosis is hard to make - especially in patients without preknown heart disease. Neither laboratory findings nor scoring systems were unequivocal or groundbreaking.

Intensive Care Medicine Experimental 2020, **8(2)**: 000298

Introduction: A dysregulated host response, which is a cornerstone of the pathophysiology of sepsis, induces alteration in vital signs. Elderly patients have a blunted host response, which may influence vital sign alterations and clinical outcomes of sepsis. We investigated the different associations between the vital signs and mortality in elderly and nonelderly patients with sepsis.

Methods: The current observational study was retrospectively conducted. A prospective multicenter severe sepsis cohort acquired from 59 Japanese ICUs (FORECAST, n=1148) was used for the derivation analyses. Significant results were tested for replication using two validation cohorts of severe sepsis (JAAMSR, prospective multicenter cohort from Japan, n=624; SPH, a single center cohort including different ancestry [Canada], n=1004). Patients were categorized into elderly and nonelderly groups (age ≥ 75 or < 75 years). The associations of the vital signs (body temperature [BT], heart rate, mean arterial pressure, systolic blood pressure, respiratory rate) within 24 hours of severe sepsis diagnosis and 90-day in-hospital mortality (primary outcome) were studied using Cox regression analysis.

Results: Nonelderly patients (n=628) with BT < 36.0 °C showed significantly increased 90-day mortality ($P = 0.025$, adjusted hazard ratio 1.70, 95% CI 1.07–2.71) in the derivation cohort. While those with BT > 38.3 °C showed decreased trend for mortality ($P = 0.11$, adjusted hazard ratio 0.71, 95% CI 0.47–1.08). In the validation cohorts, nonelderly patients with BT < 36.0 °C showed significantly increased mortality (JAAMSR, $P = 0.0024$, adjusted hazard ratio 2.05, 95% CI 1.29–3.26; SPH, $P = 0.029$, adjusted hazard ratio 1.36, 95% CI 1.03–1.80), and those with BT > 38.3 °C displayed significantly decreased mortality (JAAMSR, $P = 0.0043$, adjusted hazard ratio 0.51, 95% CI 0.32–0.81; SPH, $P = 0.018$, adjusted hazard ratio 0.76, 95% CI 0.61–0.95). These differences were not observed in elderly patients in all the three cohorts. Associations between the other four vital signs and mortality were not different in elderly and nonelderly patients.

Conclusion: Among the vital signs, body temperature showed significantly different effects on mortality between nonelderly and elderly patients. Nonelderly severe sepsis patients with hypothermia and fever showed decreased and increased mortality, respectively.

However, mortality in elderly patients was not associated with body temperature.

Intensive Care Medicine Experimental 2020, **8(2)**: 000302

Introduction: Pulmonary vascular endothelium is a key modulator in acute respiratory distress syndrome (ARDS) development (1). Recent investigations suggest that greater systemic endothelial activation might be associated with poor outcome of mechanically ventilated patients with sepsis (2).

Objectives: The aim of this study was to investigate serum biomarkers of alveolar capillary damage (sRAGE, endocan, angiopoietin-2) as outcome predictors in mechanically ventilated patients with sepsis.

Methods: A prospective, observational pilot study was conducted on mechanically ventilated patients with sepsis admitted in the ICU of the Institute for pulmonary diseases of Vojvodina (IPDV) from January until March 2018. Diagnosis of sepsis was based on Sepsis-3 criteria (3) and ARDS was defined by using Berlin criteria (4). Blood samples for the assessment of serum biomarkers (sRAGE, endocan, angiopoietin-2) were taken within the first 24 hours from starting the mechanical ventilation.

Baseline demographic data, Charlson comorbidity index, arterial blood gas analysis, Tidal volume, PEEP value, complete blood count and biochemistry findings (procalcitonin, CRP, lactate, creatinine, bilirubin) were collected. Severity of illness was defined by Acute Physiology and Chronic Health Evaluation II (APACHE II) and Sequential Organ Failure Assessment (SOFA) score.

Results: A total of 24 mechanically ventilated patients treated in the ICU of IPDV were included. Average age was 54,8 and 33,3% of patients were males. The Berlin criteria for ARDS met 14 patients (58,3%). Average APACHE II score at ICU admission was 22,71±6,9 and average SOFA score 7,13±2,74. ICU mortality was 37,5%.

There were no differences observed in levels of biomarkers with respect to 28-day mortality for sRAGE, angiopoietin-2 and endocan, as shown in Table 1. Subset of ARDS patients had significantly lower values of angiopoietin-2 (9,93±7,04 vs 16,31±7,7, p=0,047) comparing to patients without ARDS. Regrading hospital mortality and ventilator free days, there was no statistically significant difference between sRAGE, angiopoietin-2 and endocan. There was no correlation between values of specific biomarkers.

Biomarker	28 day mortalitydied	28 day mortalitysurvived	p value
sRAGE	3031±1818	3052±1983	0,979
angiopoietin-2	15,6±8,8	10,4±6,6	0,118
endocan	5,62±3,94	5,34±3,56	0,855

Table 1. Correlation between 28-day mortality and biomarkers of alveolar capillary damage.

Conclusion: Our results suggest that mechanically ventilated patients with ARDS have different expression of alveolar capillary damage biomarkers comparing to patients without ARDS. Biomarker changes are less useful for prediction of other hospital outcomes in our study.

Intensive Care Medicine Experimental 2020, **8(2)**: 000364

Introduction: Septic shock, a form of distributive shock, is the most common cause of death in patients admitted into the intensive care unit (ICU).¹ Persistent hypotension is a hallmark sign of shock and its resulting end-organ hypoperfusion is directly related to mortality.² Initial management of septic shock focuses on the maintenance of mean arterial pressure (MAP), which includes early and adequate fluid resuscitation and the initiation of vasopressors.³ Angiotensin II is a novel treatment modality for patients unresponsive to the current standard of care recommended by consensus guidelines.⁴ Its administration was associated with a 660% increased chance of obtaining MAP response when compared to placebo.⁵ We investigated the utility of angiotensin II for the treatment of patients experiencing septic shock in the ICU.

Objectives: To assess the clinical outcomes of patients that were administered angiotensin II in the ICU of two academic medical centers.

Methods: In this retrospective chart review, we evaluated patients who received angiotensin II in the ICU of two academic medical centers from July 1, 2018, to January 31, 2020. Eligible patients were at least 18 years of age, had vasodilatory shock, and received angiotensin II. Baseline characteristics included age, sex, body mass index, clinical markers, severity of illness scores, and prior exposure to an angiotensin-converting enzyme inhibitor and/or to an angiotensin receptor blocker. Data for evaluation included changes in MAP, vasopressor use prior to and during angiotensin II use, Sequential Organ Failure Assessment (SOFA) score change at hour 48, adverse events, and mortality. All the data were analyzed using descriptive statistics.

Results: A total of 28 patients received angiotensin II during the studied period. The average baseline MAP was 60±13 mmHg. The mean MAP increase from baseline at hour 3 was 12±18 mmHg (24 patients) and at hour 48 was 17±15 mmHg (13 patients). When examining vasopressor use, the specific agent(s) used varied on the patient and site,

however, the two most common vasopressors used before angiotensin II administration were norepinephrine (NE) and vasopressin. The baseline total NE-equivalent dose was 0.435 ± 0.189 mcg/kg/min, at hour 3 was 0.406 ± 0.184 mcg/kg/min, and at hour 48 was 0.385 ± 0.226 mcg/kg/min. The mean baseline SOFA score was 10 ± 4 . At hour 48, SOFA increased by 1 ± 6 points. Side effects that arose included fungal infections (18%) and new-onset thromboembolism (4%). Mortality occurred in 46% of patients at hour 24, 68% of patients at day 7, and 71% of patients at day 28.

Conclusion: Angiotensin II effectively increased MAP in patients with vasodilatory shock that did not respond to high doses of conventional vasopressors. Administration allowed the requirements of other vasopressors to be reduced over time. However, the patients still showed a rise in their SOFA scores and had a high mortality rate. More investigation is warranted to prove utility of angiotensin II at our clinical sites.

Intensive Care Medicine Experimental 2020, **8(2)**: 000403

Introduction: Recognition of mortality risk factors and early intervention of appropriate broad-spectrum antimicrobial administration may significantly improve the outcome. Selective Digestive Decontamination (SDD) has been associated with reduced ICU mortality and acquired infection rates.

Objectives: To analyze mortality risk factors in patients with nosocomial infection (NI) in an ICU after 8 years of SDD.

Methods: Prospective study. Patients with NI were included from October 1, 2010 to September 30, 2019 in a polyvalent ICU of 30 beds. SDD was applied for 8 years, from October 1, 2011 to September 30, 2019. Patients requiring mechanical ventilation for more than 48 hours, an enteral solution and a paste with colistin, tobramycin and nystatin every 8 hours until discharge were applied. Also intravenous cefotaxime were administered during the first 4 days. Rectal and pharyngeal exudates were collected on admission and weekly. The categorical variables were summarized in frequencies and percentages and the numerical variables as means and standard deviations or in medians and interquartile ranges. The percentages were compared with the X2 test or the Fisher exact test, the means with the t-test and the medians with the Wilcoxon test for independent data. A multidimensional logistic analysis was carried out. It was considered significant if $p \leq .05$.

Results: Of 8202 patients admitted, 238 (35,57%) out of 669 patients with NIs died. In an univariate analysis we did not find statistically significant difference in ICU stay. Multiresistant (MR) *Pseudomonas* and MR Gram negative bacteria (GNB) were significantly higher in patients who died (Table 1)

Table 1. Patient characteristics according to the survival

	Alive N=431	Death N=238	P
Age, years	59.6 ± 15.6	63.8 ± 13.7	<0.001

Intensive Care Medicine Experimental 2020, **8(2)**: 000420

Introduction: The most common reason for intensive care unit (ICU) admission for patients with severe coronavirus disease 2019 (COVID-19) is acute respiratory failure (ARF). However, data on organ dysfunctions (OD) other than lungs remains poorly defined in this field. The aim of this study was to analyze the rate of various OD (acute kidney injury, AKI; liver failure, LF; circulatory failure, CF; coagulopathy;

pancytopenia) in a cohort of COVID-19 patients admitted in a Intermediate Care Unit (IMCU) for ARF.

Methods: We performed a retrospective analysis, reviewing all COVID-19 patients admitted for ARF in our IMCU from March 1st to March 31st 2020. The inclusion criteria were age \geq 18 years old; diagnosis of COVID-19 by a nasopharyngeal swab. AKI was defined by KDIGO criteria; LF was defined by high levels of bilirubin ($>$ 2 mg/dL), prolonged prothrombin time (PT) $>$ 18 sec; circulatory failure was defined by mean arterial pressure (MAP) $<$ 65 mmHg and requiring the use of vasopressors; coagulopathy was defined by prolonged PT $>$ 18 sec, activated partial thromboplastin time (aPTT) $>$ 60 sec and low platelet count ($<$ 150,000/microL); pancytopenia was defined by neutrophil count $<$ 1800/microL; Hb $<$ 12 g/dL for women and $<$ 13 g/dL for men; platelet count $<$ 150,000/microL. We collected the demographic characteristics and the rate of the OD associated to ARF. We also reported the rate of COVID-19 patients affected by 2, 3 or more than 3 simultaneous OD.

Results: We reviewed 134 patients and 93/134 respected the inclusion criteria. Demographic characteristics are shown in the Table 1. All patients showed ARF with a PaO₂/FiO₂ ratio 115 ± 78 . SAPS2 score was 33 ± 9 , SOFA score was 3 ± 1 . The rate of endotracheal intubation (ETI) was 42/93 patients (45,2%). We found AKI in 19/93 patients (20,4%), LF in 23/93 patients (24,7%), CF in 7/93 (7,5%), coagulopathy in 22/93 patients (23,7%), pancytopenia 3/93 (3,2%). 45/93 (48,4%) showed multiple OD. In particular 22/93 patients had 2 simultaneous OD; 14/93 showed 3 simultaneous OD and 9 patients \geq 3 OD (see figure 1)

Demographic characteristics	Values
Sex	Male: 70/93 (75%)
Age (mean \pm SD)	64 \pm 12
Obesity	18/93 (19,4%)
Malignancy	6/93 (6,5%)
COPD/Asthma	8/93 (8,6%)
Diabetes	16/93 (17,2%)
Cardiovascular disease	26/93 (28%)
Hypertension	42/93 (45,2%)
Chronic kidney disease	5/93 (5,4%)

Table 1 - Demographic characteristics

Figure 1 - Organ dysfunction - MOD (multiple organ dysfunction)

Conclusion: In our cohort of COVID-19 patients, multiple organ dysfunction was a common finding with a rate close to 50% of cases.

Intensive Care Medicine Experimental 2020, **8(2)**: 000438

Introduction: Adequate utilization of vancomycin is essential for achieving therapeutic targets while avoiding clinical failure and development of antimicrobial resistance, especially in critically ill patients.

Objectives: We aim to determine whether there is a difference in the incidence of sub-therapeutic vancomycin level between surgical and medical patients in a mixed intensive care unit (ICU) and identify the possible factors that lead to this difference.

Methods: A retrospective electronic medical chart review was done for all adult ICU patients who received intravenous Vancomycin between 2012 and 2017 at our center. Patients with renal failure were excluded. The Vancomycin dose used in our population was 15–20 mg/kg every 8 hours, adjusted according to each patient's GFR. Blood Vancomycin trough levels below 15 mg/l before the 4th dose were reported as sub-therapeutic. The lab studies and illness severity scores of our patients during their ICU stay were also collected. A descriptive data analysis was done followed by a multivariate analysis to study the subtherapeutic Vancomycin levels between medical and surgical patients.

Results: A total of 85 patients were included in the study, divided into 44 surgical ICU (SICU) patients and 41 medical ICU (MICU) patients. No difference was found in age, gender, BMI, and eGFR between the two groups. Subtherapeutic vancomycin levels were significantly higher in SICU patients as compared to MICU patients (29(66%) out of 44 vs. 14(34%) out of 41, $P=0.003$). SICU patients were found to have a higher total volume intake, higher fluid balance, and lower Hb levels as compared to MICU patients. SICU patients also had a longer stay in the ICU before the initiation of Vancomycin treatment and lower APACHE and SAPS mortality scores as compared to MICU patients. Multivariate logistic regression including all the above factors associated with subtherapeutic vancomycin showed that admission to the ICU from a surgical service is an independent risk factor for subtherapeutic vancomycin levels ($P=0.001$, OR=6.48, CI (2.14 – 19.59)). Further subgroup analysis could not be done due to the relatively small sample size.

Conclusion: Critically ill surgical patients receiving intravenous Vancomycin in the ICU are inherently at a higher risk for subtherapeutic vancomycin levels than medical patients. We recommend further studies with larger sample sizes to further investigate the factors leading to the higher incidence of subtherapeutic vancomycin levels in surgical patients.

Introduction: Cardiac function is known to be negatively impacted by sepsis. Monitoring Cardiac Output (CO) and Stroke volume (SV) trends over the course of treatment may provide insight into cardiac function and may be used to predict patient outcome.

Objectives: The goal of this study was to explore the relationship between the change in cardiac output over time in septic shock.

Methods: FRESH is randomized controlled study, evaluating hemodynamics in critically ill patients with sepsis or septic shock (NCT02837731). Patients randomized to PLR guided resuscitation received hemodynamic monitoring for 72 or until ICU discharge, whichever occurred first (Starling SV, Cheetah Medical). Patients that exhibited an improvement in stroke volume at 12, 24, 36 and 48 hours were compared to those who did not exhibit improvement. Overall improvement in stroke volume (first SV measurement compared to last SV measurement) was also compared between groups.

Results: 90 patients with septic shock received hemodynamic monitoring over a 72 hour monitoring period. 60 % were female, and the average age was 61 years. Overall, 44% of assessments demonstrated a fluid responsive positive response after receiving initial resuscitation fluid of 2.3 L. Patients who exhibited improved SV at 24 and 36 hours exhibited a decreased fluid balance over the course of their ICU stay at both 24 hours (1.06 ± 3.40 vs 3.15 ± 4.38 , $p=0.029$) and 36 hours (1.18 ± 2.58 vs 3.41 ± 4.52 , $p=0.032$). Notably, patients who exhibited an overall improvement in SV also required less hours on vasopressors (34.50 ± 41.03 vs 64.28 ± 65.07 , $p=0.05$) and decreased ICU length of stay (3.93 ± 3 vs 5.59 ± 5.24 days, $p=0.08$) (Figure 1).

Conclusion: We have previously shown that patients who improve SV in response to the resuscitation exhibited improved outcome. Trending cardiac output over the 72 hour monitoring period revealed additional usefulness in predicting patients with improved outcome. The results highlight the importance of trending hemodynamics in therapy.

Intensive Care Medicine Experimental 2020, **8(2)**: 000468

Introduction: Current guidelines recommend to increase mean arterial pressure (MAP) in previously hypertensive septic shock patients to higher levels (80-85 mmHg) when tissue hypoperfusion has not been corrected with the initial fluid resuscitation and restoration of MAP to 65 mmHg. The impact of incremental NE titration on cardiac function depend on the balance between the effects on preload, contractility and afterload. As NE may both increase venous return and afterload, a particular concern is a potential decrease in stroke volume (SV) in fluid-unresponsive patients.

Objectives: Determine whether septic shock patients requiring a high MAP exhibit afterload dependence, defined as a decrease in stroke volume >10%.

Methods: We evaluated a cohort of previously hypertensive patients with septic shock in whom the attending physician decided to increase MAP from 65 to 85 mmHg because of persistent hypoperfusion after initial resuscitation. A comprehensive echocardiographic assessment was performed at baseline 1 (MAP 65 mmHg), after reaching the MAP target (MAP 85 mmHg), and after return to baseline 2 (MAP 65 mmHg). Preload, contractility and afterload variables were assessed. Statistical analysis was performed with Wilcoxon signed-rank test, $P < 0.05$ was considered as significant.

Results: Twelve mechanically ventilated patients (age 72 ± 9 yr, APACHE II 23 ± 5 , SOFA on admission 10 ± 3) were included in this preliminary report. No significant decrease in stroke volume was shown; in contrast, 60% of the studied patients increased their stroke volume >10% despite being fluid unresponsive at baseline and with a significant increase in afterload. Hemodynamic and echocardiography variables are shown in Table 1.

Effects of remote ischaemic conditioning on the sublingual microcirculation in septic shock patients

I. Kiudulaite¹; A. Pranskunas¹

¹Intensive care medicine, Lithuanian University of Health Sciences, Kaunas, Lithuania

Correspondence: I. Kiudulaite

Intensive Care Medicine Experimental 2020, **8(2)**: 000475

Introduction: Introduction: The severity of microcirculatory alterations is related to mortality in septic shock patients (1). Remote ischaemic conditioning (RIC) is a promising technique that may protect organs and tissues from the effects of further ischaemic episodes. Studies have shown that remote ischaemic conditioning may improve endothelial function, red blood cell deformability, reduce leukocyte adhesion and etc. These mechanisms may lead to improved microcirculation. RIC preserved microcirculation and prolonged survival in

septic shock animals (2). However, RIC's impact on microcirculation in septic shock patients has not been evaluated.

We hypothesize that RIC improves sublingual microcirculation in septic shock patients.

Objectives: This study aims to evaluate RIC effects on sublingual microcirculation in septic shock patients.

Methods: This single-center open-label trial was performed in a mixed ICU in a tertiary teaching hospital. We included patients with septic shock within the first 24 h after ICU admission. RIC procedure involved three cycles of 5 min brachial cuff inflation to 200 mmHg and then deflation to 0 mmHg for another 5 min. RIC was performed at inclusion and repeated 12 h and 24 h later. Sublingual microcirculatory measurements were obtained before and after each RIC procedure, using a sidestream dark-field imaging device. Data are reported as medians with 25th and 75th percentiles.

Results: Twenty-six septic shock patients with a median age of 65 (57-81) were enrolled in this study. The median APACHE II and SOFA scores at admission were 20 (13-23) and 10 (9-12), respectively. We found a significant increase in microvascular flow index compared before and after the first RIC procedure (p=0.003). We found no change in microcirculatory flow and density parameters during repeated RIC after 12 h and 24 h.

Conclusion: The first remote ischaemic conditioning procedure improved microcirculatory flow, while subsequent procedures did not affect sublingual microcirculation in septic shock patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000479

Introduction: Severe acute pancreatitis (SAP) is associated with multiple organ failure and systemic inflammatory response syndrome what leads to high mortality rate. Patients often require different interventional measures including surgical procedures to improve outcomes.

Objectives: to describe the evolution of patients with SAP and its associated complications. To analyze the medical and surgical management of secondary abdominal compartment syndrome (ACS).

Methods: retrospective study including patients admitted to ICU with a diagnosis of SAP during the period 2013-2019. Demographic data, cause, severity scales, and occurrence of associated complications are recorded: acute renal failure (ARF), infections, ACS, need for ventilatory support. Treatment with continuous renal replacement techniques (CRRT), the need for a surgical approach and nutritional support are recorded. Results are expressed as mean (95% CI).

Results: 43 patients were studied, 58.1% male, age 72.1 (63.3-76.9) years, APACHE 16.3 (12.9-19.8), SAPS II 38.1 (31.8-44.3), SOFA 4.3 (2.9-5.7). The cause of SAP was: lithiasic 30.2%, alcoholic 9.3%, post-ERCP 16.3%, idiopathic 44.2%. Up to 41.9% required mechanical ventilation (MV) for 17.1 (6.1-28.2) days, of which 7% underwent tracheostomy. High-flow oxygen therapy was administered to 9.3%. The prevalence of ARF was 55.8%, 18.6% of patients were treated with CRRT. ACS was present in 18.6% of patients, and laparotomy was performed in 20.9% (11.6% decompressive, 4.7% necrosectomy). After decompressive laparotomy, the duration of the vacuum-assisted closure system (VAC)

was 15.2 (0.3-30.1) days with 2.3 (0.6-4) mesh replacements. Abdominal infection rate 21%, respiratory infection 23.3%, multi-resistant colonization 2.3%. 74.4% received nutritional support (39.5% parenteral, 7% enteral, 27.9% mixed). ICU stay was 13.7 (7.4-20) days, hospital stay 24.9 (22.4-27.4) days and mortality 34.9%. The absence of ARF was associated with less need for surgery (39% in the ARF group VS 0% in the group without ARF) $p < 0.05$ (Fisher's exact test). Surgical treatment did not influence stay or mortality in our sample.

Conclusion: SAP is an entity with high morbimortality, multidisciplinary management may improve mortality and reduce sequels.

000532

Association between symptoms of early onset and mortality or ICU admission in patients with suspected infection or sepsis

F. Jaimes¹; J. Albarracín²; J. Chaparro²; J. Rojas¹; J. Valoyes²; J. Ascuntar²; D. Mendoza¹

¹Internal medicine, Universidad de Antioquia, Medellín, Colombia; ²Internal medicine, Universidad de Antioquia, Medellín, Colombia

Intensive Care Medicine Experimental 2020, **8(2)**: 000532

Introduction: The early recognition of sepsis is one of the pillars to improve its prognosis. It is necessary to explore if there are symptoms or early clinical characteristics associated with the worse outcomes such as the need for Intensive Care Unit (ICU) admission or in-hospital mortality. This information could lead to the optimization of timely care protocols.

Objectives: To identify the earliest symptoms of patients with suspected infection or sepsis that may be associated with the need for ICU admission or in-hospital mortality.

Methods: Prospective cohort study conducted between June/2019 and March/2020 in a university hospital of Medellín, Colombia. We included patients older than 18 years with diagnosis of any type of infection or sepsis (suspected or confirmed), requiring hospitalization by the emergency department (ED). Previously trained researchers collected symptoms and signs, by reviewing the clinical history and interviewing the patient and their relatives, using standardized equipment and formats. The primary outcome was ICU admission or mortality. We did univariate logistic regression models for each one of the independent variables. Then a multivariable adjusted logistic regression model was fitted to estimate the independent effect of each symptom on the outcome. The results are shown as OR with 95%CI.

Results: Among 965 eligible patients, 245 (25.4%) were included. The main causes of exclusion were use of antibiotics in the last 15 days (44%) and immunodeficiency (21%). The median age was 60 years (IQR=45-71) and 51% were male. The main comorbidities were kidney disease (23%), congestive heart failure (15.1%) and chronic respiratory disease (15.1%). The most common symptoms were general malaise (80.6%), subjective fever (76%) and chills (70.5%). The median SOFA score was 2 (IQR = 0-5) and the main foci of infection were the respiratory tract (29.4%), followed by skin and soft tissues (21.2%) and the gastrointestinal tract (19.2%). The in-hospital mortality rate was 12.7% and 119 (48.6%) patients required admission to the ICU. In the univariate analysis, the symptoms significantly associated with hospital mortality or ICU admission were chills, subjective fever, productive cough, dyspnea and altered mental status. However, after multivariate adjustment of symptoms for age, SOFA and Charlson score, only dyspnea and altered mental status remained associated, but they were not longer statistically significant (OR = 2.16, 95%CI = 0.9; 5.2 and OR = 1.51, 95%CI = 0.7; 3.2, respectively)

Conclusion: A few symptoms, easily identified in the ED by a simple interrogatory, may be early indicators of ominous prognosis in patients with sepsis. A prospective multicenter cohort study is warranted for confirmation and external validation of our findings.

Improving the diagnosis of sepsis according to the sources of infection

A. Jaimes¹; D. Mendoza¹; J. Ascuntar²; O. Rosero²

¹Internal medicine, Universidad de Antioquia, Medellín, Colombia; ²Internal medicine, Universidad de Antioquia, Medellín, Colombia

Correspondence: F. Jaimes

Intensive Care Medicine Experimental 2020, **8(2)**: 000542

Introduction: The initial clinical presentation of sepsis is heterogeneous and largely depends on the primary site of infection. This situation makes the early diagnosis of this condition a clinical challenge. Tools such as qSOFA help to assess the risk of complications in patients with suspected infections; however, this approach is indifferent to the site of infection itself. A more individualized identification would allow focusing on earlier targeted therapy

Objectives: To identify simple variables associated with risk of in-hospital mortality or Intensive Care Unit (UCI) admission, according to infection sites

Methods: Secondary analysis of a multicenter prospective cohort. We included patients older than 18 years hospitalized between 2014 and 2016 with suspected sepsis, who were admitted to Emergency Departments (ED) of three tertiary care university hospitals in Medellín, Colombia. Bivariate and multivariate logistic regression models were performed to estimate the association of widely available and clinically relevant variables with in-hospital mortality or ICU admission according to 5 infection sites: urinary tract infection (UTI), community acquired pneumonia (CAP), intra-abdominal infection (IAI), sepsis without evident source (primary) and others (soft tissue and bone infections, catheter-associated bacteremia, meningitis, surgical site infections, others). The independent effect of each variable on the outcome was estimated using Odds Ratio (OR) with its respective 95% confidence interval (CI).

Results: A total of 5,022 patients were screened, of which 2,454 entered the primary study. In this secondary analysis, we included 1,947 patients with confirmed diagnosis of infection. The most common sites of infection were UTI (n=586, 30%), CAP (n=585, 30%), IAI (n=213, 11%), primary (n=224 11.5%) and others (n=339, 17.4%) patients, respectively. After multivariable adjustment, the most significant signs varied widely according to the site of infection (Table 1): Respiratory rate (RR), Systolic Blood Pressure (SBP) and lactate for ITU; Heart Rate (HR), RR and temperature < 38°C for CAP; Glasgow coma scale (GCS), lactate and age < 65 for IAI; SBP, GCS, lactate and temperature < 38°C for primary and RR, GCS and temperature < 38°C for others.

Table 1. Relevant clinical variables according to infection site

Variable (OR 95%CI)	UTI	CAP	IAI	Primary	Others
HR > 120	1.4 (0.8 – 2.2)	1.6 (1.0 – 2.5)	1.6 (0.6 – 3.9)	1.2 (0.6 – 2.4)	1.6 (0.8 – 3.0)
RR > 22	3.0 (1.8 – 5.0)	1.9 (1.3 – 2.8)	1.8 (0.7 – 4.5)	2.0 (0.9 – 3.9)	3.4 (1.7 – 6.5)
SBP < 100	3.0 (2.0 – 4.4)	1.4 (0.9 – 2.1)	1.3 (0.7 – 2.6)	2.6 (1.4 – 4.8)	1.6 (0.9 – 2.7)
GCS < 15	1.7 (0.9 – 3.0)	1.3 (0.8 – 2.2)	9.6 (1.2 – 80.5)	4.5 (1.7 – 11.4)	3.0 (1.6 – 5.8)
Lactate > 2	1.6 (1.1 – 2.4)	1.2 (0.8 – 1.7)	3.1 (1.6 – 6.0)	2.0 (1.1 – 3.9)	0.6 (0.3 – 1.1)
≥ 38°C	Ref	Ref	Ref	Ref	Ref
< 38°C	0.7 (0.5 – 1.0)	2.1 (1.4 – 3.0)	1.0 (0.5 – 2.2)	2.1 (1.1 – 3.9)	2.9 (1.6 – 5.1)
Age > 65	1.0 (0.7 – 1.5)	0.5 (0.4 – 0.7)	2.3 (1.2 – 4.5)	0.8 (0.4 – 1.6)	1.2 (0.7 – 2.1)

Conclusion: Our results suggest that the best approach for sepsis diagnosis in clinical practice, should consider different criteria depending on the site of infection. More research efforts in the area are required to integrate these variables into a qSOFA-type tool, with the aim of achieving a more individualized treatment according to the suspicion of the infection site.

Intensive Care Medicine Experimental 2020, **8(2)**: 000587

Introduction: Sepsis is a heterogenous syndrome caused by a dysregulated immune response to infection. Numerous studies on immunomodulatory therapies have failed to improve outcome. Identification of distinct immunological phenotypes in septic patients may lead to more precise clinical immunomodulatory studies. Clinical distinct septic patient phenotypes have different clinical presentations, microbial findings and outcome¹.

Objectives: To study whether four different clinical phenotypes, based on the presence or not of preexisting inflammatory insults, differed in inflammatory mediators in intensive care treated septic patients.

Methods: For 12 months, 276 adult patients admitted to a single ICU and provided with an arterial catheter were consecutively included in a prospective study after informed consent. Plasma was obtained for the first 3 days for the analyses of heparin binding protein, NGAL, tumor necrosis factor receptor 1 and 2, endostatin, procalcitonin, calprotectin and C-reactive protein. Patients were retrospectively grouped as either septic or non-septic according to the Sepsis-3 classification. Further, the septic patients were classified based on the presence of preexisting inflammatory insults into either primary (no prior insults), secondary (one recent insult) or tertiary sepsis (several recent

insults). Independent of prior inflammatory insults, patients with immunosuppressive treatments or immunosuppressive diseases were classified as immunosuppressive sepsis.

Results: Septic patients had significantly higher plasma levels in all measured inflammatory mediators at admission to the ICU compared to non-septic patients, with the exception of procalcitonin where no significant difference could be noted ($p=0.29$). During the first 3 days, patients with primary sepsis had higher levels of heparin binding protein ($p<0.02$) than secondary, tertiary or immunosuppressive sepsis. Patients with primary and immunosuppressive sepsis had lower levels of calprotectin ($p<0.01$), than those with secondary or tertiary sepsis. No differences in plasma levels of endostatin, NGAL, procalcitonin, tumor necrosis factor receptor 1 or 2, were noted between the immunological phenotype groups.

Conclusion: Classification of patients into inflammatory phenotypes based on preexisting inflammatory insults prior to sepsis, is supported by early differences in plasma levels of heparin binding protein and calprotectin. Procalcitonin performed poorly as a biomarker to distinguish septic patients from non-septic patients in the ICU.

Clinical utility of procalcitonin in critically ill medical patients in Croatia

A. Vujaklija Brajković¹; I. Košuta¹; M. Rora¹; D. Tomek²; J. Babel¹; R. Radonić¹

¹Department of Internal Medicine, University Hospital Centre Zagreb, Zagreb, Croatia; ²Department of Oncology and Radiotherapy, University Hospital Centre Zagreb, Zagreb, Croatia

Correspondence: A. Vujaklija Brajković

Intensive Care Medicine Experimental 2020, **8(2)**: 000629

Introduction: Procalcitonin (PCT) is one of the most studied biomarkers regarding antibiotic stewardship¹. In the critical care setting, published studies differ greatly considering patient case-mix, the source of infection, the severity of the disease, exclusion criteria as well as cut-offs and laboratory methods for PCT measurements²⁻⁴.

Objectives: PCT testing was implemented in the emergency lab of the Department of Laboratory Diagnostics in October 2016. As an initial demand management strategy, only the emergency department and intensive care units gained unlimited access to direct test ordering. The study aimed to evaluate the applicability of PCT testing in severely ill patients with suspected infection in a tertiary referral hospital in Croatia.

Methods: Patients with suspected infection were included in a prospective, observational study in the medical intensive care unit (ICU) at the University Hospital Centre Zagreb, Croatia. Analysis of disease severity (APACHE II, SOFA score), microbiological cultures (blood culture (BC), urine culture (UC), endotracheal aspirate culture (ETA)), C-reactive protein (CRP), and PCT was performed.

Results: 129 patients were included, 83 males (63.6%) of median age 64 (39-89). Median APACHE II was 21 (7-35) and SOFA 7 (1-13). Sepsis (50, 38.8%) and pneumonia (37, 28.7%) were the most common diagnoses. Overall PCT was $1.66 \pm 11.43 \mu\text{g/L}$ and CRP $102 \pm 166 \text{ mg/L}$. Most patients (83,64.3%) received antibiotics before admission. No difference in PCT (1.56 ± 8 vs 1.44 ± 13 , $p=0.6$) nor in CRP (98 ± 137 vs 127 ± 171 , $p=0.5$) was observed regardless of previous antibiotic therapy.

Infection was clinically confirmed in 106 (82.2%) patients. Microbiological cultures were positive in 86 (66.7%) and 81.1% of patients with clinically confirmed infections. PCT and CRP were significantly increased in patients with positive BC, the infection caused by Gram-negative microorganism regardless of disease severity (no difference in SOFA and APACHE score) and pneumonia with complications (Table 1). PCT did not differ among patients with positive vs negative UC (4.6 ± 16 vs 1.76 ± 11.9) nor positive vs negative ETA (1.93 ± 11.4

vs 1.76 ± 1.11). The change of antimicrobial treatment based on PCT value was done in 36 patients (28%).

Table 1. Values are medians with interquartile ranges.

Variable	BC +	BC -	BC+ G+	BC+ G-	PNM, not complicated	PNM, with shock	PNM, BC -	PNM, BC +
N	54	61	24	30	46	29	35	40
PCT, µg/L	8.2±24.1*	0.6±3.7	1.99±12*	15.9±50*	1.1±3.6*	16.5±44.2*	0.9±4.0a	7.2±20.2a
CRP, mg/L	167±212*	86±116*	139±202*	181.5±222*	80±115*	194±204*	108±140NS	143.5±191NS

Conclusion: PCT level was not influenced by previous antibiotic exposure. Patients with infection caused by gram-negative strains had a higher level of both CRP and PCT. The incomplete application of PCT guided stewardship in our patient series could be at least partially explained by a lack of experience in the routine clinical application of the studied biomarker.

Introduction: Sepsis is a major healthcare problem which affects millions of people around the world each year. Despite significant advances in diagnostic tools and the increasing use of biomarkers, the early recognition of sepsis in critically ill patients could be challenging. Recently, it has been described that morphological changes in leukocyte populations, especially the morphology and size of monocytes, could be used as a new biomarker for the early detection of sepsis.

Objectives: The main purpose is to determine if the monocyte distribution width (MDW) could be used as a new biomarker of sepsis. The secondary objective is to assess if MDW could be a prognostic factor of mortality in septic patients.

Methods: Prospective, observational study carried out during 2019 in the Intensive Care Unit (ICU). Critically ill patients with all kind of pathologies were included. It has been collected demographic variables, severity scores and ICU mortality. According to Sepsis-3 criteria, patients were divided into 3 groups on admission: non-infected (NI), sepsis (S) and septic shock (SS). MDW and traditional biomarkers were analyzed on admission. Statistical analysis includes qualitative variables, presented as proportions, and quantitative variables, presented as medians and minimum-maximum (Min-Max). Kolmogorov-Smirnov test was used for the assessment of normality. Kruskal-Wallis test was used to compare biomarkers among groups. The association between

ICU mortality and each biomarker was performed using Mann-Whitney U test. The area under the receiver operating characteristics (ROC) curve (AUC) was used to assess the prediction of ICU mortality. The study was previously approved by the Hospital Ethics Committee.

Results: A total of 188 patients were included: NI 127 (0.676), S 35 (0.186), SS 26 (0.138). Age 56.7 years; males 0.59. Severity scores: APACHE II NI 15 (Min-Max: 2-58), S 16 (Min-Max: 9-41), SS 23.5 (Min-Max: 8-45; p < 0.001); SOFA NI 6 (Min-Max: 0-17), S 8 (Min-Max: 0-17), SS 10.5 (Min-Max: 3-17; p < 0.001). Biomarkers on admission: MDW NI 20.5 (Min-Max: 15.3-40.6), S 24 (Min-Max: 16.4-39.8), SS 35.5 (Min-Max: 21-58.9; p < 0.001); CRP NI 19.8 mg/L (Min-Max: 0.8-343.7), S 106.5 mg/L (Min-Max: 3.6-478.2), SS 249 mg/L (Min-Max: 86.7-437.6; p < 0.001); PCT NI 0.15 ng/mL (Min-Max: 0.2-46.7), S 1.2 ng/mL (Min-Max: 0.15-75), SS 24.5 ng/mL (Min-Max: 1.27-100; p < 0.001); lactate and total leukocytes were not statistically significant (pns). The ICU mortality was 0.138. Association of biomarkers and mortality: MDW alive patients (AP) 21.1 (Min-Max: 15.3-57.7), dead patients (DP) 28.3 (Min-Max: 17.3-58.9; p < 0.001); CRP AP 34.8 mg/L (Min-Max: 0.8-478.2), DP 112.6 mg/L (Min-Max: 9.6-355; p = 0.007); PCT AP 0.31 ng/mL (Min-Max: 0.02-100), DP 2.8 ng/mL (Min-Max 0.07-100; p = 0.005); lactate AP 1.16 mmol/L (Min-Max: 0-4.9), DP 2 mmol/L (Min-Max: 0-16.6; p = 0.001); total leukocytes were not statistically significant (pns). Mortality prediction according to each biomarker: AUC MDW 0.74 (Min-Max: 0.63-0.85; p < 0.001); AUC CRP 0.67 (Min-Max: 0.57-0.77; p = 0.007); AUC lactate 0.71 (Min-Max: 0.59-0.83; p = 0.001); AUC PCT 0.69 (Min-Max: 0.58-0.8; p = 0.005).

Conclusion: MDW could be considered as a new biomarker for the diagnosis of sepsis. Additionally, MDW could have prognostic performance in septic patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000706

Introduction: Septic shock and the underlying cytokine storm remain a major contributor to mortality in critically ill patients. The introduction of cytokine haemoadsorption techniques offer a novel approach to treatment of septic shock [1-3], nevertheless the efficacy of these devices in cytokine removal, as well as their effect on the course of disease remain to be further assessed.

Objectives: To study the effect of the Cytosorb (I) directly on the levels of Interleukin-6 (IL-6), (II) on the need for vasopressors assessed through the Vasopressor Dependency Index (VPI) [4], and (III) on intensive care unit (ICU) mortality.

Methods: We analysed 48 patients prospectively treated with a pro-inflammatory (IL-6 ≥ 1000 ng/l), therapy refractory (VPI ≥ 3) septic shock, admitted to the medical ICU of the University Hospital of Zurich between 2014 and 2018, with a Cytosorb coupled in series to a CRRT for 3 x 24 hours after septic shock diagnosis, in an "intention to treat" approach. A historical cohort of 437 patients admitted with septic shock to the same ICU between 2011 and 2018 was further retrospectively constituted. To reduce biased estimation of the treatment

effect of Cytosorb, six matching algorithms based on the variables age, sex, BMI, SAPS II, SOFA, IL-6, lactate, PCT and VPI at septic shock diagnosis were employed and compared to determine the most balanced population of control patients to the Cytosorb cohort. Finally, a genetic matching algorithm demonstrated its superiority regarding the achievement of a standardized mean difference of under 0.1 and a variation ratio of between 0.5 and 2.0 for all matching variables, selecting 48 control patients [5].

Results: After matching, all matching variables and other baseline characteristics were balanced between the matched cohort (MC) and the Cytosorb cohort (CC). Cytokine adsorption did not result in a greater relative decrease in IL-6 over 72 hours as compared to the matched control (MC: 85% [0-95] vs. CC: 54% [0-73], $p = 0.09$). Further, there was no evidence that Cytosorb use lead to an increased reduction in the VPI (MC: 88% [54-95] vs. CC: 51% [6-83], $p = 0.56$). Finally, 30-day ICU mortality was more pronounced in the CC (Hazard Ratio 1.79, CI [1.01 – 3.18], $p = 0.04$).

Conclusion: Our ambispective study suggested that broad adsorption of cytokines as provided by the Cytosorb may have, as compared to the matched control of septic shock patients, an uncertain effect on IL-6 kinetics and the need for vasopressors over an observation period of 72 hours, this with a potential deleterious effect on 30-day ICU survival. A large randomized controlled trial is urgently needed to prove the efficacy of the Cytosorb treatment in patients with septic shock. Awaiting these results its use in septic shock should be carefully considered.

A case of Lemierre Syndrome presenting with Type 1 respiratory failure and septic shock following a recent diagnosis with Covid 19

C. Costello¹; A. Gillece²; C. Cody¹; C. Murphy¹

¹Department of Anaesthesia and Critical Care Medicine, Connolly Hospital Blanchardstown, Dublin, Ireland; ²Department of clinical microbiology, Connolly Hospital Blanchardstown, Dublin, Ireland

Intensive Care Medicine Experimental 2020, **8(2)**: 000742

Introduction: Lemierre Syndrome is a rare and potentially life threatening condition characterized by septic thrombophlebitis of the internal jugular vein (IJV). First identified in 1900, it was described by André Lemierre in 1936 and had a rapidly fatal course in the pre-antibiotic era. [1] The incidence appears to be rising with a mortality of 5-18% [2]

Methods: We present a case of a Lemierre Syndrome, which was admitted to our Intensive Care Unit following a recent history of Covid19.

Results: A 39 year old male presented with a 7 day history of pharyngitis, pyrexia and vomiting. His medical history was significant for seizures associated with a traumatic brain injury. The patient tested

positive for SARS-CoV 2 infection 12 weeks previously. SARS-CoV 2 was not detected on multiple investigations during this presentation.

The patient developed type 1 respiratory failure. Chest X Ray and CT Thorax revealed a bilateral cavitating pneumonia and pleural effusions. Blood cultures were positive for *Fusobacterium necrophorum*. He was also severely thrombocytopenic.

Increasing oxygen requirements necessitated mechanical ventilation. A subsequent CT neck revealed a left sided 3.5cm peritonsillar abscess with an associated internal jugular vein thrombosis.

The patient was transferred to another Intensive Care Unit with on site ENT support. Spontaneous rupture of the peritonsillar abscess precipitated septic shock requiring debridement and washouts in the Intensive Care Unit and in Theatre. Bilateral chest drains were inserted to facilitate oxygenation and ventilation.

The patient was weaned from vasopressors and mechanical ventilation and subsequently discharged home on long term intravenous antibiotics

Conclusion: Lemierre syndrome is a rare condition precipitated by a bacterial pharyngitis typically caused by anaerobic organisms including *Fusobacterium necrophorum*. [1] It has been previously linked with Epstein-Barr Virus infection. However, given the recent pandemic we question the impact of SARS-CoV-2 on the pathogenesis of the disease and psychological factors at play leading to this critical illness?

000772**Validation of sepsis-induced coagulopathy score in critically ill septic shock patients: a post hoc analysis of nationwide multicenter registry in Japan**C. Tanaka¹; T. Tagami²; K. Unemoto¹; M. Kuno¹; S. Kudo¹; F. Nakayama¹; J. Kaneko¹; A. Kitahashi¹; S. Sato¹; Y. Ishiki¹; R. Fukuda¹¹Emergency and critical care medicine, Nippon Medical School Tama Nagayama Hospital, Tama, Japan; ²Department of emergency and critical care medicine, Nippon Medical School Musashi Kosugi Hospital, Kawasaki, Japan**Correspondence:** C. Tanaka*Intensive Care Medicine Experimental* 2020, **8(2)**: 000772

Introduction: Coagulopathy is one of the major causes of organ dysfunction and death in sepsis; however, there are no standard criteria for diagnosis of it. Recently, sepsis-induced coagulopathy (SIC) was developed as a new criterion for coagulation disorder of sepsis patients. It includes the sequential organ failure assessment (SOFA), similarly the new definition of sepsis revised in 2016 (sepsis-3 definition). Previous studies suggested that SIC score might be a prognostic value for patients with sepsis and coagulopathy, however, there are few studies about SIC of septic shock patients who are defined as a subset of critically ill sepsis patients.

Objectives: To evaluate the accuracy of SIC score as a prognostic value for both sepsis patients and septic shock patients.

Methods: Coagulation [JSEPTIC-DIC] study, which investigated patients with sepsis in 42 intensive care units (ICUs) from 2011 to 2013, were analyzed. This contained information about patients' backgrounds, examination results, treatments, and mortality. Primary outcome measure was in-hospital mortality. Firstly, we grouped subjects into two (patients with vasopressor and patients without vasopressor). This database didn't contain information about vital signs, therefore, we analyzed the patients needed vasopressor instead of septic shock patients. Secondly, we assessed patient characteristics and mortality of vasopressor groups between SIC and non-SIC, using χ^2 test or Fisher's test. Then, we compared the same things between SIC and non-SIC in no vasopressor group. Furthermore, we analyzed in-hospital mortality of vasopressor group using a logistic regression analysis adjusted for age, gender, SIC and treatment for coagulation abnormality.

Results: This study included 1894 patient: 1453 in vasopressor group, and 441 in no vasopressor groups. In vasopressor group, 965 (66.4%) were diagnosed with SIC. In-hospital mortality was significantly higher among SIC patients than non-SIC patients (35.8% vs 27.9%, $p < 0.01$). Besides, ventilator free days and ICU free days were significantly shorter in SIC than non-SIC (mean days \pm standard deviations, 14.7 ± 11.4 vs 15.5 ± 11.0 $p < 0.01$, 12.0 ± 10.2 vs 13.2 ± 10.1 $p < 0.01$, respectively). On the other hand, 186 (42.2%) were diagnosed as SIC in no vasopressor group. There were no statistically significant differences about in-hospital mortality, ventilator free days, and ICU free days (15.6% vs 12.2% $p = 0.33$, 21.9 ± 9.8 vs 22.0 ± 9.3 $p = 0.22$, 16.9 ± 9.7 vs 17.8 ± 8.6 $p = 0.29$, respectively). Moreover, the diagnosis of SIC in vasopressor group had significant association with worse outcome via a logistic regression analysis adjusted for factors independently associated with mortality (odds ratio: 1.52, 95% confidence interval: 1.23-1.86).

Conclusion: SIC might be a good diagnostic value of fatal coagulation abnormally among sepsis patients who needed vasopressor.

000774**The Apelinergic, Renin-Angiotensin & Kallikrein Systems in Early Human Septic Shock**W. Salvail¹; F. Chagnon²; D. Coquerel¹; K. Tran³; E. Marsault³; O. Lesur¹¹Médecine/icu, Université de Sherbrooke, Sherbrooke, Canada; ²icu, CRCHUS, Sherbrooke, Canada; ³Institut de pharmacologie de sherbrooke, Université de Sherbrooke, Sherbrooke, Canada**Correspondence:** O. Lesur*Intensive Care Medicine Experimental* 2020, **8(2)**: 000774

Introduction: While catecholamine reactivity and response are well-documented in septic shock, those related to the apelin and related renin-angiotensin and kallikrein-kinin systems are mostly unknown. From both experimental and human standpoints, the apelin system (i.e., apelinergics: apelins -APLNs- and Elabela -Ela-) offers an alternative pathway for hemodynamic support with evidence of efficiency and protection.

Objectives: Determine the endogenous blood contents of apelinergics; the related breakdown enzymatic profile; and the link with outcomes for septic patients.

Methods: An observational cohort study in 52 subjects: 33 patients admitted to the intensive care unit (ICU) for sepsis/septic shock (S) and 19 healthy volunteers (H) with early blood sampling and data recording up to the outcome.

Results: The endogenous apelinergic system is reactive to S (1.5-to-3-fold increase of APLNs and Ela blood contents, respectively, $p < 0.01$). Concomitantly, lower angiotensin converting enzyme-ACE2- but higher angiotensin converting enzyme -ACE1-, Nephilysin -NEP-, Kallikrein -KLK1-, and ACE1 enzymatic activities are found in S compared to H ($p < 0.01$ -to-0.0001). Such a huge elevation of systemic ACE1:2 ratio (16.5 [2.3-60.8] in S vs. 1.2 [0.9-1.3] in H, $p=0.0004$) and of related enzymatic breakdown activities can jeopardize endogenous apelinergics with potential impacts on the outcome. Indeed: 1) S non survivors exhibit much higher ACE1:2 ratio than survivors (61.2 [6.3-77.9] vs. 8.8 [0.7-27], $p=0.0352$), 2) exogenously added APLN-13 and Ela to plasma in vitro display lower stability in S, suggesting an enhanced breakdown environment (half-life (min): APLN-13; H: 194 ± 15 , S: 143 ± 20 $p = 0.045$; Ela, H: 258 ± 45 , sepsis: 69 ± 12 $p = 0.003$). Decreased APLN-13 half-life is significantly associated with higher NEP and KLK1 enzymatic activities ($p=0.0116$ and 0.0003 , respectively). Also, increased ACE1:2ratio and NEP activities are significantly linked with higher circulating Ang1-7 levels in S ($p < 0.0001$). PCA analysis showed a strong association between the following variables: arterial lactates, creatinine and cortisol circulating levels, APACHE II and SOFA scores, which altogether defined a PC1 axis. A second relationship gathering circulating APLNs, Ela, and Ang1-7 levels as well as ACE1, KLK1, and NEP activities, defined a PC2 axis. In this illustration, sepsis non-survivors were widely distributed in the positive area of the PC1 and PC2 axes, suggesting that worse sepsis outcomes could have been influenced by the profile of the apelinergic release-degradation system in the critically ill patients.

Conclusion: Sepsis-induced renin-angiotensin and kallikrein-kinin system disturbances potentially impair the apelin system-driven hemodynamic support ability and affect the outcome in human patients with septic shock.

000789**Microcirculatory, endothelial and inflammatory responses in critically ill patients with COVID-19 are distinct from those seen in septic shock: a case control study**J. Watchorn¹; SD. Hutchings¹; F. Trovato²; S. Napoli³; S. Mujib⁴; PA. Hopkins⁵; M. McPhail⁵¹Critical Care, King's College Hospital, Denmark Hill, London, UK, London, UK, United Kingdom; ²Hepatology, King's College London, London, United Kingdom; ³Hepatology, King's College Hospital, London, United Kingdom; ⁴Hepatology, King's College Hospital, Denmark Hill, London, UK, London, United Kingdom; ⁵Critical care, King's College Hospital, London, United Kingdom**Correspondence:** J. Watchorn*Intensive Care Medicine Experimental* 2020, **8(2)**: 000789

Introduction: Critically ill patients with COVID-19 infection frequently exhibit a hyperinflammatory response and develop organ failures, however the underlying mechanisms are unclear. We investigated the microcirculatory, endothelial and inflammatory responses in critically ill COVID-19 patients and compared them to a group of patients with septic shock.

Methods: Prospective observational case control study. 30 critically ill patients with COVID-19 were compared to 33 patients with septic shock. Measurements of sublingual microcirculatory flow using Incident Dark Field (IDF) video-microscopy and serial measurements of IL-6 and Syndecan-1 levels were performed.

Results: COVID-19 patients had significantly less vasoactive drug requirement and lower plasma lactate than those with septic shock. Microcirculatory flow was significantly worse in septic patients than those with COVID-19 (MFI 2.6 v 2.9 p 0.02, PPV 88 v 97% p <0.001). IL-6 was higher in patients with septic shock than COVID-19 (1653 v 253 pg/ml, p 0.03). IL-6 levels in COVID 19 patients were not elevated compared to healthy controls except on the day of ICU admission. Syndecan-1 levels were not different between the 2 pathological groups.

Conclusion: Compared to patients with bacterial sepsis an overt shock state with tissue hypoperfusion does not appear typical of COVID-19 infection. There was no evidence of significant sublingual microcirculatory impairment, widespread endothelial injury or marked inflammatory cytokine release in this group of critically ill COVID-19 patients. COVID-19 may have a different pathogenesis to bacterial induced septic shock

Intensive Care Medicine Experimental 2020, **8(2)**: 000042

Introduction: Body temperature abnormalities including hypothermia occur frequently in sepsis patients and can influence the inflammatory response to infection [1]. However, the relationship between hypothermia and clinical parameters of sepsis diagnosed with modern definitions is still unsettled.

Objectives: To estimate the impact of hypothermia upon admission to the intensive care unit (ICU) on the course and outcomes of sepsis.

Methods: We performed a retrospective analysis of the ICU charts of all patients admitted to the 44-bed adult ICU of the City hospital #1 of Arkhangelsk in 2018. We included for analysis all patients who was diagnosed with sepsis upon admission to ICU according to Sepsis-3 definitions [2] and recorded diagnosis, body temperature, demographic, clinical and laboratory data, duration of ICU stay and mortality. We used the Student's t-test, Mann-Whitney's test or chi-square test to compare the data according to their type and distribution. The correlation analysis was performed using Spearman's rho coefficient. The results are presented as n (%), M±SD or median (25–75 percentiles). p values < 0.05 were regarded as statistically significant.

Results: Totally, 3103 ICU charts were examined. Upon admission to ICU, sepsis was observed in 121 patients (3.9% from all admissions, 51.2% males and 48.8% females). The mean age was 66.5±14.7 years, the duration of ICU stay was 4 (1.0–7.2) days. The most common origins of sepsis were pulmonary and abdominal. The organ dysfunctions included septic shock (57.9% of cases), kidney injury (57.9%), delirium (53.7%), acute respiratory distress syndrome (50.4%), disseminated

intravascular coagulation (28.9%), metabolic disorders (26.4%), and hepatic failure (23.1%). The mean SOFA score during the first 24 hrs of ICU stay was 9 points; the hospital mortality was 51%. The mean body temperature on ICU admission was 36.2 (35.9–36.7)°C. Hypothermia <36°C was diagnosed in 24% of cases; 67% of patients had body temperature within 36–38°C, and 9% were febrile (> 38°C). Among hypothermic patients with sepsis, 59% were postoperative. The patients with sepsis and hypothermia had more severe lactic acidosis as compared to normal or febrile body temperature: arterial pH 7.22 (7.14–7.33) vs. 7.30 (7.20–7.41) and 7.38 (7.34–7.49) (p < 0,002), lactate 5.0 (2.5–9.5) vs. 2.6 (1.5–4.9) and 4.1 (2.1–5.3) mmol/L, respectively (p = 0,04). Body temperature on ICU admission correlated with mean arterial pressure (rho = - 0,24, p = 0,015) and platelet count (rho = - 0,34, p = 0,001). Hypothermia in septic patients on ICU admission was not related with increased mortality or duration of ICU stay.

Conclusion: In sepsis, hypothermia <36°C on admission to ICU occurs in 24% of patients and is accompanied by worsening lactic acidosis. The relationship between hypothermia and clinical outcome of sepsis requires further analysis.

Intensive Care Medicine Experimental 2020, **8(2)**: 000977

Introduction: In septic patients, the piperacillin-tazobactam (Pip-Taz) association is one of the most used antibiotics. Pharmacokinetics of Pip-Taz depend mainly on distribution volume, renal clearance, patient's weight and serum albumin level. These parameters are highly variable in sepsis. Predictive algorithms based on clinical and biological parameters may help optimise dosing and improve outcome.

Objectives: To build a Bayesian model predicting optimal dosing regimen of Pip-Taz in septic patient. We designed the OPTAZ study with a 60-patient construction cohort and a 30-patient validation cohort. We present here the pharmacokinetics in the first patients recruited.

Methods: Patients were included prospectively in 4 ICUs in France. Pip 4g and Taz 0.5g were infused every 6 hours (group 1) or 8 hours (group 2) according to clinician choice. Infusion time was of 3 hours. For patients receiving Pip-Taz every 6 hours, plasma level of Pip and Taz was assessed before infusion (H0) and 1.5, 3, 4, 6, 12, 24 and 48 hours after the beginning of the first infusion. For patient receiving Pip-Taz every 8 hours, plasma level of Pip and Taz was assessed at H0, H1.5, H4, H6, H8, H16, H24 and H48. Serum level of Pip-Taz was assessed by mass spectrometry. Values expressed as med [Q1-Q3]. We assessed the proportion of residual points over 4 times the EUCAST non-species-related breakpoint for Pip-Taz (4mg/L).

Results: Nineteen patients included. 14/19 (73%) men, age 54 [47-62] years, weight 88 [76-92] kg, BMI 27.47 [23.59-33.18] kg/m². On day 1, 5 (26%) received norepinephrine, 4 (21%) lactate \geq 2mmol/L and urine output was 1580 [1350-2180] mL/24h. Patients received 44 [39-52] mg/kg of Pip and 5.65 [5.28-6.54] mg/kg of Taz. Seven patients received the infusion every 8 hours and 12 patients every 6 hours. After the first infusion, the AUC of Pip was 280 [218-367] mg.h/L in group 1, and 437 [313-566] mg.h/L in group 2. The AUC of Taz was 22.9 [19.4-36.8] mg.h/L in group 1, and 40.0 [27.1-46.2] mg.h/L in group 2. After the first infusion, the residual concentration was 13.77 [5.75-31.95]mg/L, 33% being under 16mg/L in group 1, 71% in group 2. At H48, these values were 37.99 [15.00-48.19] and 9.68 [6.37-100.15], 33% and 71%.

Conclusion: In this prospective pilot series of patients admitted with sepsis and treated empirically with Pip-Taz, the blood exposure to the drug was consistent with the dosing interval but was highly variable, including values below the inferior (efficacy) target and over the superior (toxicity) target.

Intensive Care Medicine Experimental 2020, **8(2)**: 001078

Introduction: Biomarkers are essential to adequate triage and risk stratification of patients at hospital admission in order to provide an appropriate treatment.

Objectives: To compare the value as predictive biomarkers of different analytical parameters routinely performed in these patients.

Methods: Multicenter, prospective, observational study, carried out in the emergency department from 7 Spanish hospitals. Epidemiological and analytical data including demographics, therapy, inflammatory and immunity parameters were collected. Patients with the diagnosis of COVID-19 infection were included from two groups: patients admitted to the ICU and another group admitted to the hospital with less severity. The levels are expressed in median (IRQ).

Results: 203 patients admitted to the hospital emergency department with clinical symptoms and positive PCR for Covid-19 were recruited: 59 were admitted to the ICU during its evolution, 121 patients were admitted to the hospital for treatment and 22 were discharged and treated at home. The mortality of the patients admitted to the ICU was 42.37% and in the hospital 17%.

All Biomarkers were significantly higher ($p < 0.05$) in the most severe group. Ferritin levels were significantly elevated in patients admitted to the ICU 1319 ng / ml compared to those admitted to the hospital 468 ng/ml and 85 ng / ml in those discharged; the CRP levels were 14.12 mgs / l vs 8.65 vs 0.84 mgs / L, respectively; PCT levels 0.245 vs 0.07 vs. 0.03 ng/ml respectively; DD 1590 vs. 806.5 vs. 632 ng / ml; LDH 437 vs 280.5 vs 195 U / L; IL6 146 vs 14; Lactate 1.52 vs. 0.87. mOsm / l respectively. The lymphocyte count showed a significant decrease in the severity group 765 vs 1070 vs 1540 cel / μ l respectively.

Regarding the relationship with gender, men predominate with 66.6% of those admitted to the ICU, with a lower percentage of those admitted to the hospital (42.97%). Moreover, ferritin levels in men admitted to the hospital were significantly higher than in women at admission (625.5 vs 354 ng / ml; $p = 0.0033$) and in the highest during evolution (777 vs 393 ng / ml; $p = 0.0007$).

The ROC-AUC to predict ICU admission and the need for MV were: Ferritin 0.821; PCT 0.767; DD 0.728; LDH 0.720; Lymphocyte count 0.663. To predict mortality, the ROC-AUC were: Ferritin at admission 0.703; higher value of Ferritin 0.776; PCT 0.786; LDH 0.753; DD 0.680; PCR 0.613; Lymphocyte count 0.649. In the multivariate analysis, Ferritin and LDH levels at admission were predictors of mortality in patients with severe Covid-19 pneumonia admitted to the ICU.

Conclusion: Ferritin levels are the best marker of severity and mortality in patients infected with Covid -19 virus, with a component linked to male sex.

Intensive Care Medicine Experimental 2020, **8(2)**: 001081

Introduction: Although iron (Fe) is essential for biological processes, excessive iron levels can cause tissue damage and increased infection susceptibility. Also the immune response to pathogens could modify the iron concentration.

Objectives: To relate parameters of Fe metabolism with respiratory failure, oxygen requirements, and the need for invasive mechanical ventilation in patients with Covid-19.

Methods: Multicenter,prospective, observational study, carried out in 7 Spanish hospitals. Epidemiological and analytical data including

demographics, therapy, inflammatory and immunity parameters were collected, including iron metabolism, and compared from two groups: patients admitted to the ICU and another group admitted to the hospital with less severity. The levels are expressed in median (IRQ).

Results: 180 patients with clinical symptoms attended in the Emergency Department, including respiratory failure, and a positive PCR for Covid-19 were recruited: 59 were admitted to the ICU during their evolution and 121 patients were admitted to the hospital. The global mortality rate was 17%. Mortality rate for patients admitted to the ICU (59) was 42.3% and 55% for patients that required mechanical ventilation (47). Ferritin levels were significantly elevated ($p < 0.05$) in patients admitted to the ICU 1319 ng / ml compared to those admitted to the plant 468 ng / ml. Iron levels were 24 μg / dl (16-44.75) in ICU patients μg / dl vs. 56 (28.5-82.5) μg / dl in the control group. The ROC curve for predicting ICU admission showed an AUC of 0.820 for Ferritin and 0.711 for Fe levels. The ROC curve for mechanical ventilation showed an AUC of 0.777 for Ferritin and 0.775 for Fe levels.

In the multiple linear regression, only Fe levels were directly and significantly associated with the worst PaO₂ / FiO₂ ratio (PAFI) with a coefficient = 0.6688 ($p < 0.0001$).

Conclusion: a) Ferritin and Iron levels are related to the severity of respiratory failure and the need for mechanical ventilation in Covid-19 patients

b) Iron levels are associated with oxygenation disorders in these patients.

001084

Immunophenotypes predict need of invasive mechanical ventilation and death among Covid-19 adults: A prospective, multicenter, study

Intensive Care Medicine Experimental 2020, **8(2)**: 001084

Introduction: Multiorgan dysfunction and death in sepsis is modulated by a balance between exaggerated hyperinflammation state and persistent immune dysfunction leading to anergy.

Objectives: To compare the state of immune dysfunction present in a cohort of adults with COVID-19 compared with a control group of influenza and predict immunophenotypes identifying need for invasive mechanical ventilation (MV) and death.

Methods: Multicenter, prospective, observational cohort study, carried out in the emergency department from 7 Spanish hospitals. A cohort of adults with confirmed PCR diagnosis of COVID-19 was compared with a historical control group with confirmed H1N1pdm2009 influenza virus admitted to the ICU. Epidemiological and analytical data including demographics, therapy, inflammatory and immunity parameters were collected. Patients were stratified depending on a) no need of oxygen therapy b) Oxygen requirements and c) Invasive mechanical ventilation. Findings were adjusted by age (65 and 80 yr). Mortality and progression to invasive MV were the main end-points.

Results: 203 COVID19 symptomatic adults were assessed in the emergency department by positive PCR for Covid-19. The global mortality rate was 17%. Mortality rate for patients admitted to the ICU (59)

was 42.3% and 55% for patients that required mechanical ventilation (47), whereas in the 75 ICU admission adults with influenza A H1N1pdm2009 was 29.33%.

In comparison to immunity parameters the results were the following: the number of lymphocytes per μl were significantly lower in patients admitted to the ICU 730 (530-1150) vs. 1070 (790- 1450) at the hospital and 1470 (1030-1965) in discharged patients. This difference is at expense of the TCD4+ (584.17 vs. 921.42); BCD19+ (66.12 vs. 264.5) and NKCD56+ (69.46 vs.138.18) the number of monocytes was similar but HLA-DR expression in monocytes was significantly lower in those admitted to ICU 1323 (854.25-1739.5) vs. 4618.5 (4537- 4700) MFI.

Ferritin levels were significantly elevated in patients admitted to the ICU 1319 ng/ml compared to those admitted to the hospital 468 ng/ml and 85 ng/ml in those discharged. CRP levels 14.16 mg/dl (5.23-24.37) in ICU admitted vs. 8.58 mg/dl (3.07-15.9) in hospital admitted ($p=0.01$) vs. 0.86 mg (0.26-4) ($p < 0.0001$) in those discharged. PCT levels 0.25 $\mu\text{g/l}$ (0.1-0.62) in ICU admitted vs. 0.07 $\mu\text{g/l}$ (0.04-0.08) in hospital admitted vs 0.03 $\mu\text{g/l}$ (0.02-0.05) ($p < 0.0001$) in those discharged. IL6 levels 146 pg/ml (32.9-1201) in ICU admitted vs. 14.56 pg/ml (7.24-29.53) ($p < 0.0014$) in hospital admitted.

In survivors, the numbers of cells TCD4+ were significantly higher (921 vs. 263) as NKCD56+ (138.18 vs. 59.91), IgM (112 vs 60) and HLA-DR expression in monocytes (1600 vs. 847 IMF); IL6 levels were higher in the non-survivors: 641.55 pg/ml (114.3-1156) vs. 81.9 pg/ml (26-1624) as well as Ferritin 1172 vs 500 ng / ml.

Similar findings were reported in the control group of H1N1pdm influenza admitted to the ICU, which differed in a significantly ($p = 0.0017$) lower BCD19+ (9.750 vs 15.65) rates and IgM levels (72 vs. 160 mgs/dl) but significantly higher Ferritin median plasma levels were 1345 ng/ml (819.25-2124.25) vs. 558.1 ng/ml (180 - 1880).

The ROC-AUC analysis to predict ICU admission and the need for MV were: Ferritin 0.821; NKCD56% 0.818; CD19% 0.773; for IL6 levels 0.731; IgM 0.682; lymphocyte count 0.663. The ROC-AUC analysis to predict mortality, were: Ferritin at admission 0.703; highest value of Ferritin 0.776; IL6 levels: 0.921; HLA-DR: 0.857; IgM: 0.755; lymphocyte count: 0.649.

Stratification by age groups showed higher mortality in the 65-79 age group: 21.9% compared to those under 65, 10.3%. Likewise, they required a greater need for MV 36.1% vs. 20.8% and treatment with corticosteroids. There were no differences in immunity cells levels, but significantly higher levels of inflammatory parameters: Ferritin, CPR, PCT and IL6.

Conclusion: A) Covid-19 patients showed a patent alteration in immunity that worsen with disease severity, similar to what happened in Influenza A N1H1 pneumonia, with a marked dysfunction of lymphocytes TCD4+ lymphocytes BCD19+, NKCD56+ and monocytes manifested by the low HLA-DR expression.

B) Covid-19 ICU admitted patients showed an important proinflammatory state expressed by high levels of IL6 and Ferritin, higher than those showed by severe A H1N1pdm2009 Influenza patients.

C) Both components influence the severity and poor evolution of the patients.

D) After age stratification, there is a greater hyperinflammation, need for respiratory support and mortality in the 65-79 age group.

Intensive Care Medicine Experimental 2020, **8(2)**: 001118

Introduction: Coronavirus disease 2019 (COVID-19) may be associated with systemic hyperinflammation, with consequent increase in pro-inflammatory cytokines (e.g. interleukin (IL)-1, IL-6, tumor necrosis factors) which leads to multiple organ dysfunction and increased mortality. Anakinra, an interleukin-1 receptor antagonist, is a potential therapy in patients with severe COVID-19 and may provide clinical benefits.

Objectives: We aimed to investigate the effects of anakinra on inflammatory markers and clinical outcomes in critically ill patients with COVID-19.

Methods: This was a retrospective observational study at a university-affiliated tertiary hospital during March 18th and May 9th, 2020. We included adult patients (≥ 18 years) with confirmed COVID-19 admitted in intensive care units (ICU) and received at least one dose of anakinra. We compared them to a group of patients matched for age (± 2 years), date of ICU admission (± 2 days), type of ventilatory support. The primary outcome was the change in c-reactive protein (CRP) 72 hours post-treatment. The secondary outcomes were changes in white blood cells (WBC), D-dimer, ferritin over 72 hours, and ICU mortality. (NCT04408326)

Results: 21 patients (male 90.5%) received anakinra. Time from ICU admission to the first dose of anakinra was 8 days (interquartile range [IQR] 4-16). The duration of anakinra administration was 11 days (IQR 8-12), and the median total received dose was 2600 mg (2100-3400 mg). Compared with the control group, patients who were treated with anakinra had significantly higher pre-treatment CRP (32.7 (IQR 21.1,37.3) vs. 16.9 (IQR 7.7,30.1) mg/dL; $p=0.03$) and D-dimer (9975 (IQR 6390,72830) vs. 1580 (IQR 1000,7080) ng/mL; $p = 0.001$). Over 72 hours, there were significant differences in post-pre CRP (-13.3 (95% confidence interval [CI] -17.5,-9.2) vs. 0.2 (95%CI -3.8,4.3) mg/dL; $p=0.006$), WBC (1266 (95%CI -1171,3703) vs. 2717 (95%CI 280,5154) cells/mm³; $p=0.002$), and D-dimer (-10729 (95%CI -19089,-2369) vs. -2758 (95%CI -10441,4924) ng/mL; $p=0.004$), but similar changes in ferritin (-864 (95%CI -2903,1175) vs. -2005 (95% CI -3948,-62); $p=0.25$). ICU mortality was not different between the groups.

Table 1 Baseline characteristics between patients who received anakinra and control (n=42)

Parameters	Anakinra group (n=21)	Control (n=21)	P-value
Age (years)	49.2 \pm 11.4	49.6 \pm 11.1	0.90
Male sex (%)	19 (90.5)	18 (85.7)	1.00
SOFA score	6.5 \pm 2.9	6.8 \pm 3.2	0.73
Mechanical ventilation (%)	20 (95.2)	20 (95.2)	1.00
Vasopressor (%)	10 (47.6)	8 (38.1)	0.53
Venovenous ECMO (%)	10 (47.6)	6 (28.6)	0.20

Conclusion: Administration of anakinra in critically ill patients with COVID-19 was associated with significant decrease in inflammatory markers. Further clinical trials are required to confirm the effects of anakinra on clinical outcomes.

Intensive Care Medicine Experimental 2020, **8(2)**: 001182

Introduction: Inter-hospital transfers (IHTs) to tertiary care centers are commonly due to limited availability of time-critical interventions and resources. Transfer patients are complex often requiring organ support with treatment delays resulting in worse outcomes. In one study, IHT patients with severe sepsis or septic shock had significant delays in appropriate antibiotic and resuscitation therapy compared to non-transferred patients, with no difference in ICU LOS or mortality. In a surgical population, increased complications were observed in IHTs for acute appendicitis versus patients that presenting directly. Weekend neurosurgical IHTs had worse functional outcomes with daytime IHTs experiencing longer length of stay (LOS). The “weekend effect” has been associated with higher mortality in the emergency department.

Objectives: The objective of this study was to evaluate whether the timing of IHTs affects outcomes in critically ill patients with sepsis.

Methods: A retrospective cohort study of IHT patients ≥ 18 years old, admitted to the critical care service with a primary sepsis diagnosis during 1/1/2016-12/31/2018. Data sources were merged from the transfer center, administrative databases, and the electronic health record chart review. Timing was defined as weekday (Monday 7:00 to Friday 17:59) vs. weekend (Friday 18:00 - Monday 06:59), and daytime (7:00 - 17:59) vs. nighttime (18:00 - 06:59). Evaluation included patient characteristics, sepsis diagnosis, therapies (days on mechanical ventilation (MV), dialysis, and vasopressors, and surgical procedures), and outcomes. Descriptive analysis included 95% confidence intervals to describe the data using means (SD) or median (IQR).

Results: A total of 521 patients were included of which 199 were daytime admissions, 322 nighttime, 319 weekday and 202 weekend. Comparing weekday vs. weekend, the groups were similar for age (60 vs. 61, $p=0.61$), sex, race, BMI and APACHE II score (25.4 (8.71) vs. 26.92 (7.92), $p=0.08$). More patients received MV on the weekend (67.3% vs 58% weekday, $p=0.33$), with weekend patients on MV longer (6 (3-12) days vs 5 (3-9), $p=0.05$). Vasopressors were administered in 62% with weekend admissions receiving more days on vasopressors (3 (2-6) vs. weekday 2 (1-4), $p=0.03$). Shorter LOS was observed in weekday admissions (3 (1-8) vs 5 (2-10.25) weekend, $p=0.03$). No difference in hospital LOS, mortality, or discharge disposition. Comparing daytime vs. nighttime, no significant differences were observed for patient characteristics, treatments, or outcomes. Most IHTs had sepsis with an unspecified organism. Mortality was $\geq 27\%$, and discharge to hospice was $\geq 30\%$ in all groups.

Conclusion: In this cohort, IHTs were severely ill requiring life-sustaining therapies with increased resource use for weekend transfers. Contrary to previous studies, the timing of transfer did not have a significant effect on patient survival. Clinician awareness of IHT on the weekend with attention on weaning vasopressors and mechanical ventilation as appropriate, may contribute to decreased resource utilization and improved patient outcomes.

Evolution of rheology and red blood cell complement regulatory proteins in septic patients

J. Vanderelst¹; A. Rousseau²; BK. Zouaoui²; P. Biston¹; M. Piagnerelli¹

¹Intensive Care, Civil Hospital Marie Curie, Charleroi, Belgium; ²Experimental Medicine Laboratory, Hospital André Vésale, Montigny-le-Tilleul, Belgium

Intensive Care Medicine Experimental 2020, **8(2)**: 000310

Introduction: During sepsis, red blood cells (RBCs) rheology are altered (more spherical shape, decreased deformability and increased aggregation). Persistence of these alterations were associated with poor outcome [1,2]. Moreover, RBCs are physiologically protected by membrane surface proteins (CD35, CD55 and CD59) against the complement system activation [3]. In malaria, Waitumbi et al. reported links between the modification of the expression of these RBCs membrane proteins and the erythrophagocytosis, a cause of anaemia in this disease. [4]

Objectives: We studied the time course of RBCs deformability and the surface IgG and regulatory proteins content in RBCs from septic patients (S) compared to healthy volunteers (V).

Methods: By flow cytometry techniques, we measure at ICU admission, at day 3-5 and day 7-10, the RBC membrane expression of IgG and complement proteins (CD35, 55, 59 and CD95) from S patients compared to RBCs from V. We assessed the RBC shape by the second moment of dissymmetry of Pearson as already reported [1]. RBCs deformability was estimated by an ektacytometry technique (laser-assisted optical rotational cell analyzer) for shear stress from 0.3 to 50 Pa.

Results: RBCs from 11 S patients and 21 V were included. At ICU admission, RBCs from S patients were more spherical than V (moment S : -0.193 (-0.561; -0.033) vs V : -0.538 (-0.657; -0.491); $p=0.026$) and deformability was significantly altered for all shear stress ≥ 3.07 Pa. However, these alterations of shape and deformability persists at Day 3.

We observed only a significant decrease at ICU admission in CD35 expression in S patients compared to V (9.2 (5.02-13.18) vs 23.04 (11.39-32.57); $p = 0.011$). No significant changes were observed over time.

Conclusion: Our study suggests that a decrease in CD35 expression at the surface of the RBCs as well, as we have already observed (an increase in RBC sphericity and decrease membrane sialic acid content) [1], could be at the root of the accelerated aging of RBCs. This could contribute to the anaemia observed in septic patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000473

Introduction: Sepsis describes the condition of life-threatening organ dysfunction due to a dysregulated host response to infection. Early diagnosis and treatment can significantly reduce mortality. Microcirculatory dysfunction is an important pathophysiological feature of sepsis and may correlate with disease severity [1,2]. Infrared thermal imaging is a novel approach for monitoring the microcirculation via cutaneous temperature gradients [3]. Machine Learning shows great promise as a tool for medical image analysis, approaching the accuracy of clinicians in a growing range of tasks [4]. The combination of infrared thermal imaging and machine learning classification may be a promising approach for the automating the diagnosis of sepsis severity.

Objectives: This study is aimed at the preliminary development of a machine learning technique for identification of sepsis severity utilising infrared thermal images as a means of interrogating the microcirculation.

Methods: Participants were recruited in to two groups based on the 2009 sepsis definitions; early sepsis patients without organ dysfunction (n=33), and severe sepsis patients with evidence of organ dysfunction (n=34). Standardised infrared images were acquired of the anterior knee for each participant. A sliding window approach was used to extract image patches from the images. The patches were grouped by category and clustered with K-Means clustering. The Elbow method was applied to find the optimal number of clusters for each category. The patches were then projected onto the cluster centroids. With a large number of patches for each image, the image-wise features were reconstructed as mean values of patch-wise features. A number of classifiers were trained for the binary classification task in the space of the extracted features. The model performance was evaluated by 5-fold cross-validation, where the samples were the samples were separated 5 folds, and for each fold (testing set) four other folds were used as training set. We accumulate the validation predictions from each fold and compare them to their actual grouping for evaluation.

Results: The highest performing classifier found is a support vector machine with gridsearch optimized hyper-parameters. This classifier produced an accuracy of 83.58%, or error of 16.42%, for the binary classification of early and severe sepsis in the cross-validation protocol.

Conclusion: The preliminary results show that the presented technique, in this h dimensional yet low-sample setting, may be a feasible approach to the binary discrimination of severity for infrared thermal imaging monitoring of microcirculation in sepsis patients. Further research is required to test and develop this preliminary technique, while more data is required to assure that the model does not overfit.

Intensive Care Medicine Experimental 2020, **8(2)**: 000511

Introduction: Acute inflammatory processes like sepsis are often accompanied by a dysfunctional endothelial barrier causing hyperpermeability and organ failure. While impaired expression of cell adhesion molecules is a typical feature of barrier disruption, it is known that microRNAs (miRs) play an essential role in regulating these adhesion molecules [1]. Recently, miR-125a was found to be upregulated in the blood of patients with sepsis [2]. Therefore, we wanted to investigate whether there is a miR-125a-specific functional network controlling endothelial barrier in acute inflammatory conditions.

Methods: MiR-125a was transfected into primary human umbilical vein endothelial cells (HUVECs). After stimulation with TNF transcriptome was analyzed using Next Generation Sequencing (NGS) followed by bioinformatics pathway analysis. NGS-results were validated via immunoblot and RT-PCR. To verify a direct miR-125a-3'-UTR interaction, we analyzed luciferase reporter assays. We tested endothelial barrier function with permeability assays and with electric cell substrate impedance sensing (ECIS) in HUVECs transfected with miR-125a, specific target siRNAs and blocking antisense miRNA (Antimir). For statistical evaluation we used student's t-test.

Results: In response to various inflammatory stimuli (cytokines, hypoxia, septic serum) HUVECs significantly upregulated miR-125a (Fig. 1A). NGS identified the pathways, *GO_regulation of cell adhesion* and *KEGG_adherens junctions*, as significantly regulated by miR-125a. We focused on five potential targets with an in-silico predicted miR-125a binding site: The adhesion molecules VE-Cadherin (CDH5) and Claudin-5 (CLDN5) as well as the protein phosphatases PTPN1, PPP1CA and the transcription factor ETS-1. Validation of the NGS confirmed a significant downregulation of RNA and protein expression (Fig. 1B-D). Via reporter construct analysis, we newly identified CDH5 and PTPN1 as direct targets of miR-125a. Whereas expression of CLDN5 was dependent on CDH5 expression [3] and PPP1CA and ETS-1 are published targets of miR-125a [4, 5]. MiR-125a transfected HUVECs show a significantly increased permeability in permeability assays and decreased barrier function in ECIS. Specific knock-down of each of the five targets in the miR-125a functional network created a comparable phenotype. In contrast, hyperpermeable phenotype in the acute inflammation could be partially rescued by specific inhibition of miR-125a (Fig. 1E, F).

Conclusion: MiR-125a induced by inflammatory stimulation directly targets the five target molecules CDH5, CLDN5, PTPN1, PPP1CA and ETS-1 leading to increased permeability of the endothelial monolayer. In acute inflammatory diseases like sepsis this newly identified miR-125a-specific functional network could be a novel mechanism involved in the pathologic loss of intravascular fluids and thus blockade of miR-125a may be of therapeutic interest.

Intensive Care Medicine Experimental 2020, **8(2)**: 000618

Introduction: Acute lung injury (ALI) is the leading cause of mortality in critically ill patients. Exacerbated inflammatory response is a key mechanism of sepsis-induced ALI, so that attenuating inflammation is crucial. Previously, we showed that methotrexate (MTX) carried in lipid core nanoparticles (LDE) had powerful anti-inflammatory and anti-proliferative effects on rheumatoid arthritis² and atherosclerotic lesions³ and improved left cardiac dysfunction in myocardial infarction⁴. When MTX is associated to LDE, the cellular uptake of the drug is increased several-fold, which conceivably endows MTX with increased therapeutic action and diminished toxicity.

Objectives: To investigate whether treatment with LDE-MTX can attenuate the development of inflammatory process in septic rats with ALI.

Methods: Sepsis was induced in Wistar rats by two I.P lipopolysaccharide (LPS, 10mg/kg) injections administered at 24h interval. Rats were allocated to Control group (CT, without sepsis) and 2 groups with sepsis: LDE, treated with LDE only; and LDE-MTX, with LDE-MTX at a dose of 1mg/kg I.P. 72h after sepsis induction, the animals were euthanized for protein expression analysis by Western blot of inflammatory

apoptotic, antioxidant enzymes, angiogenesis, cell hypoxia, fibrosis and adenosine bioavailability markers in lungs.

Results: Compared to CT, the antioxidant enzymes, (catalase and superoxide dismutase-1) and fibrosis (collagen types 1 and 3) were lower in LDE and LDE-MTX groups. Although the expression of leucocytes and interleukins levels were similar in all 3 groups, septic rats treated with LDE had higher expression of macrophage recruitment marker (CD68) and tumor necrosis factor alpha, while LDE-MTX was able to decrease these levels, both compared to CT. Apoptotic markers, such as caspase 3 and b-cell associated X protein/b-cell lymphoma-2 ratio, were higher in LDE group. LDE-MTX treatment was able to lower these pro-apoptotic factors to CT levels. Regarding angiogenesis and cell hypoxia, protein expression of CD31 and angiostatin, pro and anti-angiogenesis markers, respectively, and hypoxia-inducible factor 2-alpha were normalized to CT levels by the treatment with LDE-MTX, when compared to LDE group. The increase in the bioavailability of intracellular adenosine of septic animals treated with LDE-MTX was suggested by the higher expression of A1 and A2b receptors in the lungs.

Conclusion: Possibly by increasing the bioavailability of intracellular adenosine, LDE-MTX treatment was effective in reducing the inflammatory process, decreasing cell death by apoptosis and normalizing angiogenesis and cell hypoxia factors in septic rats with ALI. The marked improvement of inflammatory response in ALI by LDE-MTX may pave the way for a novel strategy to treat this condition.

Intensive Care Medicine Experimental 2020, **8(2)**: 000670

Introduction: Regulatory T cells (Tregs) are a subset of CD4+ T cells which have an immunosuppressive function and essential for maintaining peripheral tolerance. In critically ill patients, the risk of adverse outcomes (including nosocomial infections), increase with increasing proportion of total Tregs. We hypothesised that this increase in risk is secondary to increases in proportions of effector Tregs and effector Tregs will be higher in sepsis compared to non-sepsis critical illness. Our aims were to compare the proportion of total Tregs and Treg subsets in critically ill patients with sepsis and without sepsis (non-sepsis) over the first 3-days following critical care admission.

Methods: INFECT was an observational study of critically ill adults admitted to ICU (n=148), involving measurement of percentage Tregs to predict the risk of nosocomial infection. Data from 140 critically ill adult patients were included in this post-hoc analysis. Patients were categorised into those admitted with sepsis (57/140) and those who developed nosocomial infection during their ICU stay (n=53). We measured total Treg proportions by CD25+ CD127- expression on CD4+ T cells. Treg subsets studied included naïve (CD4+, CD25+, CD127-, CD45RA+, CD15s-), effector (CD4+, CD25+, CD127-, CD45RA-, CD15s+), CD161+ cytokine-secreting Tregs (CD45RA-, CD15s-, CD161+) and CD161- non-regulatory cells (CD45RA+, CD15s+, CD161-).

Results: We found no significant difference in proportions of total Tregs (Fig. 1A), naïve Tregs (Fig.1B), CD161+ Tregs (Fig. 1D) and CD161-cells (Fig. 1E) in septic and non-septic patients at admission (T1) (p > 0.05). However, we found significantly less effector Tregs in septic patients versus non-septic patients at T1 (Fig. 1C, p < 0.05, Mann-Whitney). We further categorised septic/non-septic patients according to the development of nosocomial infection. We found no significant changes in proportions of total Tregs and Treg subsets in infected and non-infected patients at T1 and T3 (p > 0.05, Two-way ANOVA).

Conclusion: We found lower proportions of effector Tregs in patients admitted to ICU with sepsis compared to other admissions. Our data does not suggest that total Treg and Treg subsets proportions can be used to predict nosocomial infection in critically ill adults admitted to ICU.

Intensive Care Medicine Experimental 2020, **8(2)**: 000994

Introduction: Sepsis is a dysregulated host response to infection, related to devastating outcomes. Recently, interest has been shifted towards apoptotic and antiapoptotic pathobiology (1). Apoptosis is executed through the activation of caspases (2) and regulated through the activation of a number of anti-apoptotic proteins, such as survivin, with different biological functions (pro-apoptotic or antiapoptotic), depending on the expression of its different splice variants (wild type-WT, -ΔEx3, -2B, -3B) (3). The apoptotic and antiapoptotic responses have not yet been elucidated in sepsis.

Objectives: The present study seeks to ascertain whether sepsis is associated with an upregulation of certain apoptotic (caspases) or anti-apoptotic biomolecules (survivin), and also seeks to assess the prognostic value of survivin transcript variant expression (survivin-WT, $-\Delta\text{Ex}3$, -2B and -3B), in ICU patients with sepsis and non-infectious (trauma-related) SIRS.

Methods: This prospective observational study was performed in a sample of critically ill adult patients with sepsis ($n=107$) or traumatic SIRS ($n=75$), compared to healthy controls ($n=89$). The expression of survivin transcript variants was analyzed by real-time quantitative PCR in peripheral blood leukocytes, whereas the apoptotic or antiapoptotic equilibrium was specified by measuring caspases-3 and -9, along with survivin-WT serum protein concentrations, through enzyme-linked immunosorbent assay (ELISA).

Results: The survivin-WT, -2B , $-\Delta\text{Ex}3$ mRNA, survivin protein and caspases-3 and -9 showed an escalated increase in sepsis (Figure 1), compared to traumatic SIRS and controls, whereas survivin-3B was repressed in sepsis ($p < 0.05$). For discriminating sepsis, caspase-9 achieved the best receiver operating characteristic curve (AUROC) of 0.95. In predicting mortality, caspase-9 and survivin protein achieved an AUROC=0.70.

Conclusion: The upregulated apoptotic and anti-apoptotic pathways might represent attractive targets for future research in the clarification of sepsis. The mRNA expression of survivin variants and protein activity quantification of survivin and caspases could predict outcome and provide additional information about clinical management of patients suffering from sepsis.

Introduction: Sepsis is characterized by dynamic changes of the immune system resulting in deregulated inflammation. In a certain group of patients, the robust hyperactivation of inflammation occurs very early. This so-called “cytokine storm” leads frequently to patient's

death and could be considered as a potential target group for future early immunotherapy. Circulating monocytes are among the first ones to recognize and clear pathogens and thus have an important role in early stages of infection and sepsis (1). Three distinct subpopulations of monocytes have been described: classical (CD14⁺ CD16⁻), intermediate (CD14⁺ CD16⁺) and non-classical (CD14^{lo} CD16⁺) (2-3).

Objectives: The aim of the study was to evaluate monocyte populations in the early stages of septic shock in relation to patient mortality. Specifically, we focus on the group of patients with very early mortality (up to 72 hr. after ICU admission). We aim to determine whether specific changes in monocyte populations could be used as biomarker in prediction of early mortality and whether it correlates with severity of septic shock.

Methods: Patients admitted to the ICU with early septic shock were prospectively enrolled into the study. Whole blood samples and clinical data were collected at within 12 hr. after admission. Peripheral blood monocyte cells were isolated and labelled with specific antibodies. Presence of particular populations were determined by flow cytometry. With the use of Spearman correlation and Mann-Whitney test, the obtained data were related to 3-days mortality and the relationships with patient's age, sex, number of comorbidities, SOFA, CRP and the need of catecholamines were estimated. The predictive potential was assessed using receiver-operating curve. Data are provided as median (IQR).

Results: Recruited septic shock patients ($n=41$) were predominantly male (57.1 %) with median age 73.0 (66.5-77.0) years. All patients were mechanically ventilated and the SOFA score at admission were 11 (10-14). There was no statistically significant difference in the patients' comorbidities, chronic medication or age between patients who died in first 72 hours (early deaths) and the others. 3-day and 28-day mortality rate were 14 % and 51%, respectively. Group of early deaths had a lower percentage of classical monocytes (57.6 (42.5-62.0) % vs. 81.6 (65.5-90.1) %; $p=0.0098$) and conversely had a higher proportion of intermediate (29.1 (26.2-36.1) % vs. 8.9 (4.2-19.6) %; $p=0.0005$) and non-classical (5.4 (4.5-6.5) % vs. 3.1 (1.9-6.4) %; $p=0.1485$) monocytes than other patients. AUC of receiver-operating curve for prediction of 3-day mortality was 0.8357 for classical, 0.9095 for intermediate and 0.6905 for non-classical monocytes. The ratio classical/intermediate shows even higher predictive potential (AUC = 0.9238). Furthermore, there were no statistically significant correlation between monocyte subsets and other characteristics (SOFA, lactate, CRP, catecholamines, etc.).

Conclusion: The determination of monocyte subsets frequency (especially intermediate monocytes) or its ratio can be used to predict a fulminant course of septic shock and to identify patients with excessive inflammatory response who might profit from personalized immunomodulatory therapy.

Intensive Care Medicine Experimental 2020, **8(2)**: 000582

Introduction: Procalcitonin (PCT) has emerged as a tool to guide antibiotic (ABx) therapy in bacterial pneumonia, but PCT's role in distinguishing between bacterial & viral pneumonia is uncertain(1). With the novel SARS-CoV-2 pandemic there's emerging interest in the role of this biomarker for assessing COVID-19 disease severity & progress(2). In COVID-19 pts, bacterial or fungal coinfection incidence is 8%, whilst 72% of the pts have been reported to receive antimicrobial therapy(3). In the UK a recent guideline from NICE suggests early review of need for antibiotic treatment in COVID-19 on basis other than PCT(4). We have reviewed our institutional data in order to assess current practice & usefulness of using PCT as a tool for assessing disease severity, progress & for guiding ABx therapy.

Objectives: 1) Compare PCT between COVID-19 pts admitted to ICU and not

2) Describe how concurrent bacterial infection in ICU pts influenced PCT

3) Describe how PCT was associated with duration of ABx therapy.

Methods: Contemporaneous eMR records were reviewed retrospectively for 70 COVID-19 pts admitted to ICU vs 70 who were not. Evidence of concurrent bacterial infection was sought; defined as bacteraemia, positive sputum/tracheal aspirate culture or molecular testing. Duration of ABx therapy was also collected.

Student's t-test was used to compare mean PCT values, whilst diagnostic performance of PCT >0.5 µg/mL in bacterial co-infection was assessed. Duration of ABx was assessed in pts with PCT > <0.5 µg/mL threshold.

Results: Data was available from completed 70 ICU & 70 ward admissions 35/70 ward pts had PCT measured. Similarly, 17/70 ICU pts had PCT measured prior to ICU. PCT levels were not clinically & statistically significantly different (mean; ward 0.69mg/mL, ICU 0.57mg/mL, p=0.87).

Of the 70 ICU pts, PCT was tested in 6/9 pts with evidence of bacterial co-infection & in 39/61 pts without bacterial infection. PPV of PCT >0.5 to indicate bacterial co-infection was found to be 21%, but on the contrary the NPV of PCT <0.5 to exclude was found to be 95%. There was no difference in median no. of ABx-days amongst pts with PCT >0.5 & <0.5 (9.5 vs 10 days) but amongst pts with PCT > of 2mg/ml there was a trend towards longer therapy (9 vs 11 days).

Conclusion: It's not clear from this data that PCT on presentation discriminates between pts with severe & non-severe COVID-19. Although the usual threshold PCT <0.5mg/mL was able to effectively rule out bacterial co-infection, its PPV was modest. This reflects limited impact that PCT had on duration & intensity of ABx therapy. In pts with severe respiratory failure clinicians may be reluctant to stop ABx, given the non-trivial rate of bacterial co-infection. The combination of PCT & a rapid, sensitive molecular test may improve antimicrobial stewardship.

Intensive Care Medicine Experimental 2020, 8(2): 000767

Introduction: Sepsis is a host response to infection, which when exaggerated can lead to multiple organ dysfunction and death. Early treatment of sepsis decreases mortality and early diagnosis of sepsis, especially in critically ill patients, is essential.

Objectives: This study aimed to analyze abnormal body temperature patterns in intensive care patients using the PreEmpsis™ proprietary algorithm developed by Medisim Ltd. and visual inspection to see if they could predict the subsequent diagnosis of sepsis.

Methods: This retrospective study was from January 2016 to December 2016. A total of 50 patients (35 male and 15 female) out of 1365 patients admitted to the ICU were included in the study when they developed a temperature above 38.3°C at least 72 hours after admission to the ICU. 24 of them were subsequently diagnosed as septic and 26 were non-septic patients. Patients were individuals aged 18 years and above (average age 58.34 years). Sepsis was diagnosed according to the Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3, 2016) if these findings occurred 72 hours after admission to the ICU.

The temperature was measured non-invasively from the axillary, femoral, or rectal sites with a standard continuous temperature probe connected to our monitoring system. The investigators retrospectively screened all the temperature recordings retrieved from the electronic patient record of the patients admitted to the ICU during the study period. Patients with a temperature recorded at least once of more than 38.3°C were then screened for the additional criteria to determine the diagnosis of sepsis or not. The control group comprised those patients who developed temperatures above 38.3°C after 72 hours of admission to ICU but were not subsequently diagnosed as septic. Temperature curves for the 72 hours before the clinical suspicion of sepsis (for septic patients) and for the 72 hours before developing a temperature above 38.3°C (for non-septic patients) were quantitatively analyzed using visual inspection and the PreEmpsis™ proprietary, predictive temperature trend analysis algorithm.

Results: The mortality rate was 26% (13 out of 50). As expected, the mortality rate for septic patients was higher – 50% (12 out of 24) compared to the control group – 3.8% (1 out of 26). We did not find any difference between the temperatures of the two groups by visual inspection alone, but the PreEmpsis™ proprietary algorithm detected a difference by monitoring the maximum temperature changes within 24 hours. The maximum temperature change within 24 hours for septic patients was 1.8±0.54, and for non-septic patients was 2.0±0.39. In addition the algorithm also detected differences in the patterns of temperature recording between the two groups – frequency and amplitude changes, as well as change from baseline. The accuracy of the temperature changes detected by the algorithm as compared to clinical diagnosis of sepsis was 0.71, with a sensitivity of 0.78 and a specificity of 0.65.

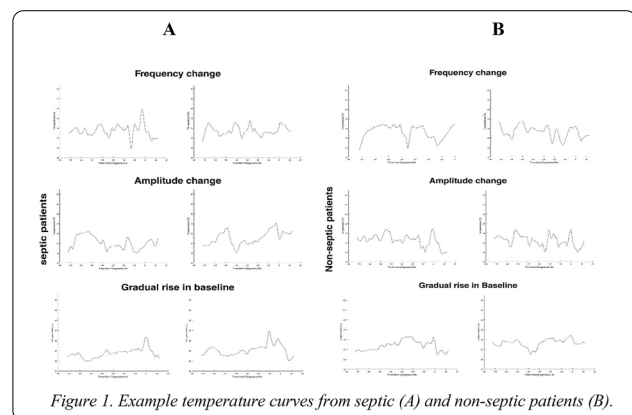

Figure 1. Example temperature curves from septic (A) and non-septic patients (B).

Conclusion: The visual inspection method of temperature changes alone is not accurate, nor specific enough to differentiate between septic and non-septic patients with high temperatures. However, PreEmpsis™ computerised predictive trends analysis was superior to visual inspection. Nevertheless, we should not use the temperature changes alone as a sole diagnostic method for predicting the onset of sepsis until validated by larger studies.

Intensive Care Medicine Experimental 2020, **8(2)**: 000970

Introduction: Vitamin C's role in the management of sepsis was first popularised in 2017 with the work of Marik et al. Vitamin C is considered a safe therapy in other contexts such as management of malnutrition, itself shown to adversely affect outcome. As such, we audited our current use of Vitamin C in sepsis.

Objectives: To investigate prescribing practice of Pabrinex (Vitamin B and C) in sepsis admissions to a district general hospital intensive care unit, and investigate its impact on mortality or requirement for organ support.

Methods: A retrospective analysis of prescribing practice was conducted studying all admissions to critical care who met the physiological parameters for Sepsis 3 during a 1 year time period. Outcomes including mortality and requirement for invasive organ support were monitored. The total dose of vitamin C prescribed during admission was calculated.

Results: A total of 253 patients met sepsis criteria between April 2018-April 2019. Pabrinex was prescribed in 91 cases (36% of admissions). There was no uniformity in prescribing of Vitamin C. Regimes ranged from 1 pair a day to 3 pairs, three times a day. There was no correlation between severity of illness and dose of Pabrinex prescribed, nor association between higher doses of Vitamin C and outcomes measured. Total dose received during admission ranged from 0mg to 32g. The mean age of those receiving Pabrinex was 61, with ICNARC mortality predicted at 30.8%. Actual mortality was 23% (SMR 0.77). 23% required vasopressors, 58% required invasive ventilation and 28% required renal replacement therapy. The non-Pabrinex group (64% of total admissions) had a mean age of 55, with ICNARC mortality 23%. Actual mortality was 12% (SMR 0.5). 59% required vasopressors, 34% required invasive ventilation and 8% required renal replacement therapy.

Conclusion: The survival rates in both groups were better than predicted using ICNARC Mortality calculators, indicating our centre performs above expectations in the management of sepsis admissions.

Due to the heterogeneity of the study groups we were unable to accurately ascertain the impact of vitamin C in modifying patient outcomes. Vitamin C was often prescribed to older, more unwell patients, possibly reflecting the severity of their illness. Concurrent use of Pabrinex in the management of malnutrition also acts as confounding factor. Due to the disparities in prescribing practice we have initiated a standard prescription bundle for all admissions with sepsis.

Intensive Care Medicine Experimental 2020, **8(2)**: 001059

Introduction: Patients in acute circulatory failure are characterized by inequality between tissue oxygen demand and supply. The difference of carbon dioxide tension between central venous and arterial blood (ΔPCO2) reflects the veno-arterial CO2 concentration difference and is inversely related to cardiac output, tissue oxygen delivery and perfusion [1]. High ΔPCO2 in sepsis and septic shock is associated with poor outcome [2]. However, there has not been any study yet to evaluate ΔPCO2 during the course of a septic episode.

Objectives: To follow and evaluate the difference of PCO2 between central venous and arterial blood sample (ΔPCO2), during the progress of a septic episode

Methods: Seventy nine (79) patients were included and were separated into two groups. Group A included 52 patients who had sepsis remission while group B included 27 patients who had sepsis deterioration. ΔPCO2 was calculated in septic patients on admission and at either deterioration or remission of the septic episode.

Results: ΔPCO2 was higher in the sepsis deterioration group on admission (6.47±3.03 vs. 7.71±3.07 mmHg, for group A and group B respectively, p=0.08), although the difference did not reach a statistically significant level. In group A ΔPCO2 increased at sepsis remission (6.47±3.03 vs. 7.41±3.24 mmHg, p=0.05). In contrast, in group B ΔPCO2 decreased at sepsis deterioration (7.71±3.07 vs. 6.30±3.23 mmHg, p=0.04). Group B patients were also characterized by increased use of vasopressors (0.532±0.315 vs. 0.258±0.166 µg/kg/min, p < 0.001), increased lactate concentration (5.2±3.8 vs. 2.4±1.3 mmol/l, p=0.001) and higher SOFA score (13.4±3.0 vs. 10.4±3.0, p < 0.001) at deterioration compared to admission, as expected.

Conclusion: The higher ΔPCO2 on admission, in the group of patients who deteriorated compared to those who improved, might indicate tissue hypoperfusion occurring early in sepsis. However, at sepsis remission/deterioration, the results of our study probably reflect the different basal metabolic rate at the different stages of sepsis. Thus, at deterioration basal metabolic rate/mitochondrial metabolism decreases, leading to decreased CO2 production and low ΔPCO2. On the contrary, during sepsis remission, mitochondrial metabolism recovers and, consequently, ΔPCO2 increases[3].

Correspondence: A.O. Badallo

Intensive Care Medicine Experimental 2020, **8(2)**: 001091

Introduction: It is known that automatic alert systems are helpful in early detection of sepsis, considering how important early diagnosis as a prognostic factor. So far, automated monitoring electronic programs have been used with this objective, but not based on Sepsis-3.

Objectives: The main aim of this study is to compare the 3 different algorithms that could define sepsis including the classic sepsis definitions (Defs.) and Sepsis-3.

As secondary goals, it is described the automatic alert system itself, representing its sensibility (S), specificity (E), negative predictive value (NPV) and positive predictive value (PPV).

Besides, some of the clinical information that is provided by the program, such as focus and source of infection and mortality rate are analyzed.

Methods: SEPSIS SAVER is a new electronic software counselled by expert clinicians of 3 different Intensive Care Units of University Hospitals in Spain.

After improvements in the software (integration of basal SOFA scale estimation for each patient before testing any of the algorithm) and a friendly & useful designed tool in pursuit of clinicians, during 2 months (February and March 2020) has been implemented as a pilot testing in our 1063-bed University Hospital of Burgos (UHB). The prospective evaluation was compared to the the Standard Sepsis Codification System (SSCS) of our UHB.

Any patient admitted in the hospital, through Emergency Room or during whole stay in ward, is monitored and after evaluating the clinical and lab tests results, the tool observes if patient matches any of the algorithms:

1. Systemic Inflammatory Response Syndrome [SIRS] ³ 2 + 1 Organ Failure [OF].
2. Sequential Organ Failure scale [SOFA] ³ 2.
3. quickSOFA [qSOFA] ³ 2. The validated clinical score in Sepsis-3 Definition.

There can be matches to any of them or to more than one. Instantly, the tool will inform to the clinician (by email, cell phone or checking the tool) = patient at increased risk of sepsis.

Results: During February-March 2020, SEPSIS SAVER 2.0 monitored 13.584 (100%) patients. Among them, 844 (6.21%) were warned at risk of sepsis and 191 (prevalence [P] 1.40%) were finally confirmed as sepsis by members of Sepsis Team. It means a rate of 703 sepsis episodes/100.000 inhabitants per month. Instead, the Standard Sepsis Codification System (SSCS) of our UHB, confirmed only 81 sepsis cases (P 0.60%) and a rate of 22,8 ep./100.000 inh./month the preliminary

software used in 531-bed Doctor Peset University Hospital (SEPSIS SAVER 1.01).

Only 9.42% of patients of the confirmed cases were admitted to ICU due to Septic Shock. Global mortality attributable to sepsis was 11%.

SOFA was the algorithm that more sepsis cases detected with 67,53% of cases. SIRS+ 1 OF 31,46% and qSOFA only 16 cases (assumption 8,40%) but these episodes were also detected at the same time by the other 2 algorithms.

	SEPSIS SAVER 2.0	SEPSIS SAVER 1.0	STANDARD CODIFICATION SYSTEM NON-AUTOMATED
Sensibility (S)	98%	79,30%	42%
Especificity (E)	95,55%	50,60%	NOT ENOUGH DATA
Positive Predictive Value (PPV)	24,23%	3,30%	NOT ENOUGH DATA
Negative Predictive Value (NPV)	99,97%	99,10%	NOT ENOUGH DATA

Conclusion: SOFA is the most sensitive tool, although S improves implementing SIRS+OF at the same time, therefore, Sepsis-2 Defs. Instead, Sepsis-3 Defs where qSOFA is used, is not valuable as sepsis detector, launching debate about validity of the "New Sepsis Defs 2016".

The SSCS of our UHB vs the use of automatic alarm tool and the enhancements of Sepsis Saver 2.0, verifies the importance & usefulness of automatic alarm guided electronic tools. The upgrade of E,S, NPV and PPV, encourage us to continue in the design of the "future perfect automatic tool" in sepsis detection.

Intensive Care Medicine Experimental 2020, **8(2)**: 000154

Introduction: Underfeeding and malnutrition are known to be associated with impaired short and long-time recovery after major surgery in patients admitted to ICU [1-3]. Although head and neck cancer (HNC) free flap surgery may have a substantial impact on normal eating, chewing and swallowing, there is a lack of studies contemplating the adequacy of nutrition during the immediate postoperative period after HNC surgery [4-5].

Objectives: The aim of the present study was to evaluate the adequacy of nutrition after free flap surgery for HNC during the immediate in-hospital recovery and to discover factors associated with inadequate nutrition delivery.

Methods: This single-center retrospective cohort study included 218 HNC patients who underwent free flap surgery in Oulu University Hospital, Finland between the years 2008 and 2018. Nutrition delivery methods, the adequacy of nutrition and complication rates were evaluated during the first 10 postoperative days.

Results: A total of 131 (60.1%) patients reached nutritional adequacy of 60% of calculated individual demand during the follow-up period. According to multivariate analysis, nutrition inadequacy was associated with higher ideal body weight (OR 1.11 [1.04-1.20]) whereas adequate nutrition was associated with higher number of days with oral food intake (OR 0.79 [0.67-0.93]). In the univariate model tracheostomy, bilateral neck dissection and postoperative surgical complications were associated to poor postoperative nutrition adequacy.

Conclusion: Inadequate nutrition is common after HNC free flap surgery. The present results suggest that more adequate nutrition delivery might be obtained by the early initiation of oral food intake and close monitoring of nutrition support.

Intensive Care Medicine Experimental 2020, **8(2)**: 000192

Introduction: Aggressive muscle wasting occurs early in critical illness. It is associated with greater duration of mechanical ventilation, and intensive care unit (ICU) and/or hospital stays, and frequent long-lasting functional impairment. No known interventions prevent this wasting.

Ketone bodies, produced by the liver from fatty acids in response to starvation, can act as metabolic fuels for muscle or other peripheral tissues, and as signalling molecules.

Increasing ketone body production by altering nutrition composition - providing it is feasible, safe and tolerated by ICU patients - may mitigate early muscle loss in critical illness by acting as a more efficient energy source, improving related outcomes.

Objectives: To perform a randomised controlled feasibility study to determine whether:

i) ICU patients during early critical illness can be recruited to and retained in a study of ketogenic enteral feed administration, and whether

ii) this feed significantly raises plasma and urine ketone body levels while being safe and well-tolerated.

Methods: A two centre feasibility study conducted over 30 months. Patients will be recruited (with consultee agreement) within 48 hours of ICU admission and randomised to either ketogenic or standard enteral feed over a 10-day period. Data will be collected during the study period, and 3, 6 and 12 months post ICU-discharge.

Inclusion criteria: (i) >18 years old (ii) prescribed enteral nutrition (iii) mechanically ventilated ≥ 48 hours (iv) likely to remain on ICU ≥ 5 days and (v) likely to survive ≥ 10 days (vi) multi-organ failure (SOFA score > 2).

Exclusion criteria: (i) existing primary neuromyopathy/significant neurological impairment (ii) uni- or bilateral lower limb amputation (iii) requiring sole/supplemental parenteral nutrition (iv) need for specialist nutrition (v) patients with known inborn errors of metabolism.

Intervention: Modular ketogenic enteral feed will be reconstituted on the ICU for each patient for 10 days, as prescribed by dietitians to meet nutritional energy targets: medium chain triglycerides (Betaquik[®], Vitaflo) increasing from 40% to 80% during the study period, plus long chain triglycerides (Fresubin 5kcal[®], Fresenius Kabi) to keep total fat at 80% of energy input; 15% protein (Renapro[®], Stanningley Pharma), provided minimum protein requirements are met; and 5% carbohydrate (Maxijul[®], Nutricia). The contribution of energy from other sources. e.g. propofol and dextrose (including additional dextrose used as drug diluents) will be taken into account.

Sample size: 24 ICU patients receiving randomised feed for 10 days or up to ICU discharge: allowing for a 34% dropout rate, up to 37 eligible patients will be required. Site-specific data and past trial experience suggest that recruitment will take 15 months.

We will assess feasibility of patient follow-up at 3, 6 and 12 months post-ICU discharge, and the views of ICU nurses on study safety, practicality and acceptability. Levels of ketone bodies and other metabolites will be determined, as well as cost-effectiveness comparisons between the two feed regimens.

Results: Nine patients have been recruited so far with no feed-related adverse effects reported.

Conclusion: If using ketogenic feed in ICU patients is shown to be safe and feasible, it may mitigate muscle loss in early critical illness, providing a new way to improve function and well-being in ICU survivors. ClinicalTrials.gov NCT04101071.

Intensive Care Medicine Experimental 2020, **8(2)**: 000251

Introduction: Hypophosphatemia (HypoP) is frequent in intensive care unit (ICU) settings and may affect up to 35% of admissions. Severe hypophosphatemia is associated with organ dysfunction and mortality. Its true prevalence and its proportional relationship to refeeding syndrome remain largely unknown.

Objectives: The aim was to learn the point-prevalence of HypoP defined as blood phosphate (P) <0.8 mmol/l on one particular day (D-Day) at international level while gathering information about the internal ICU policies/guidelines for the management of HypoP among international ICUs.

Methods: This point-prevalence survey was conducted with Ethical approval by the Section of Metabolism, Endocrinology and Nutrition of ESICM and endorsed by ESICM; each site had one D-Day during the week 11/2020: the primary endpoint was the prevalence of blood P < 0.8 mmol/l. Data were collected on ICU (number of beds, frequency of P analysis, treatment strategies) and patients (collected for hypoP patients only): age, days in ICU, nutritional therapy, renal replacement

therapy (CRRT)). Data are presented as number (percentage) for categorical and median [IQR];3 for continuous variables.

Results: 59 ICUs from 23 countries participated and 4 ICUs were paediatric: 40/59 ICUs were mixed medico-surgical, (see Table); 20 sites did measure P daily, 7 ICUs stated “never”. Out of 881 patients present on D-Day, 675 (76.6%) patients had P determined, and 99 (15%) presented hypoP, with 48 (48.5%) patients with severe hypoP < 0.65mmol/l; 50% of the hypoP were documented within the first 5 days in the ICU. Age was 62 [52;71] years. HypoP was most frequent in medical patients. HypoP was not associated with feeding (enteral in 52%, parenteral in 19%), but with being on CRRT (p = 0.045)

ICU information	Total	Small ICU	Middle ICU	Large ICU
		(<12 beds)	(13–40 beds)	(>40 beds)
ICU profile	59	20	37	2
Mixed	40	10	28	2
Medical	8	6	2	0
Cardio-Surgical	11	4	7	0
Total patients in the ICU on D-Day	881	156	647	78
Total patients with P analysis	675 (77%)	102 (65%)	500 (77%)	73 (94%)
Patients with P <0.8 mmol/l	99 (15%)	12 (12%)	75 (15%)	12 (16%)
P<0.65 mmol/l	48	31	40	1
Phosphate measure frequency:				
At least once daily	21 (35.5%)	5	15	1
3 x per week	21 (35.5%)	7	13	1
never	7 (12%)	4	3	0

Conclusion: The point-prevalence survey shows that HypoP is present at least in 15% of ICU patients, and in half of them is observed during the first 5 ICU days. Half of the patients had a severe hypoP. This number is an underestimation since systematic measurements occur only in ¾ of patients, while 12% of ICUs never monitor this electrolyte. Moreover the study was done in ICUs with metabolic interest.

Intensive Care Medicine Experimental 2020, **8(2)**: 000261

Introduction: Early provision of a high-protein nutrition improves the prognosis of patients in intensive care units (ICUs). However, high protein intake increases blood urea nitrogen (BUN). No study has compared outcomes according to protein intake, and the clinical significance of changes in BUN (Δ BUN) in ICU patients is unclear. Here, we investigated the association of high protein intake with outcomes and BUN and assessed the clinical significance of Δ BUN.

Objectives: This study aimed to investigate the effect of high-protein provision on the outcomes and BUN, and to investigate the clinical significance of Δ BUN.

Methods: This was a single-center retrospective cohort study. Between 1 January 2016 and 30 September 2019, 295 ICU patients received enteral nutrition for at least 3 days while undergoing mechanical ventilation. After applying the exclusion criteria of an age of <18 years, gastrointestinal disease, maintenance dialysis, renal replacement therapy after admission, kidney transplantation, and death within 7 days of commencing enteral nutrition, 206 patients remained.

Participants were divided into those receiving >1.2 g/kg/day of protein (high-protein group; n = 111) and those receiving \leq 1.2 g/kg/day of protein (non-high-protein group; n = 95). The groups were

balanced by propensity score matching. The primary endpoint was 28-day mortality, and the secondary endpoints were 90-day mortality, length of ICU stay, number of ventilator-free days in the first 28 days, and Δ BUN.

Results: The high-protein group had significantly lower 28- and 90-day mortality and significantly greater Δ BUN, including after propensity score matching. Δ BUN might not be associated with outcomes.

Conclusion: Provision of >1.2 g/kg/day of protein may be associated with lower mortality of tube-fed and mechanically ventilated patients. Furthermore, while high protein intake may be associated with higher BUN, these changes may not be adversely associated with outcomes.

Hypermetabolism: Does it affects prognosis in critical patients? Indirect Calorimetry as an instrument of research

G. Sousa¹; I. Mendes²; L. Tavares²; R. Carvalho²; M. Henriques¹; H. Costa¹
¹Intensive Care, Hospital do Divino Espírito Santo, Ponta Delgada, Portugal; ²Endocrinology and nutrition, Hospital do Divino Espírito Santo, Ponta Delgada, Portugal

Correspondence: G. Sousa

Intensive Care Medicine Experimental 2020, **8(2)**: 000313

Introduction: Energy expenditure (EE) evaluation in Intensive Care Unit (ICU) patients is very challenging. Critical illness is characterized by great variability in the EE, which is influenced by the disease itself and the effects of treatment. Indirect calorimetry (IC) is currently the gold standard to measure EE in ICU patients. However, calorimeters are not widely available and predictive formulas (PF) are still commonly used, which may lead to under or overfeeding and its deleterious consequences.^{1,2} Important metabolic changes occur and catabolism becomes prominent in critically ill patients.^{3,4} However, both hyper and hypometabolism are observed.⁵ Hypermetabolism is a condition mediated by the immune system, which can be affected by damaged tissue, pathogenic microorganisms, and the entry of their toxins into the bloodstream, as well as the body's response, with hormones and cytokines release. Due to this situation, hypermetabolic patients often have higher mortality rates compared to metabolically normal patients.^{6,7}

Objectives: To assess the incidence of hypermetabolism and to compare clinical outcomes between hypermetabolic and normometabolic patients in ICU with EE measured by IC.

Methods: Single-centre, retrospective, observational study including mechanically ventilated patients admitted in ICU between August 2018 and February 2020. EE was measured by IC. Basal Energy Expenditure (BEE) was estimated by the Harris-Benedict equation (HB). According to their metabolic state ($EE/BEE \times 100$), patients were divided in hypermetabolic ($\geq 130\%$) and normometabolic ($<130\%$). To determine the limits of agreement between EE and BEE, we performed a Bland-Altman (BA) analysis. Baseline characteristics, severity criteria, and main diagnosis were compared. The primary outcome considered was 30-day mortality. Other outcomes were evaluated, such as the length of stay (LOS) in ICU, LOS in hospital, and length of invasive ventilation.

Results: Of the 55 ICU patients included, median age was 62,0 [52,0-72,0] years. BA showed a mean -411 ± 554 Kcal/d for EE and BEE. Seventeen patients (30,9%) were in hypermetabolic group with a significantly higher proportion of male patients (88,2 vs 11,8%; $p=0,04$), a lower BMI (26,1 [23,0-27,7] vs 27,7 [24,7-33,8] Kg/m²; $p=0,04$), a higher proportion of patients admitted due to medical conditions (76,5 vs 47,4%, $p = 0,04$), and due pneumonia (41,2 vs 15,8%; $p = 0,04$). We did not find any statistically significant difference between the two groups, neither in 30-day mortality nor in the other outcomes compared.

Conclusion: There was no statistically significant difference between the two groups in all the clinical outcomes considered. However, we concluded that hypermetabolic patients were predominantly males, had a lower BMI, and had a higher proportion of admissions due to medical conditions and pneumonia.

Intensive Care Medicine Experimental 2020, **8(2)**: 000352

Introduction: Diarrhoea is a common concern in the intensive care unit (ICU) and incidence varies from 2-95% in previous studies. This variation is due to lack of a consistent definition of diarrhoea and scientific inattention to this clinical problem. The prevalence,

predisposing factors, and prognosis of diarrhoea during critical illness have not been well defined in prospective studies.

Objectives: To determine the incidence (using different diagnostic criteria), risk factors, management modifications, and clinical outcomes associated with diarrhoea in critically ill adults.

Methods: Design, Setting and Participants: We prospectively enrolled consecutive adults admitted to 12 Intensive Care Units (ICU), in 4 countries, during a 10-week period. We excluded patients admitted to the ICU for <24 hours.

Main Outcome: The primary outcome was diarrhoea incidence, using the World Health Organization (WHO) definition, and the Bristol Stool Chart (Bristol) and Bliss Stool Classification System (Bliss), and risk factors. Secondary outcomes included *Clostridioides difficile*-associated diarrhoea (CDAD), ICU and hospital length of stay and mortality.

Analysis: We used logistic regression to evaluate 12 potential risk factors for diarrhoea, and Cox regression to estimate the association between diarrhoea and morbidity and mortality. All models were adjusted for age, sex and APACHE II scores.

Results: Among 1109 patients age 61.4 [17.49] mean [standard deviation] years, APACHE-II 18.8 [7.98], 981(88.5%) medical patients, 645 (58.2%) mechanically ventilated, diarrhoea was common (WHO 73.8%, 95% confidence interval [CI] 71.1-76.6; Bristol 53.5%, 95%CI 46.7-50.4; and Bliss 37.7%, 95%CI 34.9-40.4). Independent risk factors for diarrhoea (WHO Definition) included enteral nutrition (OR 2.43, 95% CI 1.70-3.48), suppository use (OR 1.73, 95% CI 1.28-2.35) and number of antibiotic days (OR 1.10, 95% CI 1.05-1.14). Female sex (OR 0.71, 95% CI 0.52-0.95) and opioid use (OR 0.32, 95% CI 0.22-0.48) were associated with a lower risk of diarrhoea. Diarrhoea resulted in modifications to patient management including: enteral nutrition held or changed, stool softener or prokinetic held, rectal appliance used, or *C. difficile* test ordered (OR 10.9; 95% CI 5.74-21.03). CDAD prevalence in the ICU was 85/1109 (7.7%). Among the 99 patients with diarrhea tested for CDAD, 23/99 were positive, for a CDAD ICU incidence of 23/ 1109 (2.1%). Diarrhoea was associated with a longer length of stay in the ICU (HR 2.62, 95% CI 2.23-3.06; $p < 0.001$) and hospital (HR 1.72; 95% CI 1.46-2.01; $p < 0.001$) and increased hospital mortality (HR 2.12; 95% CI 1.61-2.78; $p < 0.001$).

Conclusion: Diarrhoea is common during critical illness; incidence varies by diagnostic definition. Several risk factors are modifiable. Diarrhoea is associated with increased morbidity and mortality.

Intensive Care Medicine Experimental 2020, **8(2)**: 000385

Introduction: The positive influence of nutritional support is under-recognized and nutrition is considered an adjunctive more than a primary therapy itself.

Objectives: The main aim of the present study was to evaluate the influence of nutritional support in outcomes in the critical care setting.

Methods: Prospective observational multicenter study. Demographic, comorbidities, cause of admission, nutritional evaluation, type and characteristics of nutritional support (during the whole nutritional-delivery or at least the first 14 days of nutritional support), and outcomes, with special attention in 28-day mortality, were registered in a database. Confounders, such as disease severity, type of patient and the length of nutritional support among others, were considered for final statistical approach (NCT:03634943).

Results: 639 patients were included with a 25.6% of mortality. Non-survivors showed older age, higher comorbidities, higher SOFA score (6.6 ± 3.3 vs 8.4 ± 3.7 ; $P < 0.001$) and nutritional risk (3.8 ± 2.1 vs 5.2 ± 1.7 ; $P < 0.001$) on admission. Nutritional support did not differ among groups, except a trend towards lower mean protein intake in non-survivors. Non-survivors suffer from higher needs on vasopressor therapy (70.4% vs 83.5% ; $P = 0.001$) and renal replacement therapy (12.2% vs 23.2% ; $P = 0.001$). Multivariate analysis showed that older age (HR:1.023;95% CI:1.008-1.038; $P = 0.003$), higher SOFA score (HR:1.096;95% CI:1.036-1.160; $P = 0.001$), higher NUTRIC Score (HR:1.136;95% CI:1.025-1.259; $P = 0.015$), the need of parenteral nutrition (PN) after the initiation of enteral nutrition (EN) (HR:2.368;95% CI:1.168-4.798; $P = 0.017$), mean Kcal/Kg/day (HR:1.057;95% CI:1.015-1.101; $P = 0.008$), and mean g protein/Kg/day (HR:0.507;95% CI:0.263-0.977; $P = 0.042$) were factors associated with mortality.

Conclusion: Elderly, higher average of organ failure and nutritional risk are nutritional related factors that may be associated with higher mortality. Patients who need of PN after initiation of EN may represent a high mortality risk subgroup due to illness severity and problems in giving appropriate nutritional support. The mean caloric and protein delivery may play a key role in outcomes.

Intensive Care Medicine Experimental 2020, **8(2)**: 000386

Introduction: There is a gap between the theoretical benefits of pharmaconutrition and the moderate benefit in clinical practice in the Intensive Care Unit (ICU).

Objectives: The aim of the present research was to evaluate the impact of immunonutrition formulas (IMN) with standard enteral formulas in outcomes during the ICU stay.

Methods: National multicenter prospective observational study (37 hospitals) from April to June 2018, conducted in ICUs throughout Spain (NCT Registry: 03634943). Patient characteristics, calorie-protein dose, life support needs and mortality were evaluated. Statistical differences were analyzed according to the administration of IMN formulas and the type of patient.

Results: 525 patients who received enteral nutrition (EN) were included in the analysis, of which 406 (77%) received only EN. 16.57% of the patients received IMN formulas. The age was 61.33 ± 15.01 years, BMI: 27.86 ± 6.06 Kg / m², the majority were medical patients (68%), malnutrition was 38.58% (SGA) and the mean nutritional risk was 4.17 ± 2.14 (NUTRIC Score). The 28-day mortality was 26.1% and the IMN formulas were not associated with lower mortality compared to the other formulas when comparing the subgroup of survivors with non-survivors.

However, a lower need for vasopressor support (75.6% vs. 60.66%; OR: 0.490; 95% CI: 0.260-0.910; $P = 0.023$) and continuous renal replacement therapies (OR: 0.130; 95% CI: 0.010-0.650; $P = 0.049$) was observed in those patients who received IMN formulas compared with standard formulas. The use of IMN formulas was associated with a higher average protein delivery during the nutritional therapy (0.74 ± 0.34 vs 0.9 ± 0.31 g/Kg/d; OR: 6.230; 95% CI: 2.590-15.540; $P < 0.001$).

Conclusion: We showed lower need of vasopressors and continuous renal replacement therapies during ICU stay with the use of IMN formulas, which may be associated with their modulatory effect over inflammatory response. A higher protein delivery may be provided with IMN formulas in the ICU.

Thyroid levels in ICU. More than sick euthyroid?

J. Nikhilesh¹; A. Thakur²; V. Joshi³

¹Dept of critical care medicine, CHL Hospital, Indore, India; ²Dept of critical care, CHL hospital, Indore, Madhya Pradesh, India, India; ³Dept of critical care services, Shalby Hospitals, Indore, Madhya Pradesh, India, India

Correspondence: J. Nikhilesh

Intensive Care Medicine Experimental 2020, **8(2)**: 000467

Introduction: Background: In critically ill patients thyroid levels have a significant role in terms of recovery from critical illness however, their replacement has not been shown to confer mortality/outcome

benefit in subsets with lower hormone levels. This communication attempts to delineate the outcomes/mortality correlations in patients with abnormalities of thyroid levels getting admitted to an intensive care unit (ICU).

Objectives: Comparison of mortality outcomes in patients of sepsis with abnormal thyroid levels and no underlying thyroid disorders getting admitted to ICU.

Setting: 60 bedded mixed ICUs of tertiary care units.

Methods: All patients getting admitted with Sepsis from Jan 2019- till date were included and their baseline samples of TSH/T3/T4 were collected. Data was collected with a focus on demographics, SOFA scores, Length of stay (LOS) and mortality. Patients with hypoalbuminemia, preexisting thyroid disorders and receiving Amiodarone were excluded. Death/discharge from ICU were considered as end points. Statistical analysis was done using SPSS version 23. Chi square test was used to delineate association with mortality.

Results: Ninety patients were included (n=90, M: F-58:32). Age of the cohort was 50±17 years (Range-22-85). SOFA scores were 11.8±3.2 (Range-6-18). Length of stay was 6.9± 4.3 days (Range-1-20) and in hospital mortality was 37.8%(n=34). Thyroid hormone levels were TSH (4.6± 2.8[Range- 1-12.6]/Ref -0.4-4.2), T3 (1.4± 0.57[Range-0.6-2.5]/ Ref-0.4-2.4) and T4 (7±2.6[Range-2.2-11.8]/Ref-6.09-12.23) respectively. On statistical analysis in isolation both low TSH levels and Low T3 levels were significant predictors of mortality [0.0006P and 0.0001P]. Combination of these variables did not improve the association and was statistically not significant

Conclusion: Low TSH and T3 levels at baseline predict mortality in sepsis cohorts. However, whether the relationship would remain sacrosanct in patients with hypoalbuminemia and patients receiving Amiodarone remains to be seen. We will need bigger subsets with more variables to enhance our knowledge levels for the same.

Intensive Care Medicine Experimental 2020, **8(2)**: 000559

Introduction: The COVID pandemic has resulted in a high number of intensive care (ICU) admissions, generally. The COVID pandemic has resulted in a high number of intensive care (ICU) admissions, generally for respiratory distress. While research has focused on respiratory and infectious characteristics, little is known about their metabolic and nutritional characteristics compared to other categories of patients.

Objectives: The aim was to compare COVID patients' status and metabolic response to persistently critically ill patients (PCI) defined as >10 days in ICU

Methods: Prospective observational study in consecutive cohorts of long stay patients on mechanical ventilation and COVID-19 patients were analysed. Variables: demographic data, severity score (SAPS2), Nutritional risk screening (NRS) score, C-reactive protein (CRP). Prealbumin values determined on admission (adm) and D6-9 (delta pre-albumin was calculated between admission and D6-9 values), nutritional management, length of stay and outcome. Nutritional recommendations were: energy target 20 kcal/kg during first week (then adapted according to indirect calorimetry measurements for LSP, no calorimetry for COVID-19), protein 1.2 g/kg, early enteral nutrition privileged (time to feeding recorded). The confined dieticians worked remotely. Statistics: median (interquartiles), percentage.

Results: Altogether 50 LST and 54 COVID-19 mechanically ventilated patients were included. Characteristics are shown in Table. The two cohorts were similar in terms of age, gender distribution (74% men) and disease severity; however, COVID patients were significantly heavier. Median NRS was 5 in both groups, several points coming from reduced eating during last days in COVID patients, which was less frequent in PCI cohort. Mortality did not differ. Enteral nutrition was initiated earlier in COVID: on Day1 in 50% vs 20%, on Day2 87% vs 33%, and Day3 94% vs 53% (p < 0.0001) respectively. Combined EN and parenteral feeding was only required on rare occasions (<2%). Admission prealbumin was significantly lower in COVID vs PCI, unrelated to NRS score, and poorly correlated to CRP (r2=0.082). Prealbumin increase (delta 0.19 g/l) was significantly higher in COVID patients, but also in survivors of both groups, where difference over time was 0.03 (0; 0.09) g/l (p < 0.0001). Protein data are in prepartion.

	PCI (n=50)	COVID (n=54)	P value
Age (yrs)	61 (53; 73)	61 (56; 71)	0.822
Weight	77 (63; 90)	85 (75; 98)	0.0001
BMI (kg/m ²)	25.5 (21.4; 31.7)	27.7 (25.7; 33.4)	0.0036
SAPS2 score	41 (33; 59)	40 (33; 46)	0.703
Length ICU stay (d)	26.1 (21.0; 38.0)	18.7 (10.4; 27.7)	0.0002
Prealbumin Adm. g/L	0.095 (0.07; 0.14)	0.070 (0.06; 0.09)	0.014
Delta prealbumin g/L	0.025 (0.01; 0.06)	0.19 (0.09; 0.32)	<0.0001
Mortality	20.0%	15.4%	0.541

Conclusion: Mechanically ventilated COVID patients were heavier both groups presenting a similar nutritional risk. Prealbumin values on admission were significantly lower and reverted faster to normal values, which might be due to a faster clearance of inflammation and related catabolism, but maybe also to nutrition. Early enteral feeding was significantly more frequent in COVID patients, reflecting the lesser impact of a single respiratory organ failure on GI tract.

Intensive Care Medicine Experimental 2020, **8(2)**: 000599

Introduction: The rapid decline of muscle mass and function in mechanically ventilated critically ill patients is associated with poor outcome, and prolonged impairment in physical function. The loss of lean body mass (LBM) is rapid and massive being close to 20% in one week. Nutrition only partly attenuates muscle loss. HMB, a metabolite of leucine, has been shown to substantially reduce loss of muscle mass in older adult healthy and sick subjects but has not been tested in ICU patients.

Objectives: The study aimed at testing the impact of HMB on LBM using ultrasound assessment and on amino acid metabolism.

Methods: RCT in 37 critically ill patients (ITT), on mechanical ventilation, with full treatment and a functional gastro-intestinal tract. Intervention: Enteral HMB 2*1.5 g/day versus placebo from day 4 to day 30 after admission. Primary outcome: muscle mass loss (ultrasound of thigh on days 4 and 15 to determine % change of skeletal muscle index (SMI). On days 4 and 15, amino acid metabolism was investigated with

the pulse administration of a mixture of stable amino acid tracers. Plasma enrichments were measured by LC-MS/MS, and areas under the curve (AUC) were calculated to determine whole body production and interconversions of several amino acids. Patients were separated in two groups at day 4 based on net protein breakdown (netPB: conversion of phenylalanine to tyrosine): low (lower than lower limit of the 95% CI) and high. Stats by 2 factor ANOVA (Graphpad Prism 8.4).

Results: Critically ill patients with age 65 ± 15 years and SAPSII 47 ± 12 were studied. Seven patients were studied only at day 4. SMI decreased significantly ($p < 0.001$) in both groups, without difference between HMB group or placebo. However, patients with a lowPB who received HMB had a smaller SMI loss compared to placebo (mean difference -3.98 (95% CI -6.29 to -1.68 ; $p=0.0155$) and mean interaction difference -5.87 (95% CI -10.48 to -1.26 ; $p=0.0148$)).

Conclusion: In a heterogeneous group of severe ICU patients, HMB did not significantly reduced muscle loss. Although, post hoc analysis showed that HMB can reduce muscle loss in patients with the lowest netPB.

Correspondence: A. Trifi

Intensive Care Medicine Experimental 2020, **8(2)**: 000757

Introduction: Patients in intensive care units (ICUs) are at high risk of unfavorable outcomes. Considering the role of vitamin D (Vit D) in cardiovascular and immune functions, Vit D deficiency could affect ICU patients' outcomes.

Objectives: To evaluate Vit D status and its predictive value for outcome in ICU patients.

Methods: prospective cohort study that included all adult patients admitted to the medical ICU of la Rabta Hospital from January 2016 to December 2018. Non inclusion criteria were: Sepsis, cancer, renal or liver failure, surgery within 3 months; immunotherapy or vitamin supplements within 6 months; pregnant or lactating, discharge or death within 48 hr of admission were the exclusion criteria. Plasma 25-hydroxyvitamin D (25(OH)D) was assessed by immunoassay. The primary outcome was the occurrence of the following major adverse events (combined MAE): the need for a central venous catheter (CVC), organ failure, and septic shock. Secondary outcomes were the occurrence of at least one ICU-acquired infection (combined ICU-AI), septic shock, organ failure, other individual adverse events, and ICU mortality. Multivariate Cox regression analyses were performed to test the associations of low 25(OH) D levels with poor outcomes.

Results: A total of 169 ICU patients were followed during ICU stay. Around 75% of patients had 25(OH) D levels < 12 ng/ml. During their ICU stay, 114 patients presented MAE, 85 patients presented an ICU-acquired infection, and 22 patients died. The comparative distribution of plasma 25-hydroxyvitamin D (25(OH)D) in ICU patients according to selected outcomes are displayed in the attached figure.

Plasma 25(OH) D levels < 12 ng/ml were associated with higher risk of major adverse events, Hazard ratio [95% CI], 4.47 [1.77, 11.3], $p=0.020$, and ICU-acquired infection, 2.67 [1.01, 7.42], $p=0.049$, but not with increased risk of ICU mortality.

Conclusion: Hypovitaminosis D is common in ICU patients. Results of the present study show that low plasma 25(OH)D levels are associated with increased risk of unfavorable outcomes. Additional research is needed to investigate the impact of Vit D status and effect of Vit D supplementation in ICU patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000760

Introduction: Vitamin D is an essential nutrient and hormone that plays role in calcium homeostasis and bone health. In the last two decades, vitamin D is known to promote innate and adaptive immunity. It may play a role in modulating the outcome of sepsis.

Objectives: This study was conducted to describe the prevalence of vitamin D deficiency in pediatric patients with severe sepsis or septic shock and to evaluate the correlation between vitamin D level and severity of illness.

Methods: This is cross-sectional study. Populations were children aged 30 days to 18 years who were diagnosed with severe sepsis or septic shock from August 2018 to May 2019. We collected demographic data, principal diagnosis, 25-Hydroxyvitamin D (25-OHD) level, 1,25-Dihydroxyvitamin D (1,25-OHD) level, severity, and clinical outcomes of the disease.

Results: Nineteen patients were included. The median age was 21 months, most of them have normal nutritional status (17/19). Source of infection were pneumonia (6), urinary tract infection (2), catheter related blood stream infection (1), and others (10). The prevalence of 25-OHD deficiency (< 30 ng/ml) and 1,25-OHD deficiency (< 19.9 pg/ml) in severe sepsis and septic shock patients were 57.9% and 10.5% respectively. All patients were survived. Vitamin D deficiency (25-OHD and 1,25-OHD) was not correlated with length of stay in pediatric intensive care unit (25-OHD: $r = 0.076$, $p = 0.756$; 1,25-OHD: $r = 0.170$, $p = 0.486$), and vasoactive inotropic score (25-OHD: $r = 0.20$, $p = 0.408$; 1,25-OHD: $r = 0.077$, $p = 0.755$). Subgroup analysis of patients who did not received antibiotics before enrollment, 25-OHD

deficiency had higher risk of positive blood culture compare to the group with normal 25-OHD level (odds ratio = 2.75, 95%CI 1.26, 6.01, $p = 0.017$) and 1,25-OHD level had statistically significant inverse correlation with PRISM III score ($r = -0.527$, $p = 0.036$) (figure 1).

Conclusion: Our findings suggested that there may be a correlation between vitamin D deficiency and severity of illness in pediatric patients with severe sepsis and septic shock. Further study with larger sample size should be performed.

"Profile of a postoperative bariatric patient admitted to our Intensive Care Unit and its post-ICU metabolic control."

R. Mancha Salcedo¹; F.L. PEREZ CABALLERO¹; MS. Pereira Gama¹; S. Godoy Boraita¹; I. Peña Luna¹; M. Diaz-Tavora Luque¹; MF. BenitezMorillo¹

¹Unidad de cuidados intensivos, Hospital de Mérida, Mérida, Spain

Correspondence: F.L. PEREZ CABALLERO

Intensive Care Medicine Experimental 2020, **8(2)**: 000777

Introduction: Obesity is defined by the World Health Organization as an excessive accumulation of fat in the body of people that can be harmful to their health, measured through a body mass index (BMI) ≥ 30 kg/m², cataloged as a chronic and identified disease in children, adolescents and adults, being recognized as the epidemic of the 21st century.

There are approximately 500 million obese adults and 42 million obese children under the age of five worldwide, hence the importance of their prevention, diagnosis and early treatment, to avoid subsequent comorbidities.

Obese patients present a high vital risk, since severe obesity is associated with cardiovascular, respiratory, metabolic, osteoarticular, digestive pathologies and even with the increase in some types of malignancies.

Surgery and bariatric procedures continue to be the most effective sustained weight loss option for patients with morbid obesity, highlighting among its main objectives to maximize weight loss and maintain nutritional health while preventing micronutrient deficiencies and loss of lean body mass.

Although it is an innovative and effective procedure, it is not exempt from post-surgical complications. It is essential to previously exhaust the resources of prevention and medical treatment, although most of these patients are not capable of maintaining a weight loss with psychological, dietary or pharmacological treatment.

Objectives: Main: To determine the profile of bariatric surgery patients admitted to our Intensive Care Unit (ICU) between May-2018 and November-2019 and its post-ICU metabolic control.

Secondary: To analyze the frequency of comorbidities, preoperative and postoperative characteristics, analytical results, ICU evolution, score on risk scales (APACHE, SOFA and SAPS II). To assess the degree of linear correlation between the BMI and the age of the patients, with the scores obtained on the risk assessment scales.

Methods: Observational, descriptive, prospective and correlational study in bariatric postoperative patients admitted to our ICU in 18 months, using a database of 40 patients, with medical and surgical history, anthropometric data, analytical results, type of surgery, postoperative treatments, and scores on the risk scales, in addition to a correlational analysis to determine the degree of linear relationship between BMI and age, with the risk scales, as well as the comparison of means of its post-ICU metabolic control.

Results: Among the 40 patients, the mean age was 42 years, women (77.5%), with an average BMI of obesity type 3 (46.55 kgm-2). The most frequent type of surgery was gastric sleeve (70%). Highlighting sleep apnea-hypopnea syndrome (SAHS) with CPAP (62.5%), trauma pathologies (37.5%), genitourinary and digestive (both 35%), hypertension (30%) and anxiety/depression (27, 5%). Complications (surgical) were found only in 2.5% of patients, with a mortality ratio of 0%.

Performing the comparison of means through T-Student for related samples, we obtain a statistically significant decrease during the first six months after discharge from the ICU in LDL ($p = 0.018$), HbA1c ($p < 0.001$) and baseline blood glucose ($p < 0.001$).

Upon their arrival in the ICU, prophylactic antibiotherapy was performed in 100% of them and anticoagulation in 75%; being 10% of the airway difficult. 95.1% were admitted intubated, with an extubation time of 5 hours, and a 1-day stay. Analgesia was performed with Remifentanil (75%), with a low incidence of complications (0.025 95% CI). 55% required Sugammadex, and 40% weaning was performed with a T-tube only, and associated with CPAP in 32.5%.

The high probability of average death is impressive: APACHE II of 19.95, SOFA 7.58 and SAPS II 55.25. We determined the level of correlation between BMI and age with the risk scales, obtaining a moderate correlation $r = 0.414$ ($p = 0.008$) between APACHE II and age; moderate $r = 0.508$ ($p = 0.001$) between SOFA and SAPS II; and low, $r = 0.353$ ($p = 0.028$) between SOFA and BMI.

Conclusion: The strongest associated variables were SAHS (with CPAP), traumatic, genitourinary and digestive pathologies, in women, obese type III, with high scores on risk scales, with a favorable evolution, with a minimum incidence of complications, and an adequate post-ICU metabolic control (LDL, HbA1c and baseline blood glucose), hence the importance that the postoperative period of these patients should be performed in the ICU.

Intensive Care Medicine Experimental 2020, **8(2)**: 000903

Introduction: Large burns are the cause of extensive skeletal muscle devastation which contributes to the risk of metabolic failure [1]. Illusory movements are a relatively new method of physiotherapy, which through functional proprioceptive stimulation (FPS) enables the integration and networking of muscle units and has a neurotrophic effect on the cerebral cortex [2]. However, illusory movements haven't been studied in the critically ill yet. How they influence human's metabolism is not known.

Objectives: Six male patients with large deep burns (> 30 % total body surface area) in the late acute phase of burn disease, median age 53 years, median day since admission 96 days, median APACHE II score 19. They suffered from prolonged catabolism and poor healing. Their basal metabolic rate (BMR) was about 32 % (means) below their calculated BMR.

Methods: We rehabilitated the patients with illusory movements for 30 minutes twice a day, for 14 days, along with standard rehabilitation. After two weeks, FPS was stopped, and patients received standard rehabilitation only. Nitrogen balance was calculated daily. On the day 1, 15, and 30, we measured BMR with indirect calorimetry, insulin resistance and glucose disposal, muscle strength, and diameter of m. rectus femoris measured with ultrasound.

Results: In all six patients, BMR increased significantly compared to baseline ($p < 0.01$), with a (non-significant) trend to improve nitrogen balance and muscle strength. 14 days after the end of FPS, BMR decreased to the level of calculated BMR, but remained significantly increased from baseline ($p < 0.05$) (Tab. 1). No adverse side effects were observed in any patient. All of them survived and were discharged from the hospital.

Table 1. Basal Metabolic Rate in study subjects

All values are group means \pm SE, * $p < 0.05$, ** $p < 0.01$

Conclusion: Illusory movements improved decreased BMR in six patients with metabolic failure. It is not known whether the observed increase in energy expenditure is a quintessential feature of FPS, or if it was specific to patients with hypometabolism.

Role of Capillary Blood Ketone Assay in Diagnosis and Management of DKA in PICU in resource limited settings

M. Shahzad¹; A. Haque²; M. Sadiq²

¹Pediatric ICU, The Indus Hospital, Karachi, Pakistan; ²Picu, The Indus Hospital, Karachi, Pakistan

Correspondence: M. Shahzad

Intensive Care Medicine Experimental 2020, **8(2)**: 000964

Introduction: Diabetic ketoacidosis (DKA) is the most common life-threatening metabolic-endocrine emergency in children. The current criterion for the diagnosis of DKA is characterized by a triad of hyperglycemia (blood glucose ≥ 200 mg/d, metabolic acidosis (venous pH < 7.3 , or serum $\text{HCO}_3^- < 15$ mEq/l) and ketonemia (blood β -hydroxybutyrate ≥ 3 mmol/L) or moderate to large ketonuria(1). In DKA, β -hydroxybutyrate (BOHB) is the major ketone body and its concentration increased to 4-10 times.(2) Urine ketone assay has several potential limitations such as delayed voiding delay the diagnosis and unnecessarily prolonged insulin infusion because of continued excretion of ketoacid in the urine.(3) The current literature strongly support the use of capillary blood BHOB in the establishing diagnosis as well as response to treatment of DKA both in children and adults. (4) (5) There is a paucity of data available its use in the management of DKA in PICU. The objective of this study to assess the clinical and statistical correlation of capillary blood β -OHB level with the traditional standard acid variables like pH, HCO_3^- , AG, and BD in the diagnosis and resolution of ketoacidosis in the management of DKA in PICU in resource limited settings.

Objectives: To affirm the Role of Capillary Blood Ketone Assay in Diagnosis and Management of DKA in PICU in resource limited settings.

Methods: We retrospectively reviewed electronic medical record of children (aged 2 mo-16yrs) with DKA from January 2018 to January 2020 admitted in PICU of The Indus Hospital. All children received the treatment according to standard protocol. Capillary blood BOHB were measured on admission and q 4-6 hourly along with blood glucose. All parameters were recorded on a structured sheet.

Results: Among 1080 admissions, 26 patients (2.4%) were diagnosed as DKA. The mean age was 9.8 ± 3.8 years and females were 54%. Half patients were newly diagnosed with 1DDM. Mild, moderate, and severe cases of DKA were 19%, 50%, and 31% respectively. The median time to resolution of acidosis was 17 (10-39) hours. At the time of resolution of acidosis, the correlation between capillary BOHB and blood pH ($r=0.11$, $p=0.56$), HCO_3^- ($r=0.37$, $p=0.86$), AG ($r=0.37$, $p=0.06$), and BD ($r=0.04$, $p=0.82$) was noted. Hyperchloremia was present in 61.5%. Five patients (19.2%) developed AKI that recovered. There was a strong clinical correlation of BHOB with standard acid variables of DKA management.

Conclusion: Bedside capillary blood BOHB is a simple, inexpensive, point-of-care test that helps in the diagnosis and treatment of DKA especially in resource-limited settings for avoiding unnecessary delays.

Intensive Care Medicine Experimental 2020, **8(2)**: 000995

Introduction: Changes in homeostasis activate the hypothalamic-pituitary axis and induce an adaptive hypercatabolic state (1), which is harmful if persistent (2). Copeptin, an equimolar indicator of serum antidiuretic hormone (ADH), has been associated with a higher mortality of critically ill patients (3). However, alterations in copeptin levels over time during an acute stress are not known.

Objectives: The aim of the present study is to investigate the correlation of copeptin levels with glycemic parameters in critically ill patients.

Methods: From June 2019 to October 2019, critically ill adult patients were prospectively enrolled and followed for 90 days. Plasma copeptin levels were quantified during the first 24 hours of intensive care unit (ICU) admission (T1), 24 h after the study entry (T2), and 48 h after the study entry (T3). Blood glucose and glycated hemoglobin (HbA1c) values were measured at study entry. ICU and hospital mortality, 30 and 90-day mortality, need for mechanical ventilation (VM), need for renal replacement therapy (RRT), time on VM and on RRT, length of stay in the ICU and hospital, and readmission to the ICU were evaluated.

Results: A total of 104 patients admitted to the ICU were included. Overall mortality was 40.4% (n = 42). Weak inverse correlations were detected between blood glucose and copeptin T2 (r = -0.23, p = 0.03), and glycemic gap (r = -0.25, p = 0.03) and SHR (r = -0.24, p = 0.03) and copeptin T3. No associations were identified between copeptin values at T1 and T2 with clinical outcomes. However, copeptin values at T3 were significantly higher in survivors than in non-survivors at hospital discharge [561 pg/mL [370 to 856] vs 300 pg/mL [231 to 693], p = 0.015], at 30 days [581 pg/mL [387 to 865] vs 299 pg/mL [231 to 690], p = 0.02] and at 90 days [517 pg/mL [380 to 884] vs 492 pg/mL [295 to 698], p = 0.03]. Copeptin values at T1 and T2 were not different between survivors and non-survivors.

Conclusion: Weak inverse correlations were found between copeptin levels and glycemic parameters, suggesting that copeptin is not a major factor in the induction of hyperglycemia during critical illness. Besides, copeptin values at the third ICU day were significantly higher in survivors than in non-survivors.

Diabetic Ketoacidosis : Do We Have to Give Too Many Intravenous Fluid ?

N. H. BRAHMI¹; R. Soedono¹

¹Anesthesiology and Intensive Care, Fakultas Kedokteran Universitas Indonesia, Jakarta, Indonesia

Correspondence: N.H. BRAHMI

Intensive Care Medicine Experimental 2020, **8(2)**: 001032

Introduction: Approach consideration in DKA are intravenous fluid, correction of hyperglycemia with insulin, electrolytes disturbances, acid base balance and treatment to precipitating condition. Many patients with DKA were given fluid more than 2 litre in the initial 4 hours developed into lung edema and longer period of hospitalization.

Objectives: To evaluate the outcome between patients in who were given more than 3 litre in the initial 4 hours of treatment to patients who were given maintenance fluid dose in emergency room

Methods: We had 6 patients diagnosed with DKA, in their 30's and 40's. They are obese type II diabetic with oral hypoglycemia medication. Before admission, all of them reported suffered from infection: CAP, UTI, gastrointestinal infection. There was no sign of nausea, vomitus, or dehydration. All of them in mild hypotension with normal serum sodium level. There were 2 group, 1 group, the liberal fluid, were given more than 3 liter NaCl 0,9% (7 to 14 ml/kg/hour, with initial boluses 1 litre NaCl 0,9% before within an hour) in the early 4 hours phase of the treatment, the other only given 1 litre initial boluses NaCl 0,9% within an hour then followed by maintenance fluid 25 - 30 ml/kg/d NaCl 0,9%. All of them were given insulin intravenously depend on their glucose status hourly, then we maintained the glucose level to 150 -200 mg/dL, deescalation antibiotics broad spectrum, continuous monitored hemodynamics and level of consciousness. We also documented fluid balance, urin output every hour, and acid base, electrolyte, and ketonuric status every 12 hour. Fluid challenge test was given if urine output not reached target, and will be given additional fluid to reach normorehydration status. If there is imbalance electrolyte present, we corrected it with supplement potassium intravenously if needed.

Results: In both groups, DKA were resolved within first 24 hours. All the patients regain their consciousness, the blood glucose were reach the target. In the liberal fluid, 1 patient developed lung edema, so we need to intubate him, 1 patient with positive balance without clinical deterioration, and the other one recovered well. The 2nd group, none had lung edema, but 1 patient was given fluid challenge test once and responded well so we gave extra 500 ml NaCl 0,9% within 3 hours to total maintenance fluid. 5 out of 6 were able to be stepped down to the ward, while 1 patient from the liberal fluid stepped up to intensive care unit.

Conclusion: DKA occurred in the obese diabetic type II patient precipitated by infection, resolved well within 24 hours with deescalation technique on antibiotics, insulin therapy, and maintenance dose of fluid.

001082**Glycaemic control predicts mortality in non-diabetic, critically ill patients with COVID-19**S. Lockhart¹; B. Petrisor¹; A. Usman¹; H. Griffiths¹; L. Heales²; V. Bansiya³; R. Mahroof¹; A. Conway-Morris⁴¹John Farman Intensive Care Unit, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom; ²Department of Anaesthetics & Intensive Care Medicine, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom; ³Department of Diabetes & Endocrinology, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom; ⁴Division of Anaesthesia, Department of Medicine, University of Cambridge, Cambridge, United Kingdom**Correspondence:** S. Lockhart*Intensive Care Medicine Experimental* 2020, **8(2)**: 001082**Introduction:** Analysis of glycaemia in non-critically ill patients with COVID-19 has suggested that hyperglycaemia is associated with poor outcomes in patients with and without diabetes. However, to our knowledge there has not been a longitudinal assessment of glycaemic control and mortality in critically ill patients with COVID-19.**Methods:** Retrospective observational study of contemporaneous electronic medical records of patients admitted to our intensive care unit (ICU) for > 24 hours with COVID-19 during the months of March and April 2020. Glycaemic control was assessed relative to the target range of 4-10 mmol/L by three related metrics: estimated time in range 4-10mmol/L, percentage of BG measurements between 4 and 10mmol/L, and mean BG.**Results:** 54 patients met inclusion criteria, 1 patient had incomplete BG data and was omitted from our analysis. Median time in range was 86%, similar to previous studies. Hypoglycaemia was rare with 4 patients experiencing mild hypoglycaemia (BG <4mmol/L) and 2 patients experiencing biochemically severe hypoglycaemia (BG < 2.5 mmol/L). In the whole cohort we did not find a difference in any glucose metric between those discharged alive from ICU or those who died in ICU. However, we did observe an interaction between diabetes status and ICU outcome with respect to mean blood glucose ($P < 0.05$), suggesting that the relationship between glycaemia and mortality may depend on diabetes status. Indeed, the percentage of BG measurements in range, time in range and mean blood glucose were significantly different in ICU survivors and non-survivors in the cohort without diabetes ($N = 42$, $P < 0.05$ for all metrics) with better glycaemic control observed in ICU survivors. In univariate logistic regression analyses mean BG (OR = 0.44, 95% CI 0.19 – 0.84, $P = 0.02$) and BG measurements in range (OR = 1.05, 95% CI 1.00 – 1.11, $P = 0.04$) predicted discharge alive from ICU with better glycaemic control positively associating with survival. Interestingly, both mean BG and BG measurements in range had superior predictive ability for ICU mortality to BMI, steroid use, sex and cross-sectional measurements of CRP, Troponin and D-Dimer in univariate analyses. To determine the additive predictive effect of glycaemia to the dominant risk factor for COVID-19 mortality, age, we examined the effect of glycaemia (BG measurements in range) in a model adjusted for age. The model explained 22% of the variance of the data, compared to 11% for age alone with a similar effect size for glycaemia as was seen in the univariate analysis (OR 1.05 CI: 1.00 – 1.11).**Conclusion:** Here we demonstrate, for the first time, an association between glycaemia and mortality in critically ill non-diabetic patients with COVID-19. Given the high prevalence of hyperglycaemia in critically ill patients with COVID-19 further assessment of the interaction between hyperglycaemia and ICU outcomes in diabetic and non-diabetic patients is warranted.**Reference(s) and grant acknowledgment(s)**

001093**Ability of NUTRIC and Modified NUTRIC score to predict ICU mortality in critically ill COVID-19 patients**A. Liberti¹; E. Piacentini¹; G. Catzula¹; E. Clemenza¹; M. Umbrello¹; S. Muttini¹
¹Uo anestesia e rianimazione, Ospedale San Carlo Borromeo, ASST Santi Paolo e Carlo, MILANO, Italy**Correspondence:** M. Umbrello*Intensive Care Medicine Experimental* 2020, **8(2)**: 001093**Introduction:** International guidelines recommend the assessment of nutrition status before the initiation of nutritional support. NUTRITION Risk in the Critically ill (NUTRIC) score has been proposed to quantify the risk of adverse outcomes that may be modified by artificial nutrition. A "modified NUTRIC score" (mNUTRIC) has been introduced without IL-6 levels. An unprecedented number of relatively young and previously healthy patients has been admitted to the ICU during the recent COVID-19 outbreak. These patients often experienced a dysregulated inflammatory response, potentially leading to a cytokine storm and multiple organ damage. In this population, IL-6 has been measured to assess the inflammatory status, allowing the calculation of NUTRIC and mNUTRIC scores.**Objectives:** To assess whether NUTRIC score is a reliable nutritional risk assessment tool in patients with COVID-19-related acute respiratory failure and to compare the prognostic performance of NUTRIC and mNUTRIC score.**Methods:** Single centre, retrospective cohort study in critically ill patients with COVID-19-related acute respiratory failure. Patients with NUTRIC or mNUTRIC score ≥ 5 were considered at high nutritional risk. The prognostic performance of NUTRIC and mNUTRIC score were compared, as well as their discriminative abilities for ICU-mortality.**Results:** 42 patients were enrolled: 34 (79%) males, age 62 ± 9 , BMI 27.6 ± 4.2 . Average NUTRIC score: 2.5 ± 1 ; mNUTRIC score: 2.6 ± 1.1 .ICU mortality was 40.5%; all non-survivors had mNUTRIC score ≤ 4 (low nutritional risk); only one non-survivor had a high nutritional risk (NUTRIC Score ≥ 5). Non-survivors were older (67.5 ± 6.7 vs. 59.0 ± 9.9 years, $p = 0.0036$), had higher IL-6 blood levels ($152 [78; 264]$ vs. $53 [12; 109]$, $p = 0.0202$) and a higher NUTRIC score ($3 [2; 3]$ vs. $2 [2; 3]$ points, $p = 0.0425$). mNUTRIC score was not different between survivors and non-survivors ($p = 0.0743$).In multivariate logistic analysis, NUTRIC score was significantly related with ICU mortality (OR 2.49 [95%CI 1.02-6.10]). The discriminative ability of NUTRIC score for ICU mortality was (AUROC) 0.67 [0.525-0.826], while that of mNUTRIC-score was 0.66 [0.514-0.817], $p = 0.4109$.**Conclusion:** Despite a relatively low nutritional risk, NUTRIC score seems to identify a subpopulation of critically ill, COVID-19 patients who may benefit from nutritional support. The prognostic performance of NUTRIC and mNUTRIC score is comparable in patients with high inflammatory status as in COVID-19.**Reference(s) and grant acknowledgment(s)**

001128**Ultrasonography skeletal muscle assessment predicts worse outcome in critically ill patients under mechanical ventilation: observational cohort study**B. Cardoso Gomes¹; B. De Freitas²; M. Jacques³; D. Toledo⁴; D. Santos²; F. Do Amaral²; R. Dib²; JM. Silva²¹Departamento de Medicina Integrada, Universidade Federal do Paraná, Curitiba, France; ²Icu, Hospital Israelita Albert Einstein, São Paulo, Brazil; ³Psicologia, UniCesumar - Curitiba Campus, Curitiba, Brazil; ⁴Medicina, USP - University City, São Paulo, Brazil**Correspondence:** B. Cardoso Gomes*Intensive Care Medicine Experimental* 2020, **8(2)**: 001128**Introduction:** Survivors of critical illness experience significant skeletal muscle wasting that may predict clinical outcome. Ultrasound (US) is a noninvasive method that can measure muscle quadriceps muscle layer thickness (QMLT) at the bedside.

Objectives: The objective of this study was to determine muscle wasting (assessed using US) in critically ill patient over a period of 7 days and the relationship between loss of muscle quadriceps thickness and hospital survival probability in critically ill patient under mechanical ventilation.

Methods: The data were entered into an electronic database (Microsoft Excel; Microsoft, Redmond, Washington) and analyzed using SPSS V.26. Data collection was halted after the successful inclusion of 70 patients. Demographic data were expressed as the means \pm SD, medians and percentiles or percentages. This study involved patients \geq 18 years of age admitted to the intensive care unit (ICU) who needed mechanical ventilation for at least 48 hours. The QMLT at the two-thirds-thigh was quantified using bedside US with a 12 MHz linear transducer. Measurements of the first (D1), third (D3) and seventh (D7) days were performed of QMLT (mean \pm SD) was displayed for left and right legs.

Results: Ultrasound quadriceps thickness measurements were performed on 74 critically ill patients. The mean age was 62.3 ± 19.5 years, 54.1% male, BMI 25.5 ± 4.6 kg/m², SAPS 3 was 55.2 ± 17.2 and NRS 3.2 ± 1.0 . Overall, the percentage muscle thickness declined at the right leg in 15% (95%CI, 10.5% to 19.4%), and 12.7% (95%CI, 9.1% to 16.3%) at the left leg assessed by the US occurred from the first to the seventh day. The decline in muscle thickness at the right leg and left leg were higher among non-survivors compared to survivors at all time points. In right leg 2.1 ± 0.7 cm in survivor vs 1.7 ± 0.5 cm nonsurvivor at D1, 1.9 ± 0.7 cm in survivor vs 1.6 ± 0.4 cm nonsurvivor at D3, 1.8 ± 0.6 cm in survivor vs 1.4 ± 0.4 cm nonsurvivor at D7; GLM- P = 0.01. In left leg 2.1 ± 0.7 cm in survivor vs 1.7 ± 0.4 cm nonsurvivor at D1, 2.0 ± 0.8 cm in survivor vs 1.7 ± 0.5 cm nonsurvivor at D3, 1.8 ± 0.6 cm in survivor vs 1.5 ± 0.5 cm nonsurvivor at D7; GLM- P = 0.04. ROC analysis showed that a cutoff of decline in muscle thickness of less than or equal to 1.64 cm at day 7 can predict survival, AUC = 0.7 (95% CI 0.582 to 0.801). Thus, in cox regression after adjusting for SAPS 3 and gender, the probability of patients remaining in the mechanical ventilation was higher with \leq 1.64 cm at day 7 of loss of thigh muscle thickness, the hazard was 2.1 times (95% CI 1.1–3.8) higher than their counterparts with p value 0.017. The same occurred \leq 1.64 cm at day 7 of loss of thigh muscle thickness about ICU survival probability; HR = 3.7 (95% CI 1.2 to 11.5) and hospital survival probability; HR = 4.5 (95% CI 1.5 to 13.7).

Conclusion: Among these critically ill patients, muscle wasting occurred during the first week of critical illness under mechanical ventilation. The patients who lost the most muscle was those with the worst survival. Decline in muscle thickness was associated with in-hospital mortality. USG has a potential to identify patients at risk of worse in-hospital outcomes.

Intensive Care Medicine Experimental 2020, **8(2)**: 001185

Introduction: We introduced the hospital policy on the management of severe symptomatic hyponatraemia (SSH), with hypertonic saline

(HS) of 1.8% and 5% saline in 2017. This is one of the few UK centres to offer this treatment, therefore the evidence is limited. The policy was based on European and American guidelines (1)(2).

Objectives: To study the adherence, and effectiveness, of this guideline in managing patients with SSH.

Methods: Patients were identified using the Biochemistry tracking system between 01/01/18 until 14/05/20. The terms - Hypona, sod, Hypertonic, 5%, 1.8% were searched. The laboratory result system was used to identify hyponatraemic (<130 mmol/L) patients at the time they were logged onto the tracking system. Clinical notes were crossmatched for the use of 1.8% and 5% saline for those with sodium <130mmol/L. 12 patients were identified.

The following data was collected using hospital records: age, gender, location, fluid status, presentation, symptoms after HS administration, volume and type of fluids. Sodium was recorded; prior to and during presentation, after HS saline, at 24, 48 hours and at discharge or death. Cause of death (if applicable), complications of HS and length of admission after treatment were also noted. This was compared to the 2017 current hospital guideline

Standard 1: patients treated with hypertonic saline should be symptomatic of hyponatraemia:	9/12 ²	75%
Standard 2a: Severe Symptomatic Hyponatraemia should be treated with 5% Saline:	0/9	0%
Standard 2b: Moderately Symptomatic Hyponatraemia should be treated with 1.8% Saline:	2/2	100%
Standard 2c: Serum Na rise \leq 5 with hypertonic saline:	5/12 ²	42%
Standard 2d: Clinical improvement of symptoms after HS:	9/11 ³	82%
Standard 2e: HS administered as per the protocol:	9/12 ²	75%
Standard 2f: Normal saline administered after hypertonic saline	10/12 ²	83%
Standard 3a: \leq 10mmol rise in 24 Hours:	5/12 ²	42%
Standard 3b: \leq 18mmol rise in 48Hours:	7/12 ²	58%

Results:

Standard 1: 11 patients had symptoms of hyponatraemia. They were confusion (6), somnolence (5), seizure (4), vomiting (3). Other symptoms included muscle twitching, fatigue and nausea. SSH was suspected in 2/11 patients, but it was not the primary diagnosis. One patient was asymptomatic - the only patient with chronic hyponatraemia.

Standard 2a/b: All patients identified were treated with 1.8% saline. None with 5% saline.

Standard 2c: 7/12 patients overcorrected (there should be a <5mmol/L increase following HS). In 4/7 there was inappropriate application of the guideline; HS was given despite improvement of symptoms or after the 5mmol/L target had been achieved.

An average volume of 481ml (range 100-1250ml) HS was given over an average of 3h 53m. This increased sodium by mean of 6.4mmol/L (range 2-12) by the end of treatment with HS.

Standard 2d: 9/11 patients had at least partial or full improvement in the symptoms at the end of treatment with 1.8% saline. In 2/11 whose symptoms were secondary to other causes (paranoia/hallucinations), did not have improvement of symptoms after HS.

Standard 2e: 9/12 patients had HS administered as per the recommended guideline calculation for rate. 2 patients were hypervolaemic and were treated with a slower infusion to prevent overload. 1 patient was treated using 100mls 1.8% saline for no clear reason.

Standard 2f: 2 patients were clinically hypervolaemic - NS was avoided due to risk of overload. 1 patient had a 9mmol increase after 24 hours, (<10mmol increase advised).

Standard 3a/b: There was 7/12 who overcorrected at 24 hours, and 5/12 at 48 hours (should be <10mmol/L and <18mmol/L, respectively). The mean increase in serum sodium at 24 and 48 hours were 12.25mmol/L (range 7-21) and 17.25mmol/L (range 10-26) respectively. 11/12 patients eventually normalised (>130mmol/L) their serum sodium. 1 patient self discharged before this. The mean length of time to achieve this was 6.5 days.

In addition: 3 patients died. No deaths were attributed to treatment with 1.8% saline. Specifically, no patients developed central pontine myelinolysis

Conclusion:

1. Our audit showed symptomatic improvement in moderate and SSH, following HS use.

- Patients with symptoms due to other causes, did not show improvement in symptoms following HS. Before administrating HS, SSH should be the most likely diagnoses.
- 5% Saline was not administered, it should be removed from the guidelines. 1.8% can safely be used in severe and moderate cases.
- The guideline was inappropriately followed for cases where there was overcorrection following HS. It should be clearly stated that HS can be stopped once there is symptomatic improvement, even if this occurs prior to the 5mmol/L target.
- The increase in serum sodium at 24 hours and 48 hours should be <10mmol and <18mmol from baseline. This includes administration of HS followed by NS.
- No adverse events were identified from treatment with HS or from overcorrection.

Intensive Care Medicine Experimental 2020, **8(2)**: 000348

Introduction: Critical illness-induced weakness is prevalent and associated with increased morbidity and mortality. Interestingly, obesity attenuates both muscle wasting and weakness.^{1,2} We here aimed to investigate whether the adipokine leptin mediates this protective effect.

Methods: In a catheterized, antibiotic-treated, fluid-resuscitated mouse model of sepsis, evoked by cecal ligation and puncture, impact of leptin availability was compared in obese and lean mice. In four groups of septic mice (n ≥ 11 survivors per group) - diet induced obese (Ob-DIO), leptin-deficient obese (Ob-KO), placebo-treated lean (Ln) and leptin-treated lean (Ln-lep) mice - body composition (MRI), specific muscle force (ex vivo contractibility in mN/mm² per mass EDL) and plasma markers of lipolysis and inflammation were measured.

Results: Prior to sepsis, plasma leptin was undetectable in Ob-KO, and higher in Ob-DIO (12.4[8.2-15.1]ng/ml) than Ln (1.8[0.9-3.0]ng/ml) (p < .0001). Ob-DIO and Ob-KO were similar in body weight (p = .5) but 46% heavier than lean mice. Ob-KO (22.4 ± 2.6g) had more fat mass than Ob-DIO (19.3 ± 1.8g) and Ln (2.7 ± 1.2g), but less lean mass (19.3 ± 1.8g) than Ob-DIO (25.8 ± 2.2g) or Ln (24.8 ± 2.1g) (p < .0001 for all). After 5 days of sepsis, mortality was highest in Ob-KO (53%) (p ≤ .06) but was comparable in Ln (39%), Ln-lep (36%) and Ob-DIO (23%). Plasma leptin was undetectable in Ob-KO, higher in Ob-DIO (15.4[12.6-19.4]ng/ml) and Ln-lep (34.7[14.7-135.4]ng/ml) than Ln (0.2[0.1-0.7]ng/ml) (p < .0001). Loss of lean mass loss was 2x more pronounced in lean than in obese mice (p < .0005), but not affected by leptin availability in lean (Δ 4.2 ± 1.6g Ln and 3.3 ± 2.0g Ln-lep, p = .2) or obese (Δ 1.8 ± 1.1g Ob-DIO and 1.3 ± 1.1g Ob-KO, p = .2). Functionally, Ob-DIO and Ob-KO mice maintained their specific muscle force (p ≥ .1) up to healthy levels (98.8% and 116.5% of healthy control, respectively), whereas Ln and Ln-Lep mice suffered from reduced specific muscle force (77.9% and 65.4% of healthy control, respectively, p ≤ .01), again not affected by leptin availability (p ≥ .2). In contrast to muscle, fat mass loss was 2x more pronounced in obese than in lean (p < .0001), greatest in Ob-DIO (Δ 4.2 ± 0.8g Ob-DIO and 3.2 ± 0.7g Ob-KO, p = .0002), but was not affected by leptin in lean (Δ 1.9 ± 0.5g Ln and 2.1 ± 0.8g Ln-lep, p = .4). In accordance, both Ob-DIO and Ob-KO mice

had increased plasma free fatty acids, glycerol and peak 3-hydroxybutyrate concentrations compared to Ln and Ln-lep (p ≤ .01). Both obese groups showed an attenuated inflammatory response compared to both Ln and Ln-lep, evident by a 50% lower plasma TNFα increase (p < .005).

Conclusion: Not increased leptin availability, but adiposity attenuated critical illness induced muscle wasting and weakness. A more efficient mobilisation of fat stores and ketogenesis, as shown previously², but also a blunted inflammatory response might play a mediating role.

Bio-electrical impedance analysis (BIA) in healthy volunteers in various conditions by various observers with various devices: what matters?

I. Myatchin¹; A. Minini¹; M. Diltoer¹; MLNG. Malbrain¹

¹Intensive care unit, University Hospital Brussels (UZB), Jette, Belgium

Correspondence: I. Myatchin

Intensive Care Medicine Experimental 2020, **8(2)**: 000425

Introduction: To examine 1) inter-device, inter- and intra-observer variability of BIA measurements and 2) effect of fluid load on BIA measurements in healthy adult volunteers.

Methods: We studied two groups of ten healthy adults (women:men = 1:1 in each group). In the first group, three observers performed in each participant three tests on the right and three tests on the left side with two BIA devices (BioScan Touch i8 (Maltron Int. Ltd) and Nutrilab (Akeron SRL)). In the second group, BIA tests were done in each participant before and after (immediately – 30 min – 60 min – 120 min later) the fluid load (i.e., drinking of 0.5L or 1L of bottled still water). TBW (total body water), ECW (extracellular water), ICW (intracellular water), ECW/ICW, BCM (body cell mass), FM (fat mass), FFM (fat-free mass), plasma and interstitial fluid volume, and PhA (phase angle at 50 kHz) were compared.

Results: 1) No significant differences between BIA parameters while tested by the same observer. Significant differences were seen in all BIA parameters between BIA devices (p < 0.001). In tests obtained with BioScan, no significant interobserver difference was seen, while significant (p = 0.004) and almost significant (p = 0.091 and 0.06) differences between observers were found with Nutrilab. 2) Water load led to significant change in ECW, ICW, ECW/ICW, interstitial fluid, PhA (p < 0.001) and BCM (p = 0.002) with time, which was most pronounced in the measurements taken as latest.

Conclusion: 1) BIA measurements show low intraobserver variability. With BioScan, inter-observer variability was low as well, while with Nutrilab it was significantly high. Various BIA devices reproduce significantly different results. 2) After fluid load, ECW, ICW, interstitial fluid, PhA and BCM changed significantly with time.

Intensive Care Medicine Experimental 2020, **8(2)**: 000778

Introduction: Both physiological theory (1) and anecdotal observations (2) support the principle that most mammalian cells may sustain their metabolism using lactate instead of glucose. Combined hyperlactatemia and hypoglycemia (HLHG) may constitute a novel treatment for various diseases, including cancer and malaria. However, induction, maintenance and reversal of HLHG may be challenging and leading to profound derangement of the electrolyte and acid-base equilibrium.

Objectives: To develop a porcine model of HLHG by extracorporeal administration of lactic acid (HLA) and hyperinsulinemic clamping.

Methods: Five female swine (36.0 ± 6.5 kg), received an oral dose of 1000 mg metformin before anesthesia induction and connection to an extracorporeal circuit for HLA administration (3). Target lactatemia level was 8–10 mmol/L. Once lactatemia achieved 7.5 mmol/L, deep hypoglycemia (target glycaemia: 23–31 mg/dL, 1.3–1.7 mmol/L) was induced and maintained with hyperinsulinemic clamp, i.e. continuous infusion of insulin and concentrated glucose. Hypoglycemic counter-responses were inhibited by infusion of labetalol and octreotide. Respiratory rate (RR) was adjusted targeting an arterial pCO₂ of 40 mmHg. After 4 hours of stable HLHG, normal glycaemia and lactatemia were restored. Numerous blood samples were obtained for gas and biochemistry. Data are reported as mean \pm standard deviation.

Results: The figure shows the time course of lactatemia and glycaemia. The initial target lactatemia (8.3 ± 1.2 mmol/L) was achieved by infusing a total amount of 190.8 ± 82.2 mmol of HLA over 48 ± 22 minutes. Subsequently, hypoglycemia was obtained in 44 ± 18 minutes by infusing 81.6 ± 53.2 IU insulin. In this phase hyperlactatemia (8.9 ± 1.1 mmol/L) was maintained by infusing 267.1 ± 41.5 mmol of HLA, while a total amount of 20.0 ± 8.0 mcg octreotide and 16.2 ± 7.9 mg labetalol was administered. HLHG was maintained for 260 ± 23 minutes with a glycaemia of 25 ± 4 mg/dL requiring low dose insulin continuous infusion (0.4 ± 0.5 UI/h). In order to avoid serum glucose dropping below 18 mg/dL, 50% glucose administration was required in all animals at an average rate of 5.1 ± 2.7 g/h, for a total infused dose of 23.7 ± 10.1 g. Labetalol infusion was performed at a rate of 26 ± 22 mg/h for a total labetalol dose 124.5 ± 99.4 mg. After the HLHG phase, 20.7 ± 12.1 g of glucose over 72 ± 24 minutes were required to restore normoglycemia (>60 mg/dL). No major hemodynamic derangements occurred. A mild positive fluid balance was observed, but not exceeding 1 L. RR was increased from 20.4 ± 3.3 bpm at baseline to a maximum of 29.8 ± 3.8 bpm and returned to 19.6 ± 2.6 bpm after restoration of normal glucose and lactate levels. Minimum values of arterial pH and bicarbonate were 7.25 ± 0.09 and 19.3 ± 3.4 mmol/L, respectively. Biomarkers of hepatic, renal and myocardial damage did not increase throughout the experimental procedures.

Conclusion: In a large mammal model, induction, maintenance and reversal of HLHG was feasible and without major hemodynamic or metabolic derangements. Further studies will be required to evaluate safety and possible therapeutic effects of HLHG.

Intensive Care Medicine Experimental 2020, **8(2)**: 000009

Introduction: Skeletal muscle atrophy is common in critically ill patients. Although monitoring of muscle mass is important, biomarkers associated with muscle atrophy have not been reliably identified. Titin is a spring-like protein in muscle, and has become measurable as a marker of muscle breakdown. We hypothesized that urinary titin is a useful biomarker for monitoring muscle atrophy in critically ill patients.

Objectives: We conducted a two-center prospective observational study to investigate titin level and its association with muscle atrophy in critically ill patients.

Methods: We recruited adult patients who were expected to remain in the intensive care unit (ICU) for more than 5 days. We excluded post-operative patients due to the increased titin level by surgery. Urine sample was collected on days 1, 2, 3, 5, and 7. The urinary N-terminal fragment of titin was measured using an enzyme-linked immunosorbent assay (ELISA) kit. We corrected titin with urinary creatinine (normal range: 1–3 pmol/mg Cr). In order to assess muscle atrophy, rectus femoris cross-sectional area and diaphragm thickness were measured with ultrasound on days 1, 3, 5, and 7. The primary outcome was the relationship between cumulative titin level and the atrophy rate of rectus femoris muscle. Secondary outcomes included the relationship between urinary titin level and the change of diaphragm thickness, the incidence of ICU-acquired weakness (ICU-AW), ICU mobility scale (IMS), and mortality in the ICU.

Results: Fifty-six patients (33 males and 23 females; mean age, 72 \pm 13 years) were included at 232 titin measurements. The APACHE II score was 25 (19–29) and the length of ICU stay was 6 (4–9) days. The titin level was 27.9 (16.8–59.6), 47.6 (23.5–82.4), 46.6 (24.4–97.6), 38.4 (23.6–83.0), and 49.3 (27.4–92.6) pmol/mg Cr on days 1, 2, 3, 5, and 7, respectively. The cumulative titin level was significantly associated with the atrophy of rectus femoris muscle on day 3 ($P < .01$), day 5 ($P < .01$), and day 7 ($P = .03$), although titin was not associated with the change of diaphragm thickness ($P = 0.54$). Furthermore, the cumulative titin level was associated with ICU-AW ($P = 0.01$) and mortality in the ICU ($P = 0.02$), but not with IMS ($P = 0.18$).

Conclusion: In non-surgical critically ill patients, the urinary titin level was increased approximately 10–30 times the normal level. The increased titin level was associated with lower limb muscle atrophy, incidence of ICU-AW, and ICU mortality.

Systemic involvement and epidemiology of diabetic patients admitted for Acute Coronary Syndrome

A. M. González González¹; A. M. Garcia Bellon¹; M. Cano-García¹; M. De Mora-Martin¹

¹Cardiology, Regional Hospital of Malaga, Málaga, Spain

Correspondence: A.M. González González

Intensive Care Medicine Experimental 2020, **8(2)**: 000165

Introduction: Diabetes Mellitus(DM) is a chronic disease, which is associated with a marked increase in cardiovascular morbidity and mortality

Objectives: Our aim was to analyze the clinical and metabolic control, as well as the degree of systemic affection in this group of patients (p)

Methods: An observational analytical prospective study including 161diabetic patients, consecutively admitted to the Intensive Care Unit with acute coronary syndrome (ACS).

Results: Mean age at diagnosis:69.1 years \pm 9.2.Male:63,2%.Years of evolution of DM 11.9 \pm 2.3. Ambulatory treatment:23 p(14.3%) diet; 44p(27.3%)oral antidiabetic(OAD)monotherapy,32p(19.9%) combined OAD,24p (14.9%)OAD+insulin and 38 p(23.6 %)insulin. Average weekly controls: 7 \pm 3.Monitoring was performed by 72% general practioner; Endocrinology 13%, 8% without follow-up and 6.8% by other specialists;with 2 annual reviews of average. During their hospitalization, the mean glycemic level was: before breakfast:115.8 \pm 37mg/dl; before lunch:209.2 \pm 63mg/dl and before dinner:187 \pm 70mg/dl.Mean Glycosylated hemoglobin level was 7.5%. Regarding macrovascular affection:previous heart disease:74.5% (22.9% type angina, 37.9% acute myocardial infarction,other heart disease 13.7%).Previous stroke:17p (10.5%).37p intermittent claudication (23.5 %).Pedal pulses present in 43.5%,weak in 42,8% and absent in 13.6%.Microvascular affection:retinopathy 32p(19.8%).Nephropathy 39p (24.2%).Neuropathy in 34p (21.1%).History of lower limb ulcers in 15p (9.3%). Monofilament examination:sensitivity 6/6 in 56.5%,5/6 in 11.1%, 4/6 in 8.7%, 3/6 in 13.6%, 2/6 in 4.9%, 1/6 in 2.5%, 0/6 in 3.1%.

Conclusion: The clinical profile of diabetic patients admitted in our Unit corresponds to a middle-aged man, with insulin regimen and improvable metabolic control.Cardiovascular complications were found in a remarkable percentage.Therefore,it must be highlighted the importance of a strict control of blood glucose levels in these patients to slow the progression of the disease.

The impact of volume therapy (VT) with NaCl 0.9% vs Ringer lactate as a part of complex intensive therapy (CIT) for early rebalancing of the diabetic patient

I. Camerzan¹; C. Gutu-Bahov²

¹Intensive Care Unit, Municipal Clinical Hospital "Sfanta Treime", Chisinau, Moldova; ²Professor department intensive care unit, Municipal Clinical Hospital "Sfinta Treime", Chişinău, Moldova

Correspondence: I. Camerzan

Intensive Care Medicine Experimental 2020, **8(2)**: 000714

Introduction: Rapid crystalloid fluid loading in ketoacidosis is essential to restore the patient to normal metabolic state. The main objective of the CIT is to identify triggers and to fix it as soon as possible.

Objectives: To evaluate DKA's triggers; to appreciate the role of early VT with NaCl 0.9% vs Ringer lactate on acid-base balance values and time spent in ICU for patients with DKA.

Methods: A retrospective study (conducted in the hospital "Sfanta Treime", Chisinau, during the 2018-2019 years) based on 64 critical ill patients (mean of age 35.68 \pm 3.45 years, P=0.204) who needed VT, mechanical ventilation (MV), acid-base balance and glycemic correction in 24 hours. Patients were divided in 2 groups. Group I (n=34) – patients received NaCl 0.9% and group II (n=30) – Ringer lactate as VT. In these patients were appreciated clinical manifestation, BP (blood pressure), HR (heart rate), PICCO parameters, acid-base balance (ABB), glycemia, lactate, anionic gap (AnGap), blood osmolarity.

Results: According to this study triggers for DKA were: neglected insulin therapy regimen n=28 (43,75%), wrong diet n=6 (9,37%), inflammatory process n = 30 (46,87%). At admission in ICU in group I were found a higher APACHE II and SOFA score (group I – APACHE II 16p \pm 2.1, SOFA 14p \pm 1.9 vs group II – APACHE II 14 p \pm 2.3, SOFA 12 \pm 2.0) and at the end of the treatment – a shorter hospital stay (group I-3.4 days vs group II-4.8 days). Also, in the group I was observed a faster improvement of the ABB values (lactate = 8.2-3.5mmol/l, glycemia = 31-16 mmol/l, blood osmolarity – 275-290 mmol/kg, AnGap 12-16mmol/l) vs group II (lactate = 8.2-4.5mmol/l, glycemia =30-18mmol/l, blood

osmolarity – 285-900mmol/kg, AnGap 14-18mmol/l). Mortality in group I was 5.88%; P = 0,012 vs. group II-6.66%; P = 0,023.

Conclusion: Clear identifying of the DKA's triggers and early VT with NaCl 0.9% given to critical ill patients showed a faster improvement in ABB values, shorter hospital stay and reduced mortality rate.

Professionals of an Intensive Care Unit's perception of dysphagia in critically ill patients

Santana-Cabrera¹; J. Alcaraz Jimenez¹; J. Rico-Rodriguez¹; JD. Martin Santana²; B. N. Santana-Lopez¹

¹Intensive care unit, Maternal and child Hospital, Las Palmas de Gran Canaria, Spain; ²Economics, Universidad de las Palmas de Gran Canaria, Las Palmas de Gran Canaria, Spain

Correspondence: B.N. Santana-Lopez

Intensive Care Medicine Experimental 2020, **8(2)**: 000799

Introduction: Oropharyngeal dysphagia and its consequences are problems that seem frequent among critically ill patients, although this question has yet to be resolved, since its incidence in this patient profile is not clearly known.

Objectives: To study the perception of dysphagia among ICU physicians and nurses.

Methods: Cross-sectional, prospective, descriptive and quantitative study through a personal, self-administered survey, which has been translated from a reference work and adapted to our environment.

Results: 102 questionnaires were fulfilled. Almost 80% of ICU professionals consider dysphagia as a problema. In addition, more than 60% of the interviewees believe that dysphagia prolongs the length of stay in the ICU of the patients and almost half believe that dysphagia increases morbidity and mortality (46.1%). However, no screening is done (65.7%), but when this is accomplished, it is through a test meal (38.2%).

On the other hand, they believe that the main risk factors for developing dysphagia during admission are prolonged intubation, ICU admission for acute or pre-existing neurological disease. Finally, regarding the complications produced by dysphagia, a large majority of professionals point to aspiration pneumonia as the main one.

Conclusion: The staff perceive that dysphagia is a problem, although it is not very frequent, it can have an impact on the patient's morbidity and mortality. Furthermore, being determined of the need to improve their level of awareness, we believe that it is necessary to implement standardized screening protocols, guided by experts from multidisciplinary areas and focused on early suspicion, diagnosis and treatment of dysphagia.

Intensive Care Medicine Experimental 2020, **8(2)**: 000441

Introduction: Although several devices were tested in randomized controlled trials and are in use currently, the role of artificial and bio-artificial liver support systems (ALSS) in acute-on-chronic liver failure (ACLF) is still controversial. There is a lack of evidence for survival benefit, therefore most international societies do not advise the routine use of these devices in ACLF. Network meta-analyses enable indirect comparison of interventions without the need for head-to-head trials, therefore may produce additional evidence.

Objectives: Our aim was to perform the first network meta-analysis comparing different liver support systems to each other and to standard medical therapy (SMT) in patients with ACLF.

Methods: The protocol was registered with PROSPERO (CRD42020155850). The systematic search was conducted in MEDLINE, CENTRAL, Scopus, Embase and Web of Science databases. Selection and data extraction was performed in duplicate and a Bayesian network meta-analysis of randomized controlled trials was conducted. Risk ratios and 95% credible intervals (CrI) were calculated and interventions were ranked by their posterior probability via calculating the surface under cumulative ranking (SUCRA) curve values. SUCRA values range from 0 to 100%. The higher the SUCRA value, and the closer to 100%, the higher the likelihood that a therapy is in the top rank or one of the top ranks. Version 2 of the Cochrane risk-of-bias tool for randomized trials (RoB 2) and a modified GRADE approach were used for the assessment of risk of bias and quality of evidence.

Results: The systematic search yielded 2774 records. Twenty-three studies were included in the qualitative synthesis from which sixteen were incorporated in the meta-analysis, using MARS[®], Prometheus[®], ELAD[®], plasma exchange (PE) and BioLogicDT[®]. Overall (OS) and transplant-free (TFS) survival were assessed at 1 and 3 months. PE significantly improved 3-month OS compared to SMT (RR 0.74, CrI: 0.6–0.94) and ranked first on the cumulative ranking curves in three out of four outcomes. Other comparisons did not reach statistical significance. ELAD ranked first before PE for 1-month TFS. MARS performed better in the analyses for OS than for TFS. Quality of evidence was very low except for PE considering 1 month OS and both TFS outcomes with moderate certainty. Hepatic encephalopathy, laboratory parameters and safety were assessed in the systematic review.

Conclusion: This is the first network meta-analysis evaluating the effects of all available and tested artificial and bioartificial liver support therapies on survival in ACLF. Plasma exchange seemed to be the most beneficial for this patient population at present, but based on the low quality of evidence more and better-designed trials are needed refining evidence for already existing options and introducing new devices.

Intensive Care Medicine Experimental 2020, **8(2)**: 000601

Introduction: Chronic liver failure is frequently a terminal event unless there is a specific and potentially reversible precipitant such as variceal haemorrhage. Increasing organ failure carries a poor prognosis with renal failure having a “particularly high mortality”.

It has also been well-established that patients with or without a specific and potentially reversible precipitant have a mortality in excess of

89% when three or more organs (including the liver) have failed. Most available literature is from tertiary liver centres (1).

Objectives:

- Investigate the ICU-mortality of patients with liver cirrhosis referred to ICU in a district general hospital
- Assess the mortality within one year

Methods: Data was collected over a one year period from 1st April 2018 to 31st March 2019 by retrospectively reviewing patient notes, Wardwatcher[®], and ICU referrals audit data.

Patients were classed as having liver cirrhosis if they had documented biopsy or radiological evidence of liver cirrhosis before referral to ICU and had been reviewed in a hepatology clinic for management of chronic liver disease.

Results: 39 patients were referred to ICU with liver cirrhosis: 21 were admitted to ICU, 7 improved following an endoscopy, 2 were transferred to a specialist centre, 7 required level 1 care and 1 required end of life care.

15 patients were admitted to ICU due to decompensated liver cirrhosis, 6 were admitted for other reasons (e.g pneumonia). ICU mortality was 87% in the decompensated liver disease group and 93% at 1 year. All patients with cirrhosis admitted to ICU for other reasons survived ICU however 1-year mortality was 33%. 1-year mortality was 19% in the patients not admitted to ICU.

Conclusion: Patients with liver cirrhosis have a high mortality regardless of the reason for ICU admission. Most patients admitted to ICU with decompensated liver cirrhosis as their main problem died; no patients with liver cirrhosis died in ICU if their primary reason for admission was not related to liver cirrhosis.

We recommend that patients with liver cirrhosis should be assessed on an individual basis and be considered for ICU admission if there is a potentially reversible cause for their presentation. We advise ward-based teams to discuss with regional specialist centres at an early stage to assess whether an episode of decompensation is reversible (e.g. Transjugular Intrahepatic Portosystemic Shunt). Daily consultant reviews of patients could avoid late referrals, improve the rate of timely interventions and avoid the need for critical care.

Introduction: CytoSorb (CytoSorbents, USA) is a relatively new extracorporeal blood purification device. It was primarily used in septic shock and other hyperinflammatory conditions for removing inflammatory mediators, preventing the harmful effects of cytokine storm. Acute liver failure is a severe, devastating condition that usually necessitates intensive care. Data from the International CytoSorb Registry shows that Cytosorb is often used in liver failure to prevent the development of multiple organ failure.

Objectives: We report on the biggest case-series to date on CytoSorb use in liver failure as a subgroup from the International Cytosorb Registry.

Methods: The International CytoSorb Registry (NCT02312024) prospectively collects data from adult patients who underwent CytoSorb treatment. No exclusion criteria are defined. Data was recorded at baseline, up to 24 hours before treatment (T1), up to 24 hours after the last CytoSorb therapy (T2) and at discharge from hospital or mortality onelectronic case report forms. Descriptive statistical methods were used. Changes were calculated from T1 and T2 values using t-test as well as a linear model for selected variables. 95% confidence intervals (CI) were provided.

Results: From May 2015 until November 2019, 930 patients were entered into the Registry from 9 countries by 42 centres. In 89 cases the stated indication for therapy was liver failure, being the third most frequent indication after sepsis and pre-emptive use during cardiac surgery. In this subgroup the mean age was 48.2 years and the majority of patients were male (56.2%). Patients received a median of 2 treatments (i.e.: 2 adsorbers), with a median overall treatment duration of 43 hours. The median time of use per adsorber was one day and time between treatments was less than 1 hour (median).

More than 90% of patients were alive at the termination of CytoSorb therapy. Forty-seven patients died in the ICU and 3 more during hospitalization, which corresponds to a 57.5 % in-hospital mortality. Attending physicians observed improvement in 62 cases (70.4%). No change was registered in 15 cases (17%) and in 4 patients the condition worsened. SOFA scores hardly changed (T2-T1). Changes in CRP and PCT were not significant. Serum total bilirubin (TBIL) showed a significant reduction (T2-T1; mean [CI]: -61.7 [-92.7 to -30.8]). Regarding safety, device-related serious adverse events were not reported.

Conclusion: We report on the largest case series on CytoSorb application in patients with liver failure. The therapy proved safe, reduced TBIL significantly and resulted in subjective improvement in the patient's condition due to CytoSorb treatment in 70% of the cases. These encouraging results underline the need for randomized controlled trials assessing CytoSorb in liver failure.

Intensive Care Medicine Experimental 2020, **8(2)**: 000900

Introduction: Several studies have identified abnormal liver function tests (ALFT) during the clinical course of Covid-19. [1, 2] Acute liver injury (ALI) in Covid-19 patients may be caused by direct viral effects, systemic inflammatory response, drug toxicity or haemodynamic factors. There is currently no literature comparing incidences and characteristics of liver dysfunction between critically ill patients with and without Covid-19.

Objectives: To assess whether infection with Covid-19 has any impact on liver function in critically ill patients with respiratory failure who are infected with Covid-19 and is relevance for clinical outcomes.

Methods: This is retrospective cohort study of patients admitted to an intensive care unit (ICU) over 5 months. Laboratory data related to liver pathology and function (Alanine transferase (ALT), alkaline phosphatase (ALP), bilirubin, albumin, prothrombin time) was collected at day 1, 7 and 14 of admission. ALFT are defined as a rise in ALT/ALP greater than the normal limit, whereas ALI is defined as a rise in ALT/ALP by ≥ 3 times the upper limit of normal. Any ALFT or ALI cases were classified into hepatocellular, cholestatic, or mixed liver injury. Categorical data was assessed with χ^2 test and odds ratio (OR). The Mann-Whitney U test was used to assess continuous variables between patients infected with Covid-19 (as confirmed by positive viral PCR swab) and those who were not. *P* values lower than .05 were considered statistically significant.

Results: There were 256 admissions into intensive care during the study period. 132 (51.6%) was infected with Covid-19. ALFT was present in 80 (60.6%) of Covid-19 patients; 90% had a hepatocellular pattern, 10% had a mixed pattern and 2% was cholestatic. ALFT was present in 55 (44.4%) non-Covid-19 patients (*p* = .009, OR 1.9, 95% CI 1.2, 3.2). ALI was observed in 10.1% of non-Covid patients and 10.7% of Covid patients (*p* = .87). At day 1 of admission, Covid-19 patients had a median ALT of 44 (28, 78) compared to non-Covid-19 patients with a median of 29 (18, 58; *p* < .001). At day 7, Covid-19 patients had a median albumin of 17 (14-19) compared to 19.5 (16, 24, *p* = .01) in non-Covid-19 patients. On day 14, there was no significant differences in distribution of liver biochemistry or prothrombin time between the two cohorts. Within the Covid-19 group, there are no significant differences between patients with or without ALFT or ALI in 28-day mortality, requirement of renal replacement therapy, duration of mechanical ventilation or duration of vasoactive support

Conclusion: ALFT is more prevalent in Covid-19 patients compared to other patients with respiratory failure, and mainly with a hepatocellular pattern. Covid-19 patients may display poorer liver synthetic function in early stages of the disease (<14 days). There is no impact on clinical outcomes.

Intensive Care Medicine Experimental 2020, **8(2)**: 001008

Introduction: Acute-on-chronic liver failure (ACLF) was defined in the CANONIC study by acute development of one or more major complication of decompensated liver cirrhosis, plus organ failure and high risk of short-term mortality. ACLF is common, affecting approximately 30% of hospitalised cirrhotic patients and may develop in patients without previous decompensation. Precipitants include infection, alcoholic hepatitis and surgery, but in more than 40% of patients no precipitating event is identified. Clinical management focuses on treatment of a precipitant, whilst addressing the characteristic systemic inflammation and physiological disturbance of the critically ill patient with liver disease. Given the high risk of short-term mortality, much of the literature relates to the use of prognostic scores to contextualise the degree of ACLF organ failure and arguably the utility of critical care admission; with the CLIF-C ACLF score shown to have greater predictive accuracy in ACLF than other cirrhotic liver disease scoring systems.

Objectives: This study retrospectively identified patients with ACLF, admitted to our general adult critical care service (ICU), in order to review their admitting aetiology, level of organ support and survival. In addition, we sought to apply a range of available prognostic scores for cirrhotic liver failure to determine their efficacy.

Methods: The Intensive Care National Audit and Research Centre (ICNARC) database was searched for patients admitted to ICU at Oxford University Hospitals (OUH), between 1st April and 31st December 2019, with a diagnosis code of: liver cirrhosis, acute alcoholic hepatitis, encephalopathy, portal hypertension, or gastrointestinal/variceal haemorrhage. Also identified were cirrhotic patients with sepsis or acute renal failure by necessary association with these codes.

Review of these patient records identified patients with ACLF; including their clinical data, admission reason, survival to unit and hospital discharge, and 28- and 90-day mortality. CLIF-C organ failure, UKELD and Child-Pugh scores were calculated for time of critical care admission and, given their association with predicted mortality for a given score, compared between survivors and non-survivors with the aim of comparing prognostic ability. CLIF-C was also calculated with 48 hours post-admission data, to give delta-CLIF scores.

Results: 21 patients (M:F/13:8, median age 51 [38-76] years), were admitted to ICU due to ACLF – though this specific diagnosis was rarely made.

Stated admission cause included: remaining intubated post-endoscopy for upper gastrointestinal (UGI) haemorrhage (9/21, 43%), vasopressor treatment (5/21, 24%), invasive monitoring (4/21, 19%), reduced conscious level (2/21, 9.5%), palliative care (1/21, 4.5%). Commonest aetiology was gastrointestinal (GI) bleeding; variceal (7/21, 33%), non-variceal (1/21, 4.5%), lower GI (2/21, 9.5%). Other causes included bacterial infection (3/21, 14%), acute alcoholic hepatitis (3/21, 14%), ischaemic bowel (1/21, 4.5%). In four cases, no clear precipitant for ACLF was identified (4/21, 19%).

81% (17/21) were admitted with CLIF-C ACLF grade 3, 19% (4/21) admitted with ACLF grade 2; giving a median CLIF-C ACLF prognostic score of 68 [IQR 11.5], which, for the median age of 51 years, would convey 85% predicted mortality at 1 month and 95% at 3 months. Actual mortality at 48-hours was 48% (10/21), at ICU discharge, 67% (14/21), and hospital discharge, 28 day- and 90-day mortality rates were the same at 71% (15/21). Of 11/21 patients alive at 48 hours, median delta-CLIF organ failure score was 0 [IQR 2].

Median CLIF organ failure, UKELD and Childs-Pugh scores were compared between those patients alive at 28/90 days and those who had died: CLIF, 13 vs. 15 ($P=$.31); UKELD, 58 vs. 59 ($P=$.33); Childs-Pugh, 11 vs. 12 ($P=$.15).

Conclusion: Studied mortality was lower than predicted by the most well-validated prognostic score available in this context (CLIF-C ACLF). Possibly due to small sample size, the difference in severity between prognostic scores in survivors and non-survivors was not statistically significant – nor was the CLIF-C score shown to have superior prognostic ability. Unchanged average delta-CLIF scores was likely a result of the advanced degree of organ failure on admission, which is recognised to correlate with slower improvement in this context. Further prospective study of ACLF scores and outcomes, ideally in both referrals and admissions to critical care, are needed in order to understand the potential role for prognostic scoring in guiding critical care intervention.

Aneurysmal subarachnoid hemorrhage: A decade of surgical intensive care experience

N. Shaikh¹; K. Adnan²; K. Mohsin²; A. Aisha²

¹Hamad Medical Corporation, Doha, Qatar; ²Neurosurgery, Hmc, Doha, Qatar

Correspondence: N. Shaikh

Intensive Care Medicine Experimental 2020, **8(2)**: 000012

Introduction: Spontaneous subarachnoid hemorrhage (SAH) is one of the significant aetiologies for stroke. SAH causes higher morbidity, mortality with loss of productivity resulting in increased disease burden. A few studies about SAH are from the region and the epidemiological features of SAH and aneurysmal subarachnoid hemorrhage (aSAH) have not been comprehensively studied before in Qatar.

Objectives: Aim of our study was to describe the epidemiological profile of patients with SAH and aSAH in the State of Qatar

Methods: A retrospective chart review was performed for all spontaneous subarachnoid hemorrhage and/or ruptured aneurysm cases that were consecutively admitted to Hamad General Hospital (600 bedded tertiary care facility) during the period January 1, 2007 until December 31, 2016. A quantitative analysis of demographics, clinical characteristics, diagnostic findings, interventions and overall mortality was done. Data was entered in SPSS version 18. Chi square and student t tests were used to compare between the groups. *P* value of <0.05 was considered statistically significant.

Results: A total of 323 patients were included in the study composed of both aneurysmal and non-aneurysmal subarachnoid hemorrhage. Mean age at presentation was 47.4 ± 12.2 years. Men comprised 68.7% of the cases. 86.6% of the patients presented with acute onset headache. 217 patients had 1 aneurysm and 32 patients had multiple aneurysms. ACOMA (Anterior communicating artery) aneurysm was the most common aneurysm. Non Aneurysmal Subarachnoid hemorrhage occurred in 74 patients (22.9%) and was more common in men. 23.7% of the patients underwent microsurgical clipping of the aneurysm and 52.6% of the patients underwent coiling of the aneurysm. Overall mortality was less in WFNS 1 and 2 SAH than in higher grades (28.6% vs 71.4%). 69 out of a total of 323 patients died within 1 month post ictus, accounting for an overall mortality rate of 21.2% in our study.

Conclusion: The annual incidence of aneurysmal SAH in Qatar is on the rise. Males had a higher incidence of aSAH. ICA aneurysms have been found to be more common in Qatari women which may have a genetic basis. Lower WFNS grades of aSAH was associated with better prognosis. The overall mortality associated with aSAH in Qatar has declined over the last 3 years.

Status epilepticus: a retrospective observational study of current practice and outcomes at a single UK tertiary centre neurocritical care unit

B. Scally¹; A. Boyle¹; M. Blackstock¹

¹Intensive care unit, western general hospital, NHS Lothian, Edinburgh, United Kingdom

Correspondence: B. Scally

Intensive Care Medicine Experimental 2020, **8(2)**: 000034

Introduction: Evidence for the treatment of refractory and super-refractory status epilepticus in intensive care is mostly based on case reports and small case series; there is a strong imperative to publish larger cohorts and share data on clinical outcomes.

Objectives: To describe the demographics, management, and outcomes of patients with status epilepticus requiring critical care support at a single UK tertiary centre neurocritical care unit.

Methods: A retrospective observational study of all consecutive patients admitted with status epilepticus to intensive care for level two or level three organ support at the Western General Hospital, Edinburgh over a five year period (Jan 1st 2014 - Dec 31st 2019).

Results: During the study period, there were 141 admissions to intensive care from 133 unique patients with a confirmed diagnosis of status epilepticus. 56% of patients were male; mean average age at admission was 51 years; and mean average length of stay was nine days. The mean average APACHE II score for the study population was 16 corresponding to a predicted non-operative mortality of 25%. The actual observed mortality in our study population was only 15%. Mortality was higher among patients admitted following out-of-hospital cardiac arrest or neurosurgical procedures and lower for patients with a pre-existing diagnosis of any epilepsy syndrome. The drug treatments most frequently prescribed for each step of management were

as follows: (1) benzodiazepines; (2) phenytoin; (3) levetiracetam; (4) midazolam infusion; and (5) phenobarbitone or thiopentone coma. Overall, 74% of patients required general anaesthesia and mechanical ventilation. 46% of patients received formal EEG testing and 10% were diagnosed with super-refractory status epilepticus treated with formal burst suppression. The observed mortality among patients with super-refractory status epilepticus was 29%.

Conclusion: Mortality in patients admitted to intensive care with status epilepticus is higher following out-of-hospital cardiac arrest and neurosurgical procedures. More than 70% of patients in super-refractory status epilepticus at our site survived to hospital discharge.

Correspondence: V. Papaioannou

Intensive Care Medicine Experimental 2020, **8(2)**: 000127

Introduction: Delayed cerebral ischemia (DCI) constitutes a major complication following subarachnoid hemorrhage (SAH) and is partly associated with vasospasm (VS) and impaired cerebral autoregulation. Different surrogate markers of cerebral blood flow (CBF), such as non-invasive transcranial doppler (TCD), are frequently used to monitor development of VS, as well as integrity of autoregulation. In this respect, different physiological parameters can be estimated, such the dynamic index of autoregulation Mxa, which is a moving correlation coefficient between spontaneous fluctuations of cerebral blood flow velocity (CBFV) and arterial blood pressure (ABP). A positive correlation signals disturbed autoregulation. Other indices include cerebral arterial time constant (τ) that reflects arterial filling time distal to insonation vessel and critical closing pressure (CrCP), which estimates the theoretical lowest value of ABP that is needed for maintaining CBF.

Objectives: We investigated how VS affects different TCD-derived indices of cerebrovascular dynamics in patients suffering from SAH. Secondly, we explored the potential differences of such VS-associated changes between subgroups of patients with and without DCI, in both temporal and spatial settings.

Methods: A retrospective analysis was performed using recordings from 32 SAH patients, admitted to the Neurocritical Care Unit at Addenbrooke's Hospital, in Cambridge, UK, diagnosed with VS through bilateral TCD measurements. Patients were divided in 2 groups, depending on development of DCI (DCI group, N=19 vs non-DCI group, N=13). Cerebral autoregulation was estimated using the index Mxa. We also measured τ as the product of arterial resistance (Ra) and compliance (Ca) and estimated CrCP, as the intercept point of a regression line between systolic and diastolic ABP plotted along the x axis and systolic and diastolic CBFV plotted along the y axis.

Results: In the whole population, VS caused shortening of τ (ipsilateral to spasm: 0.17 ± 0.08 vs before spasm: 0.25 ± 0.17 sec, $p = 0.04$), decrease in CrCP (ipsilateral to spasm: 9.69 ± 23.28 vs before: 27.23 ± 23.31 mmHg, $p = 0.01$) and interhemispheric asymmetry with lower values on ipsilateral side ($p < 0.01$). Ipsilateral CrCP during VS was negatively correlated with Mxa ($r = -0.43$, $p = 0.01$) and positively correlated with τ ($r = 0.74$, $p < 0.001$). In patients with DCI, VS caused increase in Mxa (ipsilateral to spasm: 0.36 ± 0.18 vs before: 0.26 ± 0.23 , $p = 0.04$), decrease in CrCP (ipsilateral to spasm: 6.61 ± 24.5 vs before: 17.24 ± 19.4 mmHg, $p = 0.04$) and lower values on ipsilateral side ($p < 0.01$).

Conclusion: VS was associated with reduced tau and CrCP in both temporal and spatial assessments, in all patients with SAH. Impaired autoregulation and shortened tau correlated with decreased CrCP. VS in patients who developed DCI, reduced CrCP (temporal and spatial effect) signifying vasodilatation, and increased Mxa, reflecting disturbed autoregulation.

A safe strategy for early weaning and tracheostomy avoidance in cervical spinal cord injury: a single-center experience

M. Guarnieri¹; F. Fossi²; F. Pozzi²; F. Curto²; A. Chierigato²
¹Department of medicine and surgery, university of Milano bicocca, Milan, Italy; ²Department of neurointensive care, ASST Great Metropolitan Niguarda, Milano, Italy

Correspondence: M. Guarnieri
Intensive Care Medicine Experimental 2020, **8(2)**: 000145

Introduction: High cervical spinal cord-injured (C-SCI) patients experience severe disability and are at risk of ventilator-dependency and tracheostomy(1,2). In the acute phase, they need invasive ventilator support. Conventional weaning parameters such as P 0-1, pressure muscleindex (PMI)(3) and negative inspiratory force (NIF) are not always informative in C-SCI, because most of them will not match the conventional targets and still undergo successful weaning. The global incidence of tracheostomy in C-SCI varies widely among the different studies, and is described up to 60%, with a higher risk in males, AIS A grade, upper C-SCI, high injury severity score (ISS), GCS≤8, thoracic injury, and patients with respiratory complications(4). Some studies suggest that the use of non-invasive mechanical ventilation (NIMV) and mechanically cough assist (MAC) can allow extubation without further complications(5).

Objectives: To retrospectively assess the safety and efficacy of an aggressive respiratory approach with early extubation coupled with NIMV, MAC, and intensive nursing assistance on C-SCI patients (C3 to C6 SCI).

Methods: This was a single-center retrospective study. Clinical records of the patients with spinal cord injury from January 2018 to December 2019 were revised. All the patients with cervical spinal cord injury were included, with no limits of age or comorbidities.

Standard management of quadriplegic patients in our department is based on aggressive respiratory management, early extubation, NIMV and MAC performed regularly at least 4 times a day; the clearance of respiratory secretions is also facilitated by alternated side positioning.

Results: Twenty-five patients with acute cervical spinal cord injury were admitted to our department in the study period. Age was 39 ±17 years and 72% of them were male. Full data of the initial population are shown in Table 1. Twenty-four of them were traumatic, 1 ischemic. Median ISS in traumatized patients was 25 and most of the patients (80%) were isolated cervical traumas. The full data of the initial population are shown in table 1.

All patients except 2, were intubated, only 3 patients (12%) were tracheostomized. Five patients (20%) failed an extubation trial, only 1 of them underwent a tracheostomy. In one of the tracheostomized patients, our protocol was not applicable because it came from another hospital three months after the trauma. Among patients who failed the extubation trial, 3 came from other hospitals, 2 were treated in our institution from the beginning. The extubation failure rate in patients admitted to our institution first was 8%. One patient was diagnosed with pneumonia, while another patient experienced complete atelectasis of a pulmonary lobe, treated with bronchoscopy. The incidence of tracheostomy was different according to the level of lesion, being (50%) in C3 lesion, 28% in C4 lesion and 0 in the lower levels. ASIA A patients underwent tracheostomy in the 8% of cases, ASIA B in the 28%, while no ASIA C patient received a tracheostomy. At

1-year follow-up (when available) no new tracheostomy has been performed, no urgent re-admission to ICU occurred for any reason. The intubation rate at admission was 23/25 (92%). An extubation trial was performed in 21/25 patients (84%).

Table 1. Demographic data. Data are presented as N(%) or mean ±standard deviation where appropriate.

Age		39±17
Level of lesion		
	C3	2 (8%)
	C4	7 (28%)
	C5	10 (40%)
	C6	6 (24%)
ASIA		
	A	12 (48%)
	B	7 (28%)
	C	6 (24%)
Traumatic injury		24 (96%)
ISS		27±4.5

List of abbreviations. ASIA: American Spinal Injury Association – ISS: Injury Severity Score.

Conclusion: We present a C-SCI group of patients, with a lower rate of tracheostomy compared to current evidence(1,4,6,7), and a low rate of respiratory complications, such as pneumonia or atelectasis. Our data suggest that an aggressive weaning program tailored to specific patient’s needs could lead to a higher rate of respiratory autonomy without side effects.

Comparative analysis of serum iron in patients with favorable and unfavorable outcomes of the treatment of traumatic brain injury

D. Markevich¹
¹Department of Anesthesiology and Resuscitation, Mogilev City Emergency Hospital, Mogilev, Belarus

Correspondence: D. Markevich
Intensive Care Medicine Experimental 2020, **8(2)**: 000147

Introduction: TraumaTraumatic brain injury (TBI) is considered as a generalized process in which a systemic inflammatory response syndrome often develops [1]. Iron is a co-factor of metalloproteases and its metabolism is actively changing with multiple organ dysfunction [2,3]. Monitoring changes of serum iron is very interesting as a prognostic criterion of treatment outcome in patients with head injury [4].

Objectives: To study the dynamics of serum iron in patients with head injury in the postoperative time and its potential in predicting treatment outcome.

Methods: A prospective study was held from 01.05.2018 to 31.12.2019. The ethics committee received permission for this study. 76 adult patients (13 women and 63 men) who needed surgical treatment of traumatic brain injury were included in the study. The age of the patients was 54 (43.5; 60) years. 45 patients underwent general anesthesia, and 31 patients underwent combined general anesthesia and scalp block with using small volumes (0.5-1 ml for one nerve) 0.75% ropivacaine. General anesthesia was total intravenous anesthesia using propofol and fentanyl. In 3-6 months after craniotomy the Glasgow Outcome Scale (GOS) was taken for rating the outcome of treatment in patients with head injury. The treatment outcome was unfavorable 1-3 points by GOS (1 - patient's death, 2 - vegetative state, 3 - severe disability). The treatment outcome was favorable at 4 or 5 points by GOS (4 - the possibility of self-care, 5 - full recovery). Two groups of patients were formed. Group 1 included 46 patients with a favorable outcome, and group 2 included 30 patients (of whom 17 patients (56.7%) died) patients with an unfavorable outcome.

The groups of patients did not differ in age, weight, sex, method of anesthesia. Patients of groups 1 and 2 significantly reliably differed at the volume of intracranial hematomas, the intraoperative bleeding and estimated Glasgow Coma Scale (in group 1 - 14 (11; 15) in group 2 - 7 (6; 10)), $p < 0.05$.

Serum iron was compared between groups 1 and 2. A BA 400 Biosystems biochemistry analyzer (Spain) was used for analysis of serum iron. The reference values of serum iron was 11.6-31.3 $\mu\text{mol/l}$. Blood sampling was performed 1-2 hours before the operation, and further in 11 (6; 17) hours on the 1st day after the operation, then in 35 (29; 40) hours on the 2nd day, in 60 (52; 65) hours on 3 day, after 108 (100; 113) hours on the 5th day, in 155 (148; 161) hours on the 7th day and in 226 (220; 233) hours on the 10th day after craniotomy.

Statistical analysis was performed by Statistica 8.0 and Microsoft Excel 2007. The normal distribution was checked using the Shapiro-Wilk's test. Nonparametric methods were used to test the significance of statistical hypotheses. Descriptive statistics are presented as medians and lower and upper quartiles Me (LQ; UQ). The hypothesis of a statistically significant difference in the independent groups was tested using the Mann-Whitney test. The determination of serum iron as an unfavorable classifier of outcome was evaluated using logistic regression with the construction of ROC-curves and calculating the area (AUC), sensitivity (Se) and specificity (Sp).

Results: Significant differences in the serum iron between patients of groups 1 and 2 were revealed on the 5th, 7th and 10th days after the operation. Before surgery, the serum iron in patients of group 1 was 13.5 (5; 17) $\mu\text{mol/l}$, in group 2 it was 7.7 (6.5; 14.3) $\mu\text{mol/l}$, $p = 0.82$. On the 1st day after the operation, in group 1 the iron was 6.6 (4.2; 13.7), and in group 2 it was 7.5 (5.5; 13.2) $\mu\text{mol/l}$, $p = 0.48$; on 2th day after surgery in group 1 - 3.9 (2.8; 6.6), and in group 2 - 4.9 (2.8; 8.1) $\mu\text{mol/l}$, $p = 0.61$; on 3th day in group 1 - 5.1 (2.7; 7.6), and in group 2 - 3.1 (2.3; 5.6) $\mu\text{mol/l}$, $p = 0.12$; on 5th day after surgery in group 1 - 6.1 (2.6; 14.5), and in group 2 - 2.5 (1.9; 5.2) $\mu\text{mol/l}$, $p = 0.02$; on 7th day in group 1 - 7.3 (4; 13.5) $\mu\text{mol/l}$, $p = 0.02$; on the 10th day after craniotomy in group 1 the iron was 7.3 (3.6; 12.3), and in group 2 - 3.6 (1.9; 5.7) $\mu\text{mol/l}$, $p = 0.03$.

Using logistic regression, a statistically significant difference was revealed between patients of groups 1 and 2 in serum iron on 5th and 10th days after the operation for an unfavorable outcome. On 5th day: AUC 0.71, sensitivity (Se) 70.6%, specificity (Sp) - 65.2%. On 10th day: AUC 0.73, Se 75%, Sp - 60%.

Conclusion: 1. Patients with an unfavorable outcome of treatment's TBI on the 5th, 7th and 10th days after craniotomy revealed significantly lower level of serum iron than in patients with a favorable outcome.

2. Lower value serum iron starting 5th day after craniotomy can be considered a predictor of an unfavorable outcome in the treatment of patients with TBI.

Malnutrition in patients with ischemic stroke

A. Gritsan¹; N. Dovbysh¹

¹Anaesthesiology and intensive care, Krasnoyarsk State Medical University, Krasnoyarsk Regional Clinical Hospital, Krasnoyarsk, Russia

Correspondence: A. Gritsan

Intensive Care Medicine Experimental 2020, **8(2)**: 000157

Introduction: It is known that patients with ischemic stroke may have nutritional deficiency. However, the frequency of its occurrence, primarily at the beginning of the disease and the possible connection with mortality remain issues of discussion.

Objectives: To assess the incidence of malnutrition in patients with ischemic stroke at the beginning of the disease and its relationship with mortality in these patients.

Methods: An observational study was conducted of patients with IS admitted to the NICU within 1 randomly selected month. The criterion for exclusion from the study was the presence of a terminal stage of cancer. A total of 84 patients were included in the study, of which 61 (73%) were women and 23 (27%) were men. The age of the patients is 71.5 [68.0; 80.8] years. All patients on admission were evaluated on the Nutritional Risk Screening (NRS) scale. Estimated height, weight of patients, calculated body mass index (BMI). Data are presented as median and 25% and 75%. Statistical analysis was performed using the χ^2 criterion.

Results: The weight of patients at admission was 76.5 [66.3; 88.0] kg, body mass index (BMI) - 27.5 [26.8; 28.5]. When assessing the presence of risk factors for malnutrition according to the NRS 2002, the only risk factor was hospitalization in the intensive care unit. In the final assessment, in 57 (68%) patients, the total score was more than 3 due to the following parameters - age over 70 years and the presence on the APACHE II scale of more than 10 points. From these 16 (19%) patients were diagnosed with mild malnutrition due to a decrease in the absolute number of lymphocytes. Moderate and severe malnutrition were not diagnosed in these patients.

12 (14.3%) patients died. Of these, 7 (43.8%) patients died in the group of patients with mild malnutrition. It is significantly higher than in the group of patients without malnutrition ($\chi^2 = 14.013$, $p = 0.001$).

Conclusion: Patients with ischemic stroke have at admission a low risk of malnutrition assessed according to the INR 2002. The presence of mild malnutrition in patients with IS is due to the age of patients older than 70 years and the presence of an APACHE II score of more than 10 points. Mortality in patients with mild malnutrition is significantly higher than in patients without malnutrition.

A Retrospective Review of Intensive Care Admissions with Acute Ischaemic Stroke in an Irish Tertiary Referral CentreD. Edgeworth¹; O. Nichoileann¹; D. O'leary²; G. Curley¹; RA. O'leary¹¹Anaesthesiology & Critical Care, Beaumont Hospital, Dublin, Ireland;²School of medicine, University College Dublin, Dublin, Ireland**Correspondence:** D. Edgeworth*Intensive Care Medicine Experimental* 2020, **8(2)**: 000198

Introduction: Acute Ischaemic Stroke (AIS) remains a significant cause of morbidity and mortality worldwide. With increasingly advanced techniques for reperfusion and prevention of secondary injury, the role of intensive care management in AIS is expanding. Beaumont Hospital, Dublin is the national neurosurgical and interventional neuroradiology referral centre in the Republic of Ireland with 17 Intensive Care beds. There were 2531 ICU admissions across all categories during this time period.

Objectives: The study sought to review the number and nature of admissions, baseline characteristics, interventions and outcomes of patients with AIS and compare these to international data.

Methods: A retrospective review of admissions from January 2017 to July 2019 was performed using standard data points collected by the National Office of Clinical Audit (NOCA). Approval for retrieval and assessment of data was granted by NOCA. Patients with a primary admission diagnosis of AIS were included. Other causes of cerebrovascular accident including subarachnoid haemorrhage were excluded. Eighty-seven pre-determined data points were examined. Statistical analysis was performed in RStudio, Version 1.1.456. Results are presented as percentages, mean/median and 95% Confidence Interval as appropriate.

Results: 68 patients were admitted in this period with a primary diagnosis of AIS. 34% were female. Mean age was 60 years (95% CI 58.8-61.2). The MCA territory was implicated in 38% cases.

16% of patients presented locally. Referring hospitals ranged from 5.6 to 243 kilometres in distance from our centre.

Thrombectomy was performed in 36 patients (52%). The majority of patients (89.7%) were mechanically ventilated. The median mechanical ventilation days was 4 (range 1-22 days). Tracheostomy was performed in seven patients. The majority of patients in this group had posterior circulation involvement. 43% of patients were treated for hyperglycaemia.

Median Intensive Care length of stay was 6 days (range 1-26 days). 63% of patients survived to ICU discharge. Middle Cerebral Artery decompression was performed in 16 patients (24%). This group of patients had a lower median age, higher rates of stroke-associated pneumonia and a similar survival to ICU discharge. Increasing age was associated with reduced survival to ICU discharge (OR 0.94; CI 0.90-0.99; $P = 0.02$). Other variables such as body mass index, hyperglycaemia, mechanical ventilation days and ICU length of stay did not reach statistical significance. This may be reflective of the relatively small study numbers.

Conclusion: This data confirms the high acuity and treatment burden posed by this evolving group of patient. Rates of mechanical ventilation, pneumonia and ICU mortality were similar to data previously reported (1). Increasing age was predictive of ICU mortality.

Purine metabolites, magnesium, corticosteroid and thyroid hormones, lethal outcome in acute cerebrovascular pathologyE. Oreshnikov¹; S. Oreshnikova¹; A. Oreshnikov²¹Anaesthesiology & intensive care, Chuvash State University namedI.N.Ulyanova, Cheboksary, Russia; ²Internal medicine, Chuvash State University named I.N.Ulyanova, Cheboksary, Russia**Correspondence:** E. Oreshnikov*Intensive Care Medicine Experimental* 2020, **8(2)**: 000270

Introduction: We study the possibility of predicting the onset of death with the help of various hormonal and metabolic indicators in the acute period of cerebral stroke.

Methods: In 626 adult patients in the acute period of cerebral stroke (regardless of its type, variant, etc.) who were treated in the intensive care unit, along with generally accepted instrumental and laboratory tests, in cerebrospinal fluid and venous blood samples colorimetric determination of adenine, guanine, hypoxanthine, xanthine, uric acid, magnesium was carried out, enzyme-linked immunosorbent assay for cortisol and dehydroepiandrosterone, thyroid-stimulating hormone, thyroxine and triiodothyronine.

Results: The most specific factors were: increased concentration of uric acid in the blood serum on the 1st and 3rd day of stroke (0.89 and 0.98), combination of an increased content of uric acid in blood serum and cerebrospinal fluid on the 1st and 3rd day of a stroke (0.90 and 0.97); reduced guanine in cerebrospinal fluid (0.84) on the 3rd day of stroke; increased content of free fractions of triiodothyronine and thyroxine on the 1st day of stroke (0.86 and 0.76). The relative risk of a fatal outcome is high when a stroke of increased concentration in the blood serum of cortisol is detected on the 1st and 3rd day (3.25 and 7.39); increased content of hypoxanthine (2.49), xanthine (2.49) and uric acid (3.53) on the 3rd day of stroke, a combination of increased serum uric acid and cerebrospinal fluid (2.71). The highest chances of a fatal outcome when a stroke is detected on the 1st day of a stroke are elevated concentrations of cortisol and free thyroxine in blood serum (OR 4.98 and 2.59, respectively), uric acid in cerebrospinal fluid (OR 2.79); when a stroke concentration of adenine (OR 2.61), guanine (OR 3.75), hypoxanthine (OR 4.55), xanthine (OR 3.60), urine is detected in the blood serum on the 3rd day of a stroke acid (OR 20.0), cortisol (OR 10.4), a combination of high uric acid in blood serum and cerebrospinal fluid (OR 23.3).

Conclusion: In patients in the acute period of cerebral stroke (regardless of its type), indicators of the purine spectrum, stress-adaptive hormonal status are highly informative factors in predicting the onset of a fatal outcome. The most prognostically "powerful" of the studied parameters is the blood level of uric acid.

Purine metabolites, magnesium, corticosteroid and thyroid hormones, lethal outcome in acute cerebral ischemia: diagnostic and prognostic aspectsE. Oreshnikov¹; S. Oreshnikova¹; A. Oreshnikov²¹Anaesthesiology & intensive care, Chuvash State University namedI.N.Ulyanova, Cheboksary, Russia; ²Internal medicine, Chuvash State University named I.N.Ulyanova, Cheboksary, Russia**Correspondence:** E. Oreshnikov*Intensive Care Medicine Experimental* 2020, **8(2)**: 000272

Introduction: We study the possibility of predicting the onset of a fatal outcome using various hormonal and metabolic parameters in acute cerebral ischemia.

Methods: In 402 adult patients in the acute period of cerebral ischemic stroke, who were treated in the intensive care unit and intensive care unit of the angioeurological department, along with generally accepted instrumental and laboratory tests, colorimetric measurements of adenine, guanine, hypoxanthine, xanthine were carried out in samples of cerebrospinal fluid and venous blood uric acid, magnesium, malondialdehyde. Based on the concentration ratio of uric acid / xanthine, xanthine / hypoxanthine, uric acid / hypoxanthine, the activity of the first and second stages of the xanthine oxidase reaction and the total xanthine oxidase activity were calculated. Enzyme immunoassays examined the levels of cortisol and dehydroepiandrosterone, thyroid stimulating hormone, thyroxine and triiodothyronine.

Results: The most sensitive predictors of lethal outcome of ischemic stroke were: increased xanthine concentration on the 1st and 3rd day of stroke (0.83 and 0.76), reduced xanthine oxidase activity (in the second stage of the xanthine oxidase reaction - 0.61). Among the most specific such factors: an increased concentration of uric acid in the blood serum on the 1st and 3rd day of a stroke (0.91 and 0.98), a combination of an increased content of uric acid in the blood serum and cerebrospinal fluid on the 1st day of a stroke (0.93). The relative risk of death is highest when a stroke concentration of uric acid in the blood serum is detected on the 3rd day (3.93). The highest chances of a fatal outcome when a stroke is detected on the 3rd day of an elevated blood serum uric acid (OR 21.5), adenine (OR 3.55), guanine (OR 3.27); a combination of increased serum uric acid and cerebrospinal fluid (OR 3.37), increased serum uric acid (OR 2.87), decreased xanthine oxidase activity in the second stage of the xanthine oxidase reaction on the 1st day of stroke (OR 2.67).

Conclusion: In patients with acute cerebral ischemia in the acute period of cerebral ischemic stroke, the most prognostically "powerful" lethal outcome factors are uric acid level and xanthine oxidase activity.

Spontaneous Subarachnoid Hemorrhage: Impact of Demographic, Clinical and Monitoring Data in Patient Outcome

D. Cruz¹; J. Fernandes²; E. Monteiro²

¹Faculty, Faculty of Medicine of Porto University, Porto, Portugal; ²Intensive care medicine department, São João University Hospital Center, Porto, Portugal

Correspondence: D. Cruz

Intensive Care Medicine Experimental 2020, **8(2)**: 000294

Introduction: Subarachnoid Hemorrhage (SAH) is a medical emergency and the most frequent etiology is a ruptured aneurysm. It remains a major cause of morbidity and mortality due to the initial insult but mainly as a result of secondary brain injury (SBI). Multimodal Monitoring provides an individualized care at bedside, giving tools to guide therapeutic interventions, preventing or minimizing SBI.

Objectives: To identify possible factors with impact in outcome in patients admitted with spontaneous SAH.

Methods: A retrospective case-series study that included all patients with SAH admitted to a Neurocritical Unit (NCCU) of a tertiary hospital at intensive care level between the first January 2018 and the 30th June 2019. Primary outcome was defined by Glasgow Outcome Scale at discharge from NCCU and at 28, 90 and 180 days after the event.

Results: Forty-six patients (29 females) were included. Median age was 55.5 years (50.0-63.3). In 41 patients an aneurysm was identified. The most frequent aneurysm locations were Anterior Communicating Artery and Middle Cerebral Artery, in 11 (23.9%) and 9 (19.6%) cases, respectively. The median length of stay in the NCCU at intensive care level was 20.5 (4.8-31.0) days. Fourteen (30.4%) patients were submitted to neuroradiology procedure. No patient submitted to neuroradiology procedure had a bad outcome at six months. At all moments of follow-up, Glasgow Coma scale (GCS) at admission, Hunt & Hess (H&H) scale, duration of invasive ventilation (IMV) and delayed cerebral ischemia (DCI) had an association with patients' outcome ($p < 0.05$). The three deaths (6.5%) recorded occurred during NCCU stay: two patients with severe SAH (GCS of 3, Fisher scale of 4 and H&H scale of V) and a third patient who developed many complications (hydrocephalus, re-bleeding and vasospasm requiring intra-arterial administration of verapamil), despite admission with GCS of 15, Fisher scale of 4 and H&H of II.

Association between variables and outcome				
	At Discharge from NCCU (p value)	At the 28th day (p value)	At the 90th day (p value)	At the 180th day (p value)

Bad Outcome (GOS 1, 2 and 3)	25 (54.3%)	25 (55.6%)	13 (32.5%)	6 (23.1%)
Good Outcome (GOS 4 and 5)	21 (45.7%)	20 (44.4%)	27 (67.5%)	20 (76.9%)
Total of patients included	46 (100.0%)	45 (100.0%)	40 (100.0%)	26 (100.0%)

Conclusion: SAH related complications were common and associated with worse outcomes, therefore treatment approach should be focused on its avoidance and prompt resolution. Endovascular treatment had better outcomes at six months than surgical intervention.

Introduction: Chronic hydrocephalus (CH) is a common and potentially modifiable complication of spontaneous subarachnoid hemorrhage (SAH) requiring prompt treatment for optimal outcomes. Risk factors for CH have been extensively investigated, but reliable scores to predict shunt dependency after aneurysmal SAH (aSAH) are scarce. A newly developed shunt dependency in aSAH (SDASH) score based on the combination of acute hydrocephalus (aHP), Hunt and Hess grade, and Barrow Neurological Institute (BNI) score was found to be a reliable tool for predicting shunt-dependent hydrocephalus (SDHC). This prediction model, however, was based on a single-center retrospective population.

Objectives: The present study was designed to validate the SDASH score in an external cohort of aSAH patients.

Methods: The study population included 214 of 249 (85.9%) patients with aSAH admitted to our hospital (2016-2019). In each patient, the SDASH score, the Hijdra score, the BNI score, the chronic hydrocephalus ensuing from SAH score (CHESS), the Graeb, and the modified Graeb score (mGS) were calculated, and the reliability of these models were compared. Logistic regression analysis was used to determine the reliability of the SDASH score, and the area under the receiver operating characteristics (ROC) curve (AUC) to assess the discrimination capacity of the model.

Results: 40 patients (18.7%) developed SDHC. Older age, high Hunt and Hess grade, high grade of the WFNS classification scale, EVD placement, ventricular hemorrhage, CSF daily output and higher bicaudate index, correlated significantly with an increased rate of ventriculo-peritoneal shunt insertion. The AUC for SDASH score was 0.816. The SDASH score reliably predicted SDHC in aSAH (odds ratio of 2.93; 95% confidence interval 1.99-4.31; $p < 0.001$). No statistically significant differences were found between SDASH score and the other predictive scores.

Conclusion: The SDASH score was found to be a reliable tool for predicting SDHC and could be used in daily practice. The SDASH score may be added to the list of other scores such as CHESS, Graeb, or mGS which may help to early management of hydrocephalus in aSAH.

Introduction: Delayed cerebral ischemia (DCI) is a major contributor to the high fatality and morbidity case rates of aneurysmal subarachnoid hemorrhage (SAH). About 30% of the SAH patients develop DCI but it is difficult to predict which patients will develop it.

Objectives: To assess the development of DCI risk factors in patients with SAH, admitted in a Neurotraumatic ICU.

Methods: Prospectively collected data of patients admitted from October, 2013 to December 2019 to a 10-bed Neurotraumatic ICU. We analyzed: main diagnosis at admission; demographic data including sex and race; neurological data (clinical examination, pupils reactivity and size, and Glasgow Coma Score: GCS; localization and aneurysm size; presence of intracranial hematoma (ICH); presence and volume of intraventricular bleeding; days to develop vasospasm; development of DCI; Fisher scale, Modified Fisher scale (MFS), Hunt and Hess scale (HHS), Word Federation of Neurosurgeons (WFNS) scale; presence of vasospasm in doppler arteriography; delayed of admission in ICU; treatment of the aneurysm; complications, including infections; Glasgow Outcome Scale (GOS) at ICU discharge and 6 months after ICU discharge and several other risk factors. A univariate analysis of DCI was performed. To obtain a predictive rule for the DCI, a model for the prediction was obtained using the classification and regression trees (CART) procedure [1]. CART classifies data using a sequence of if-then rules. The basis of the decision tree algorithms is the binary recursive partitioning of the data. The most discriminative variable is first selected to partition the data set into child nodes. The splitting continues until some stopping criterion is reached. At each terminal node, the probability of DCI was estimated as the proportion of patients belonging to that node that developed the event. The tree was constructed according to the following algorithm: in the first stage, the tree grows until all cases are correctly classified, and in the second stage, we used the tenfold cross-validation method of successive pruning [1]. Finally, the tree that minimized the error measurement (deviance) was chosen. For this predictor the corresponding ROC curve was obtained and the AUC was estimated by means of a 95% CI. **Results:** One hundred forty two SAH patients were collected, 32 (22.5%) of them developed DCI. Demographic data and types of admission are shown in Table 1a and 1b.

SDC: selective digestive decontamination; MV: mechanical ventilation; ICH: intracerebral hemorrhage; DCI: delayed cerebral ischemia; GOS: Glasgow outcome score; WFNS: World Federation Neurological Societies; COPD: Chronic obstructive pulmonary disease; RRT: renal replacement therapy

Figure 1. Deviance according the number of nodes. Thus, the optimal tree has three nodes

Conclusion: Our data show 22,5 % of our studied patients had DCI. GOS reflected low disability of DCI patients both at ICU discharge and six months later. Classification tree showed: HHS 1 has a high probability of not having DCI. MFS >3 and HHS >1 have probabilities of around 30% of DCI. Finally, mortality was not significantly greater in the studied patients.

Anterior communicating (Aco) artery aneurysms were the most frequently found and most of them were located in the left side. The most frequent DCI patient complications were stroke 24 (75%) and hydrocephalus 18 (56.2%). GOS at ICU discharge was 4 and, six months after ICU discharge, was 5 in patients with SAH. Patients who developed DCI had GOS at ICU discharge of 4 and it was also 4 six months later. Also 19 (59,37%) had GOS > 3 at ICU discharge. Thirty two (22.9%) SAH patients died. Seven (22.6 %) DCI patients died. There was not statistical significant difference in mortality in DCI vs SAH patients. Classification tree showed:HHS 1 has a high probability of not having DCI.MFS >3 and HHS >1 have probabilities of around 30% of DCI.

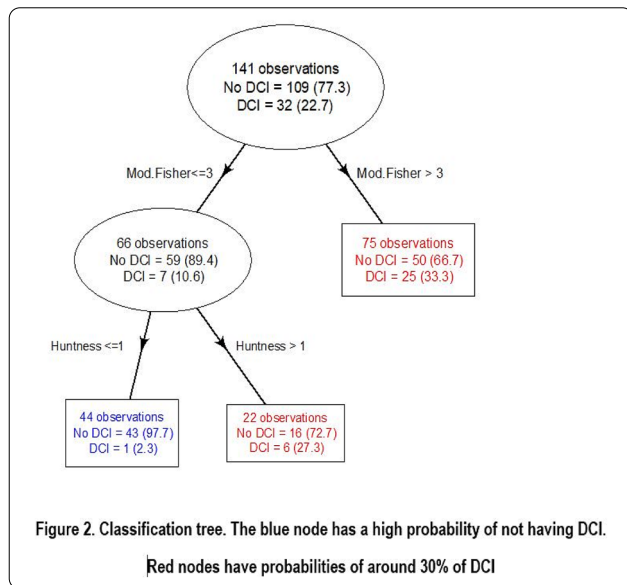

Figure 2. Classification tree. The blue node has a high probability of not having DCI.

Red nodes have probabilities of around 30% of DCI

Introduction: Aneurysmal subarachnoid hemorrhage (SAH) is a worldwide health burden with serious outcomes such as permanent disability. It is important to learn the disability risk factors and identify those potentially preventable, to reduce them.

Objectives: To assess disability risk factors in patients admitted with subarachnoid hemorrhage (SAH), admitted in a neurotraumatic ICU.

Methods: Prospectively collected data of patients admitted from October, 2013 to December 2019 to a 10-bed Neurotraumatic ICU. We analyzed: main diagnosis at admission; demographic data, including sex and race; neurological data (clinical examination, pupils reactivity and size, and Glasgow Coma Score (GCS)); location and aneurysm size; presence of intracranial hematoma (ICH); presence and volume of intraventricular bleeding; days to develop vasospasm; development of delayed cerebral ischemia (DCI); Fisher scale, modified Fisher scale, Hunt and Hess scale, Word Federation of Neurosurgeons (WFNS) scale; presence of vasospasm in doppler or arteriography; delayed admission in ICU; treatment of the aneurysm; complications, including infections; Glasgow Outcome Scale (GOS) at ICU discharge and 6 months after ICU discharge and several other risk factors. Disability was defined as GOS ≤ 3. In order to identify those factors that maintain independent association with disability, a multivariate logistic regression analysis was performed. It was considered significant if p ≤ .05.

Results: Among 152 SAH admitted patients, 58 (38.15%) out of 94 patients had GOS ≤ 3. Univariate analysis is shown in Table 1a and 1b

GCS in emergency room	15.0 (13.0 - 15.0)	8.5 (6.0 - 13.0)	< .001
GCS at ICU admission	15.0 (8.8 - 15.0)	5.5 (3.0 - 8.0)	< .001

Values are frequencies (%), means ± SD and medians (IQR). SDD: selective digestive decontamination, MV: mechanical ventilation, ICH: intracerebral hematoma, DCI: delayed cerebral ischemia, GOS: Glasgow outcome score, WFNS: World Federation Neurological Societies, COPD: Chronic obstructive pulmonary disease, RRT: renal replacement therapy

Twenty four SAH patients (16.1%) died at ICU discharge. Decompressive craniectomy was performed in 7 (4.7 %) SAH patients, all of them with GOS ≤ 3. The independent risk factors associated with disability (GOS ≤ 3) were: Apache II at ICU admission per unit OR (95% CI) 1.547 (1.229; 1.948); number of platelets x 10³ at ICU admission OR: 1.12 (5.4; 2304); SDD OR: 0.064 (0.008; 0.538); stupor OR: 6.479 (1.223; 34.336); isochoric pupils OR: 0.05 (0.004; 0.652); hydrocephalus OR: 6.708 (1.359; 33.103) and MV > 7 days OR: 36.861 (3.90; 340.497) (Table 2).

Table 2. Multivariate logistic regression for disability at ICU discharge

	P-value*	AIC**	Odds-Ratio (95% CI)
Apache II at ICU admission per unit	< 0.001	98.3	1.547 (1.229; 1.948)
Number of platelets at ICU admission x 10 ³	< 0.001	77.2	112 (5.4; 2304)
SDD	0.004	73.8	0.064 (0.008; 0.538)
Stupor	0.020	71.1	6.479 (1.223; 34.336)
Isochoric pupils	0.009	72.5	0.05 (0.004; 0.652)
Hydrocephalus	0.013	71.9	6.708 (1.359; 33.103)
MV > 7 days	< 0.001	80.2	36.861 (3.990; 340.497)

(* Likelihood ratio test, (**) If the factor is omitted, AIC for the full model = 67.7, AIC is a measure of lack of fitted. Note that the remove of any variable leads to a model with greater lack of fit. SDD: selective digestive decontamination, MV: mechanical ventilation

Conclusion: In SAH patients admitted to a neurotraumatic ICU, risk factors that were independently associated with disability were: Apache II at ICU admission per unit, number of platelets at ICU admission, SDD, stupor, isochoric pupils, hydrocephalus and MV > 7 days.

Introduction: Second level therapeutic actions for controlling intracranial hypertension (ICH) proposed by the European Brain Injury Foundation include barbiturates, moderate hypothermia and decompressive craniectomy (DC), but outcomes are controversial. Our aim was to evaluate the factors associated with disability and mortality after ICU discharge in patients undergoing DC.

Objectives: To assess the factors associated with disability and mortality, after ICU discharge, in DC patients after 7 years.

Methods: Prospective study of patients admitted from January 1, 2013 to March 2020 who required DC. DC was performed due ICH refractory to medical treatment. We analyzed: main admission diagnosis; demographic data; neurological data (clinical examination and Glasgow Coma Score: GCS); hypotension type of craniectomy and DC complications; Rankin scale, and Glasgow outcome scale (GOS) at 30, 60 days after ICU admission, at ICU discharge and 6 months after ICU discharge; preoperative serum lactate levels; hypo and hyperglycemia; application of mannitol or hypertonic saline solution before and after DC; leukocytes and platelets previous and after DC and other factors related to prognosis. Univariate analysis of disability (Rankin > 3) and mortality in ICU, 60 days after ICU admission and 6 months after ICU discharge were performed. Statistical significance was set at p ≤ 0.05.

Results: Thirty five DC patients were collected. Demographic data and types of admission are shown in Table 1

Table 1.	N 35
Age years, n (IQR)	47.1 (34.9 - 55.3)
Female, n (%)	22 (62.9)
Dislipemia, n (%)	22.5 (19 - 26)
Diabetes, n, (%)	4 (11.4)
Hypertension, n (%)	6 (17.1)
Antiplatelet therapy, n(%)	2 (5.7)
APACHE-II, n ,(±SD)	22.14 ± 4.88
TBI on admission, n (%)	13 (37.1)
Diagnosis on admission	
Subarachnoid hemorrhage, n (%)	17 (48.6)
Stroke Malignant middle cerebral artery, n (%)	10 (28.6)
Tumor, n (%)	3 (8.6)
Acute Subdural Hemorrhage	14 (40)
Mortality	12
ICU, n (%)	6 (17.1)
Hospital, n (%)	2 (5.7)
Upon discharge from hospital, n (%)	4 (11.4)
Highest GCS, in ICU	14 (9;15)
GOS at ICU discharge	3 (3-3)
GOS 30 days after ICU admission	3 (3-4)
GOS 60 days after DC / 6 months after ICU discharge	3 (2.5-4)
Rankin at CU discharge	4 (3-5)
Rankin 60 days after ICU admission	4 (3-5)
Rankin 6 months after ICU discharge	4.5 (2-5.75)

Most DC were subarachnoid hemorrhages (SAH) 17 (48.6%) and 75% of them were hemispheric. The most frequent complications were reoperation due to complications (42,9% of them) and hydrocephalus (42,9%). Six patients died at ICU discharge (17,1%), 4 (66,6%) of them were SAH. Rankin score at ICU discharge was 4 and GOS was 3. Rankin score at 6 months after ICU discharge was 4,5 and GOS was 3. Obliteration of basal cisterns was found to be a significant risk factor associated with disability, six months after ICU discharge (Table 2)

Table 2. Disability six months after discharge

	Disability		P
	No: Rankin<3 N=7	Yes: Rankin= 3 N=28	
Age, (years)	51.1 (38 - 58.7)	47.1 (33.9 - 55.2)	0.594
Male sex	4 (57.1)	18 (64.3)	1

None reactiv pupils previous DC	1 (14.3)	2 (7.1)	0.499
Extracranial injured	0	3 (11.1)	1
Midline shift, on CT at admission	1 (0 - 8)	5 (0 - 8.8)	0.601
GCS at admission	8 (4 - 12.5)	10 (6 - 14)	0.565
GCS at ICU admission	3 (3 - 4)	3.0 (3.0 - 6.5)	0.773
Number of platelets, after DCx 10 ³	277 (252 - 298)	217 (182 - 272)	0.102

Values are medians (IQR) and frequencies (%).DC: decompressive craniectomy;; SAH: subarahnoida hemorrhage; BTI: Brain trauma injured.

Mortality 6 months after discharge was significantly associated with bilateral pupillary reactivity prior to DC, female sex and the presence of focal contusion with edema and expansivity (Table 3).

Table 3.Mortality risk factors six months after DC

	Exitus		P
	No N=23	Yes N=12	
Age (years)	44 (30 - 55)	47 (40 - 56)	0.302
Female Sex	17 (80.0)	5 (41.7)	0.050
APACHE	22 (18 - 25)	24 (22 - 27)	0.082
Diabetes mellitus	1 (5.0)	2 (16.7)	0.54
Hypertension	5 (25.0)	1 (8.3)	1
Dyslipemia	3 (15.0)	2 (16.7)	1
Tumor	1 (5.3)	2 (16.7)	0.543
ASH	10 (52.6)	7 (58.3)	0.314
Stroke Malignant middle cerebral artery	6 (30.5)	4 (33.3)	0.696
Acute subdural hematoma	10 (52.6)	4 (33.3)	0.293
Obliteration of basal cisterns	7 (36.8)	4 (33.3)	1
Focal contusion with edema and expansivity	11 (52.6)	2 (16.7)	0.050
Evacuated Injury	2 (10.5)	3 (25.0)	0.35
TBI	10 (52.6)	3 (25.0)	0.274
Both reactiv pupils previous DC	21 (94.7)	5 (41.7)	0.002
None reactiv pupils previous DC	1 (5.0)	2 (16.7)	0.540
Pre-Hospital Endotracheal intubation	8 (25.0)	2 (16.7)	0.683
Emergency Endotracheal intubation	7 (35.0)	5 (41.7)	0.724
Endotracheal intubation at surgery	5 (25.0)	3 (25.0)	1
Transfusion previous DC	4 (21.1)	3 (27.3)	0.481
Seazures before DC	1 (5.3)	3 (27.3)	0.126
Midline shift, on CT at admission	2 (0 - 5.5)	7 (0.5 - 9.5)	0.193
GCS at admission	10 (3.5 - 14.5)	11 (6 - 14)	0.82
GCS at ICU admission	3 (3 - 6)	3 (3 - 4.2)	0.875

Values are medians (IQR) and frequencies (%).DC: decompressive craniectomy;; SAH: subarahnoida hemorrhage; BTI: Brain trauma injured.

Conclusion: DC patients showed low ICU mortality (17,14%) Rankin and GOS reflected moderate / severe disability of these patients, at ICU discharge. Rankin and GOS also showed disability, sixty days and 6 months after ICU discharge. Obliteration of basal cisterns was significantly associated with disability 6 months after ICU discharge. Mortality, 6 months after discharge, was significantly associated with female sex, bilateral pupillary reactivity prior DC and presence of focal contusion with edema and expansivity.

Management and Outcomes of Cerebral Vasospasm after Aneurysmal Subarachnoid Haemorrhage in the National Neurosurgical Centre in Ireland

P. Wiseman¹; C. Larkin¹

¹Intensive Care Medicine, Beaumont Hospital, Dublin, Ireland

Correspondence: P. Wiseman

Intensive Care Medicine Experimental 2020, **8(2)**: 000571

Introduction: Cerebral vasospasm continues to account for high morbidity and mortality in patients following aneurysmal subarachnoid haemorrhage (SAH).[1] Recent advances in neuroimaging have led to improved detection of vasospasm in this cohort but, despite many years of research, choice of hypertensive therapies remains highly variable between neurosurgical centres.[2]

Objectives: Demonstrate the morbidity caused by vasospasm in patients admitted to Beaumont Hospital, the national neurosurgical centre in Ireland, following aneurysmal SAH.

-Examine current practices and outcomes in treatment of vasospasm in the national centre.

Methods: We identified all patients admitted with aneurysmal SAH over a three year period from February 2016 to February 2019. We conducted a retrospective chart analysis examining demographics, clinical features and outcome data. A subgroup who developed clinically

significant vasospasm was further analysed to examine management and outcomes.

Results: 532 patients with aneurysmal SAH were identified, of which 68 developed significant vasospasm. Patients who presented with a higher Fisher grade were more likely to develop vasospasm ($p < 0.05$). A significant increase in morbidity was shown in patients who developed cerebral vasospasm versus those who did not, with median Glasgow Outcome Score (GOS) at three months of 3 versus 4, respectively ($p < 0.05$). The 68 patients with vasospasm stayed a combined 783 days in ICU, with mean LOS of 11.5 days (range 1-38 days).

Regarding hypertensive treatment of vasospasm, 27 patients (39.7%) were treated with noradrenaline (NA) alone and 35 (51.5%) with NA plus vasopressin. There was no difference between the two groups in grade of presentation (Fisher or WFNS), MAP targets set or the percentage of days MAP targets were met. Of note however, worse GOS at three months occurred in those who received double agent hypertensive therapy vs NA alone ($p < 0.05$). In addition, of those treated with NA plus vasopressin, 28/35 (80%) developed hyponatraemia, versus 8/27 (<30%) of those treated with NA alone ($p < 0.01$).

Conclusion: Cerebral vasospasm after SAH is a significant cause of morbidity for patients in the national neurosurgical centre in Ireland. Vasospasm also causes a significant burden due to duration of ICU stay. Hypertensive therapies used in vasospasm are not benign treatments. Despite equal MAP control in both groups, patients treated with NA and vasopressin had significantly worse outcomes than those treated with NA alone, with associated high rates of severe hyponatraemia. This may call into question the benefit of the addition of vasopressin in this cohort. There are no consensus guidelines regarding treatment of vasospasm. Ideally, well designed, multicentre randomised control trials are required to evaluate the optimal treatment of this patient cohort.

Intensive Care Medicine Experimental 2020, **8(2)**: 000627

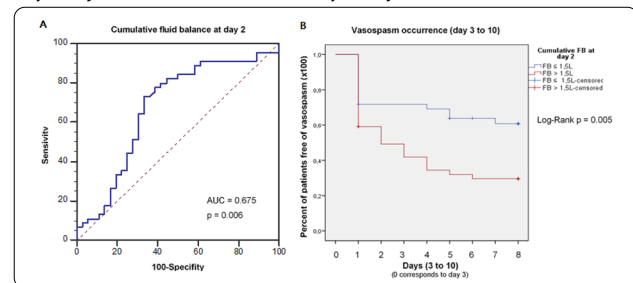

Introduction: The ultimate goal of therapy of spontaneous Subarachnoid Hemorrhage (sSAH), after acute phase, is to prevent secondary cerebral injury. Induced hypertension, hypervolemia and hemodilution (triple H) therapy have been used to increase cerebral blood flow. Recently, the physiological effects of components of triple-H therapy have been questioned. Hypervolemia may result in potentially life-threatening complications, like pulmonary and cerebral edema. Optimal fluid management after sSAH is variable throughout different centers but maintaining euolemia is what is recommended by ESICM consensus 2018, through vigilant assessment of fluid balance (FB) along with arterial blood pressure. A positive FB has been associated with worse functional outcomes at 3 months but has not been widely assessed during the critical period when patients are most likely to develop symptomatic vasospasm.

Objectives: To assess the impact of early FB in the occurrence of vasospasm in patients (pts) with sSAH.

Methods: Retrospective single-center study that includes pts admitted in a neuro-ICU with sSAH, during a period of 2 years. Data were collected during the first 10-days of ICU. We hypothesized that an

early more positive FB, particularly at 48 hours, may influence the development of vasospasm in the following days. All reported p values are two-tailed, with a p value of 0.05 indicating statistical significance. Receiver operating characteristic (ROC) curve and area under curve (AUC) were calculated, a cutoff point of the cumulative fluid balance at day 2 was identified and two groups were formed: (i) pts with cumulative FB at day 2 >1.5 Litres (L) and (ii) pts with FB \leq 1.5L. Multivariable logistic regression was used to adjust for potential confounders. Analyses were performed with the use of SPSS[®] software v22 and MedCalc[®] v19.2.3.

Results: A total of 83 pts were included, 57% male, with a mean age of 56 ± 12.1 years. Hunt-Hess was IV-V in 21 pts (25%) and Modified Fisher scale was III-IV in 70 pts (84%). Only 7 (8.4%) did not developed sonographic vasospasm criteria during the 10-day period. The mean FB at day 2 was 1.6 ± 1.3 L and it was significantly higher in pts who developed vasospasm after 2nd day (vasospasm: 1.8L [IQR 1.2]; no vasospasm: 1.1L [IQR 1.5]; $p=0.007$). A ROC curve was calculated (Fig. A) and the AUC was 0.675 ($p=0.007$; CI 95% 0.1-0.8). Kaplan-Meier curve (Fig. B) demonstrated that pts with less positive FB on 2nd day had lower occurrence of vasospasm. A cumulative FB at 2nd day >1.5L was associated with increased odds of vasospasm occurrence from the 4th to the 7th day. After adjustment for possible confounders, FB >1.5L on the 2nd day remains an independent predictor of vasospasm occurrence from 4th to 6th-day [day 4: adjusted (adj) OR 5.3, 95% CI 1.4-19.9; day 5: adj OR 6.9, 95% CI 1.7-28.4; day 6: adj OR 6.1, 95% CI 1.5-24.0].

Conclusion: The main finding of this study is that a high FB in sSAH pts, in the first 48 hours after admission, is an independent predictor of vasospasm occurrence.

Neurologic outcomes in Spontaneous Subarachnoid Hemorrhage patients and vasoreactivity—is there a relationship?

A. Mota¹; R. Varudo²; E. Pereira³; C. Dias³

¹Intensive care department, Central Hospital, Funchal, Portugal; ²Intensive care department, Garcia de Orta Hospital, Almada, Portugal; ³Neuro-intensive care unit, São João University Hospital Center, Porto, Portugal

Correspondence: R. Varudo
Intensive Care Medicine Experimental 2020, **8(2)**: 000631

Introduction: Cerebral blood flow is compromised following spontaneous subarachnoid hemorrhage (sSAH), not only due to the early consequences of the acute bleeding, namely intracranial hypertension, but also due to late complications such vasospasm and vasoreactivity impairment in response to acute changes either in oxygen or carbon dioxide levels.

Objectives: To assess the vasoreactivity response to oxygen and carbon dioxide after sSAH and its impact on neurologic outcome.

Methods: Retrospective single-center study that includes patients (pts) admitted in a neuro-ICU with sSAH diagnosis, from January 2017 to December 2018. Patients' demographics, clinical grading of SAH, Glasgow Coma Scale (GCS) at admission and at hospital discharge, Glasgow Outcome Scale (GOS) at 6 months and gasometric parameters during the first 10 days were recorded. Categorical variables are presented as frequencies and percentages and were compared with the use of Fisher's exact test or chi-square test. Continuous variables were expressed as means and standard deviations, or medians (Mdn) and interquartile ranges (IQR) and compared with the use of Student's t-test or Mann-Whitney U-test. All reported *p* values are two-tailed, with a *p* value of 0.05 indicating statistical significance. Multivariable logistic regression was used to adjust for potential confounders. Analyses were performed with the use of SPSS® software v22.

Results: A total of 83 pts with sSAH were included, 57% male, with a mean age of 56±12 years. At admission, mean GCS was 12±4 but with 18,6% (n=16) of pts presented GCS 3-8; at hospital discharge the mean of GCS was 14±3 with a decrease in number of patients with GCS ≤ 8 (n=6, 7%). The difference between GCS at the discharge and at admission was 1.3±3.5 and each increase in 1 mmHg in PaO₂ was associated with an increase of 0.31 points in that difference. About 55% of pts (n=47) had GOS 5 at 6 months, 17 pts (19,8%) had poor neurologic outcome (GOS 1-3) and 5 pts died. During the first ten days, median of PaCO₂ and PaO₂ are significantly higher in the group of pts with GOS 1-3 at 6 months (PaCO₂: 40.3, IQR 4.2; PaO₂: 143.9, IQR 52.8) than in pts with GOS 4-5 (PaCO₂:35.8, IQR 4.0; PaO₂ 103.1, IQR 44.1) (PaCO₂: *p* < 0.001; PaO₂: *p*=0.017). Each additional increment of 1 mmHg in PaCO₂ was associated with a 49% (95% CI 1.2-1.9) increase in the odds of having a GOS 1-3. After adjustment for potential confounders (Fig. 1), PaCO₂ (adjusted OR 1.99, 95% CI 1.17-3.37), but not PaO₂, remains an independent predictor of poor neurologic outcome.

Conclusion: In our study PaCO₂ was an independent predictor of poor neurologic outcomes in patients with sSAH with significantly higher levels in pts with GOS 1-3 at 6 months. PaO₂ was associated

with an increase in the difference between GCS at the discharge and at admission.

Decompressive Craniotomies in Traumatic Brain Injury: The Intensivist's point of view

F. Ortuño-Andérez¹; ME. Fuentes-Ferrer²; F. Rascón-Ramírez³; C. Galbán-Malagón¹; A. Palazón-Blanco¹; M. Calle-Romero¹; AL. Blesa-Malpica¹

Correspondence: F. Ortuño-Andérez
Intensive Care Medicine Experimental 2020, **8(2)**: 000641

Introduction: The usefulness of Decompressive Craniotomy (DC) after a Traumatic Brain Injury (TBI) is not clear, so it is impossible to prepare Guidelines with adequate evidence. Furthermore, there are no early clinical or radiological findings before the development of refractory Intracranial Hypertension that appropriately indicate a DC surgery.

Objectives: To perform a score with early clinical and radiological findings after a TBI that identify the patients who in their subsequent evolution are going to undergo DC.

Methods: Observational study of a retrospective cohorts of patients who, after a TBI, enter the Neurocritical Section of the Intensive Care Unit of our hospital for a period of 5 years (2014-2018). Main event of the study: DC. Detection of clinical (GCS, mydriasis, shock) and radiological (CT) criteria and generation of all possible models with significant, clinically relevant and easy to detect early variables. Selection of the one with the lowest Bayesian Information Criterion (BIC) and Akaike Information Criterion (AIC) values for the creation of the score. Calibration and internal validation of the score using the Hosmer-Lemeshow and a bootstrapping analysis with 1,000 re-samples respectively.

Results: 37 DC were performed in 153 patients who were admitted after a TBI. The resulting final model was:

Dependent variable: CD	Odds Ratio	p	95% CI
Cerebral Midline Deviation	6,35	0,0001	2,37-17,04
TCE according to GCS (mild/moderate-severe))	4,32	0,025	1,20-15,50
Ventricular collapse	5,27	0,002	1,89-14,74

Area under ROC Curve: 0.84 (95% IC 0.78-0.91). Hosmer-lemeshow *p*=0.71. A value of 1 was assigned to each of the factors. A score value of 2 had a very high Sensitivity and Specificity (greater than 78%) with acceptable Positive and Negative Predictive Value to detect patients who were going to need a DC. The developed score detected well those patients who were going to need an early (primary) DC after a TBI (2.5+/-0.5) but not those who would need it in a later stage of their disease (secondary) (1.7 +/- 0.8). However, it seems to advice us about the patients who, although not requiring a primary DC are likely to need it later in their evolution (secondary DC vs do not require DC 1.7+/-0.8 vs 1+/-0.7; *p*=0.002).

Conclusion: We have developed a prognostic score using early clinical-radiological criteria that, in our environment, detects with good

sensitivity and specificity those patients who, after a TBI, will require a DC.

Intensive Care Medicine Experimental 2020, **8(2)**: 000732

Introduction: The risk of intracranial hemorrhage (ICH) in patients with left ventricular assist devices is high. Surgical intervention and reversal of anticoagulation is not without risk. There is limited, published information regarding the surgical management of LVAD patients and often decision making is difficult, requiring a multidisciplinary approach.

Objectives: We aim to review the relevant literature regarding surgical and medical management of intracranial hemorrhage in patients with LVAD and present a case from our ICU.

Methods: A systematic review of the literature was undertaken using the key words "intracranial hemorrhage" and "left ventricular assist device" in the Scopus, PubMed, and Google Scholar databases. Published case reports and series written in English were included with adult patients. Abstracts were not included in the review. Data was extracted regarding the number of surgical interventions performed to total number of patients reported, and the type of ICH and surgical procedures performed. Data was also extracted regarding preoperative and postoperative anticoagulation as well as the outcome of the surgical patients. A case of a young patient from our ICU is also presented.

Results: In total 9 studies (7 case series, 2 case reports) were included in our review regarding a total of 292 patients with intracranial bleeding. Surgery was undertaken in 49 (16.7%) patients with surgery ranging between 5.7% and 40% in the case series patients. Type of bleeding, surgery performed, anticoagulation and outcome parameters are summarized in Table 1. Spontaneous intraparenchymal hematomas (IPH) were more common and presented with the worst outcomes throughout all the included studies. No significant correlation was established between elevated INR and the incidence nor severity of ICH. Immediate thromboembolic events were not encountered in any patients. Interestingly decision for surgical treatment was not specified in most studies. Three studies indicated that surgical intervention provided no improvement in outcome although it was not linked to increased mortality. Several limitations exist due to the heterogeneity of data provided and the fact that often little data was given regarding surgical intervention patients.

A 29-year-old female, with LVAD placement one-month prior was admitted to our ICU due to a spontaneous large left sided IPH. The patient's INR upon admission was 1.6. Immediate extensive left side craniectomy and hematoma removal was performed. Re initiation of anticoagulation commenced 5 days after craniectomy following stable CT scan imaging of the hematoma with argatroban infusion due to a history of HIT. APTT values of 1.5 to 2 times initial aPTT were aimed (45 to 60 seconds). The patient was successfully discharged from the hospital 2 months after ICU admission with a GOS of 4, on warfarin, to a rehabilitation center.

Table 1: Summary of included studies									
Author (Year)	Horito et al (2013)	Wilson et al (2013)	Feroli et al (2014)	Ikeda et al (2014)	Krenzlin et al (2014)	Ramey et al (2017)	Ahmed et al (2018)	Tahir et al (2018)	Lai et al (2019)

Outcome	0	0	0	0	0	1 (AD)	NR	0	NR
Death within 30 days - (n/N, %)	0	4/5 (80%)	0	6/7 (86%)	9 (75% - 4 in < 24h)	2/2 (100%)	NR	4/6 (67%)	NR
Outcome	Hemiparesis but good outcome	NR for 1 patient	Complete recovery	SDH - discharge	mRS 2 - discharged	mRS 2 - died later mRS 3 - died later	NR	2 subdural survived - NR	NR

Abbreviations: EVD – external ventricular device, INR – international normalized ratio, PTT – partial thromboplastin time, mRS – Modified Rankin Scale, NR – not reported, CR – case report, AD – other discharge †2 of the 7 patients also received EVD placement

Conclusion: Early surgical treatment with craniectomy in large IPH that present a midline shift and large volumes may be lifesaving. Medical anticoagulation may be withheld from patients with LVAD treatment for a certain period without thromboembolic events. A possible bridge to re-initiation of warfarin in patients presenting with HIT or heparin resistance may be achieved with argatroban infusion with set aPTT levels of 1.5 to 2 times initial values according to our experience. The current literature is lacking regarding effective surgical and medical management and further research is of great necessity.

Intensive Care Medicine Experimental 2020, **8**(2): 000869

Introduction: Patients with large vessel occlusion stroke (LVOS) eligible for mechanical thrombectomy (MT) are at risk for stroke- and non-stroke related complications resulting in the need for tracheostomy (1). Evidence suggest that early tracheostomy might exhibit distinct advantages over continued orotracheal intubation, ventilation and sedation (2).

Objectives: To investigate clinical-, peri-interventional- and imaging factors to predict the need for tracheostomy in major stroke patients undergoing MT.

Methods: Prospectively derived data from patients with LVOS and MT being treated in a large, academic neuro-ICU between 2014 and 2018 were analyzed in this monocentric study. Predictive value of peri- and post-interventional factors, stroke imaging and pre-stroke medical history were investigated for their potential to predict tracheostomy during ICU-stay using logistic regression models.

Results: From 635 LVOS-patients treated with MT, 40 (6.3%) underwent tracheostomy during their neuro-ICU stay. Patients receiving tracheostomy were younger (71 (62–75) vs. 77 (66–83), $p < 0.001$), had a higher National Institute of Health Stroke Scale (NIHSS) at baseline (18 (15–20) vs. 15 (10–19), $p = 0.009$) as well as higher rates of hospital acquired pneumonia (HAP) (39 (97.5%) vs. 224 (37.6%), $p < 0.001$), failed extubation (15 (37.5%) vs. 19 (3.2%), $p < 0.001$), sepsis (11 (27.5%) vs. 16 (2.7%), $p < 0.001$), symptomatic intracerebral hemorrhage (sICH) (5 (12.5%) vs. 22 (3.9%), $p = 0.026$) and decompressive hemicraniectomy (DH) (19 (51.4%) vs. 21 (3.8%), $p < 0.001$). In multivariate logistic regression analysis, HAP (OR 21.1 (CI, 2.7–163.3), $p < 0.003$), Sepsis (OR 5.6 (1.8–18), $p = 0.003$), failed extubation (OR 8.9 (3.2–24.5), $p < 0.001$) and DH (OR 9.1 (3.5–23.3), $p < 0.001$) remained as strongest predictors for tracheostomy. Patients with later timepoint of tracheostomy had longer ICU length of stay ($r = 0.384$, $p = 0.030$). There was no association between time to tracheostomy and clinical outcome (NIHSS at discharge: $r = 0.125$, $p = 0.461$; mRS at 90 days: $r = -0.179$, $p = 0.403$).

Conclusion: Patients with LVOS undergoing MT are at high risk to require tracheostomy if extubation after the intervention fails, DH is needed and severe infectious complications occur in the acute phase after ischemic stroke. These factors are likely to be useful for the indication and timing of tracheostomy to reduce overall sedation and shorten ICU length of stay.

Intensive Care Medicine Experimental 2020, **8**(2): 000878

Introduction: EEG slowing (a relative increase of slow frequency and decrease of high-frequency power) is a common feature associated with loss of consciousness. We previously described how the EEG power spectrum slope (1/f decay) is steeper when consciousness is lost (e.g. during propofol and xenon anesthesia) and flatter when consciousness is preserved despite similar behavioral unresponsiveness (e.g. during ketamine anesthesia). The *Spectral Exponent* β describes how steep is the decay of the power spectral density over frequencies

(PSD=f- β , i.e. the EEG slowing)¹. Similarly to both sleep and pharmacologically induced conditions, coma due to acute brain injury is typically associated with EEG slowing, whereas exit from a coma is associated with a recovery of fast frequencies and low amplitude EEG activity typical of normal wakefulness.

Objectives: We tested the hypothesis that the recovery of consciousness after acute brain injury is paralleled by a progressive flattening of the PSD decay.

Methods: We collected 107 longitudinal EEG at different days from injury from 22 patients (mean 4,6 EEG for each patient, IQR 3 – 6) with acute brain injury with transient loss of consciousness and good recovery (functional communication at discharge). Patients are divided into two subgroups based on etiology: post anoxic groups (n=14) and generic acute brain injuries (different etiologies but post anoxic, n=8). Recordings with any anesthetics or status epilepticus were excluded. We obtained the *Spectral Exponent* (SE) for each EEG. We then estimated if the modifications of the β values were linearly predictable by two variables: time from injury and a clinical feature expressed by the Glasgow Coma Scale (GCS). A mixed-model effect was used to estimate whether the variation of β was dependent across subjects to either time post injury or the GCS, beyond the effects observable within each subject.

Results: For both groups we found a significant effect of the two independent variables on the *Spectral Exponent* β : β decreases significantly as a function of the time after injury ($p < 0.005$ for both groups) and as a function of GCS ($p < 0.0001$ for both groups).

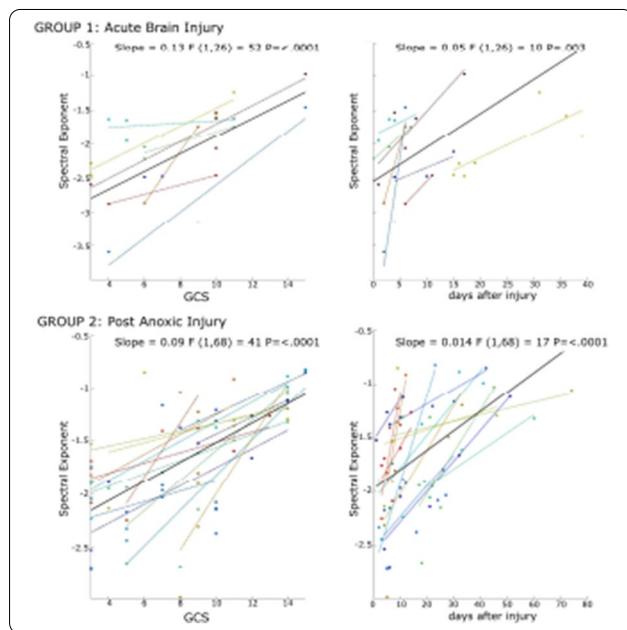

Figure: each coloured dot represents the value of the spectral exponent colour-coded for patients who recovered from coma (acute brain injury, Group 1; post anoxic, group 2). Regression lines are represented with colour coding for patients. Bold black line represents the mixed model effects: slope, F Fischer and p value are reported for the two variables of each group.

Conclusion: Together with the traditional clinical evaluation, the *Spectral Exponent* β seems to be a reliable measure for tracking brain state transitions leading to the recovery of consciousness after acute brain injury. The theoretical background about the genesis of the slow rhythms in disorders of consciousness provides a framework for the clinical use of the spontaneous EEG in objectively monitoring brain states behind clinical signs. The *Spectral Exponent* may help clinicians to identify the underlying brain processes that steer from slow rhythms to a recovery of more balanced EEG activity patterns able to support consciousness.

Intensive Care Medicine Experimental 2020, **8(2)**: 000937

Introduction: The value of serial lactate measurements in patients after SAH has not been well studied. The aim of this study was to assess the prognostic role of serial lactate measurements on survival and neurological outcomes in aneurysmal subarachnoid hemorrhage (aSAH) patients.

Methods: We reviewed data of all patients admitted to our Department with the diagnosis of aSAH from January 01, 2007 to March 31, 2019. Arterial blood lactate levels were routinely obtained at least once a day. We collected the highest lactate level daily during the first 5 days. We reported hospital mortality and 3-month unfavorable neurological outcome (UO) defined as a Glasgow Outcome Scale of 1-3.

Results: Of a total of 456 patients, 64% were female, with a median age of 54 [46-63] years. Hospital mortality occurred in 158 (35%) patients and UO in 209 (46%) patients. The highest lactate level was on admission (2.1 [1.2-3.4] mmol/L) and then progressively decreased until day 5. Patients with UO had significantly higher lactate levels over time than the other patients, in particular on the day of admission (2.9 [1.9-4.1] vs. 1.5 [0.9-2.6] mmol/L; $p < 0.01$). In a multivariable analysis, lactate levels measured on admission were significantly associated with UO (OR 1.25 [CI95% 1.0-1.6]; $p = 0.049$).

Conclusion: Initial lactate levels have prognostic implications in SAH patients; their value in conjunction with other variables should be evaluated in larger cohorts.

Intensive Care Medicine Experimental 2020, **8(2)**: 000984

Introduction: Refractory and super-refractory status epilepticus (SE) in children are associated with high morbidity and mortality. Refractory SE (RSE) is defined as persistent seizures that fail to respond to antiepileptics and is only controlled with continuous infusions of anesthetic solutions, while super-refractory SE (SRSE) persists after induction of anaesthetics or leads to rebounds after withdrawal of anaesthesia (1,2). Thorough imaging, metabolic, immunological and genetic investigations are often necessary to identify the cause.

Objectives: The present study aims to describe characteristics of status epilepticus in children and adolescents, focusing on RSE and SRSE.

Methods: This is a retrospective, single-centre study of SE, RSE, and SRSE cases treated in the pediatric ICU of the University Hospital of Heraklion from 2009 to 2019.

Results: A total of 93 hospitalisations for SE, concerning 86 patients (50% females), were included in the study. The median age of the

patients at first SE was 5 years (IQR 1.86–9.5). 63 admissions (67.7%) were due to RSE and 15 to SRSE (16.1%). Compared to idiopathic SE (53.8%), which predominated in the new-onset RSE (NORSE) ($p < 0.001$), acute symptomatic (60%) and febrile infection-related Epilepsy Syndrome (FIRES) (88.9%) more often evolved to SRSE ($p = 0.04$). The likelihood of abnormal EEG or CT did not differ between SE, RSE, and SRSE, while abnormal MRI findings were most commonly observed in the group of SRSE ($p = 0.023$). When the initial investigation was inconclusive, a definitive diagnosis was reached by genetic testing (7.5%), or brain biopsy, followed by viral detection with PCR (7.7%). Higher incidence of autoimmune, mitochondrial diseases, and FIRES characterized SRSE compared to SE or RSE ($p = 0.017$). NORSE or FIRES were diagnosed in 25% of cases, most commonly presenting as SRSE (53%) rather than RSE (24%) or SE (0%) ($p < 0.001$). In RSE/SRSE, immunomodulatory treatments ($p = 0.05$) and ketogenic diet ($p = 0.005$) were more frequently used. Also, in RSE/SRSE, weaning off of anaesthetics was prolonged ($p < 0.001$), and mechanical ventilation duration and ICU/hospital length of stay ($p < 0.001$) were increased. Mortality was 3.2% and concerned younger patients <5 years ($p = 0.013$). The prognosis was particularly poor in patients with NORSE or FIRES or with acute symptomatic SE and progressive encephalopathy ($p < 0.001$).

Conclusion: A high percentage of pediatric SE episodes evolve to RSE or SRSE, which is characterized by a high incidence of FIRES, NORSE, autoimmune and mitochondrial diseases. Further research in this area is necessary and evidence-based protocols for the management of SRSE need to be established.

Intensive Care Medicine Experimental 2020, **8(2)**: 000990

Introduction: Subarachnoid hemorrhage treatment has been changed over the last years because of the improvement of Interventionist Radiologist technology, but has it changes the mortality and the incidence of complications?

Objectives: To study the differences in complications, mortality and hospital stay between the patients admitted in ICU suffering subarachnoid hemorrhage (SAH) before and after the Interventionist Radiologist team 24 h disponibility started.

Methods: We performed a cohorts study including all patients admitted to ICU because of SAH since 1996 until 2019. We divided them into two groups (group 1: before; group 2: after the team started), since the admission to ICU until hospital discharge. We took sex, age, initial symptoms (GSC, H&H, Fisher, WFNS), APACHE II. We studied location of aneurysm, type of treatment and delay, hospital length of stay and mortality.

Statistical analysis: basic descriptive statistics. Mann-Whitney U test and T-student for continuous variables between groups, as appropriate; chi-square for qualitative variables. We considered statistically significant $p < 0.05$.

Results: 1233 patients were analyzed, 59.1 % women. 1111 in group 1 and 122 in group 2. There were not significant differences between groups in sex, age ($56,2 \pm 14,5$), APACHE II ($13,1 \pm 8,6$), location of aneurysm or initial symptoms (measured by GSC, H&H and WFNS). Delay in treatment, either endovascular or surgical, has been significantly reduced in group 2 ($6,05 \pm 9,3$ vs $1,34 \pm 1,86$), as well as

incidence of rebleeding and brain stroke. It has been shown a trend to reduce the incidence of vasospasm. There have been no significantly differences in mortality or hospital length of stay.

Conclusion: After the start of a specific program for endovascular treatment disponibility, delay on treatment and incidence of complications have been reduced, even though we have not found differences in mortality and hospital length of stay yet.

Intensive Care Medicine Experimental 2020, **8(2)**: 000997

Introduction: Aneurysmal subarachnoid hemorrhage (ASAH) is a sudden and infrequent acute brain injury. Despite fatality rates tending to improve in the last years, preventing or minimizing secondary brain lesion remains a challenge with significant impact on outcomes.

Objectives: Characterization of the ASAH population and identification of clinical and therapeutic predictors of outcome.

Methods: Retrospective analysis of all adult patients admitted from 1st January 2018 to 31st December 2019 at a Neurocritical Care Unit of an University Hospital in Portugal, who underwent treatment for ruptured cerebral aneurysms (endovascular coil embolization or surgical clip intervention). The primary outcome was unfavorable functional outcome defined by Glasgow Outcome Scale (GOS) of 1, 2 or 3 at 28th day, 3rd and 6th month of follow-up.

Results: Sixty-five patients were included, 43 females (66.2%), with a median age of 55 (47.5–66.5) years, 35 (53.8%) had pre-ictus hypertension and 19 smoking habits (29.2%). All except two patients had a previous Modified Rankin Score (mRS) of 0 or 1. Initial Glasgow Coma Score (GCS) inferior to 8 points was observed in 14 (21.5%), Hunt and Hess score of 4 or 5 in 25 (38.5%) and Fisher score of 3 or 4 in 58 (89.2%). Forty-two patients (64.6%) were submitted to surgical clipping and 23 (35.4%) underwent endovascular coiling, with similar clinical severity in both groups. Regarding complications associated with ASAH, 42 (64.6%) had Doppler documented vasospasm (66.7% submitted to intra-arterial infusion of verapamil), 26 (40.0%) developed delayed cerebral ischemia, 23 (35.4%) hydrocephalus and 7 (10.8%) rebleeding. ICU-mortality was 10.8%. Among the patients with a registered medical follow-up, mortality was 9.4% (6 of 64) at 28th day, 14.0% (8 of 57) at 3rd month and 16.7% (8 of 48) at 6th month. Analyzing the patients with a previous mRS of 0 or 1, an unfavorable GOS was observed in 53.2% (33 of 62) at 28th day, in 36.4% (20 of 55) at 3rd month and in 26.1% (12 of 46) at 6th month. At 3rd month there was a significant difference in patient's outcome comparing the two therapeutic approaches (45.9% vs. 16.7%, $p = 0.03$), favoring endovascular coiling, but it was not observed at 28th day and 6th month. In final multivariate logistic regression models, adjusted for age, two independent predictors of unfavorable functional outcome were identified at the 3 follow-up periods considered: lower initial GCS (28th day: OR 0.49, 95% CI 0.21–0.76; 3rd month: OR 0.76, 95% CI 0.61–0.92; 6th month: OR 0.67, 95% CI 0.48–0.94) and development of delayed cerebral ischemia (28th day: OR 14.75, 95% CI 2.28–95.38; 3rd month: OR 16.08, 95% CI 2.82–91.83; 6th month: OR 91.38, 95% CI 3.26–2564.56); hydrocephalus was also a predictor of poor outcome at 28th day (OR 10.60, 95% CI 1.37–82.11), no other variables persisted in the models after adjustment.

Conclusion: ASAH mortality rates remain high. In this non-selective ASAH location, surgical or endovascular methods had similar outcomes at 28th day and 6th month of follow-up. Lower GCS and delayed cerebral ischemia are independent predictors of unfavorable functional outcome.

Intensive Care Medicine Experimental 2020, **8(2)**: 001016

Introduction: On the frontline of the battle against coronavirus disease 2019 (COVID-19) the importance of identifying symptoms early and understanding their clinical relevance is crucial. Up to 36% of Covid 19 patients exhibit some form of neurological symptoms, such as anosmia and headaches on presentation (1, 2). However, it is not known whether patients presenting with neurological symptoms are at higher risk of neurological complications in an intensive care unit (ICU).

Objectives: This study aims to assess whether critically ill patients presenting with neurological symptoms are at higher risk of subsequent neurological sequelae in critically ill patients infected with Covid-19.

Methods: This is a retrospective observational study of PCR positive Covid-19 patients admitted to ICU in a single tertiary hospital. Anosmia and headache were considered neurological symptoms at presentation (3). Neurological complications, including stroke and intracranial bleeding, were diagnosed using a combination of clinical evidence and consultant level neuroradiology review of computer tomography (CT) imaging (4). Chi-square statistic with risk estimation was used to assess association between categorical variables. P values lower than 0.05 were considered significant.

Results: 132 patients were included in the study. 14 (10.6%) presented with headache and 11 (8.3%) with anosmia. In terms of complications, 21 (15.9%) had an intracranial haemorrhage, and 3 (2.3%) also had a stroke. Among 21 patients who had neurological complications in ICU, 3 patients presented with headache (21.4%) and 2 patients had anosmia on presentation (18.2%). These associations are neither significant for headache ($p = 0.55$, OR 1.5, 95% CI 0.4, 6.0) nor for anosmia ($p = 0.83$).

Conclusion: Anosmia or headache at presentation is not associated with higher incidence of neurological complications in critically ill patients infected with Covid-19.

Intensive Care Medicine Experimental 2020, **8(2)**: 001049

Introduction: The determinants of decisions to limit life support (withholding or withdrawal) in ventilated stroke patients have been poorly investigated.

Objectives: We sought to describe the incidence, timing, and factors associated with life support limitation in critically ill patients, with either ischemic or hemorrhagic stroke, requiring mechanical ventilation.

Methods: In a prospective multicenter observational cohort (2005-2016), we evaluated limitation of life support in ventilated stroke patients and in a non-brain-injured population and identified factors associated with this limitation using Fine and Gray competing risk models.

Results: We identified 373 stroke patients (ischemic, $n=167$ (45%); hemorrhagic, $n=206$ (55%)), and 5683 non-brain-injured patients. Decisions to limit life support were taken in 41% of ischemic stroke cases (vs. non-brain-injured patients, sHR 3.59 [95% CI 2.78-4.65]) and in 33% of hemorrhagic stroke cases (vs. non-brain-injured patients, sHR 3.9 [95% CI 2.97-5.11]). Time from ICU admission to the first limitation was longer in ischemic than in hemorrhagic stroke (5 [3 - 9] vs 2 [1 - 6] days, $p<0.01$). Limitation of life support preceded ICU death in 70% of ischemic strokes and 45% of hemorrhagic strokes ($p<0.01$). Life support limitation in ischemic stroke was associated with a vertebrobasilar location (vs. anterior circulation, sHR, 1.61 [95% CI 1.01 - 2.59]) and in hemorrhagic stroke, it was associated with an age >70 years (2.29 [1.43 - 3.69]), a Glasgow score <8 (2.15 [1.08 - 4.3]) and a lower neurologic admission SOFA score (per point, 0.89 [0.82 - 0.97]).

Conclusion: In ventilated stroke patients, decisions to limit life support are more than 3 times more frequent than in non-brain injured patients, with different timing and associated risk factors between ischemic and hemorrhagic strokes.

Timing of Pharmacological Thromboprophylaxis Administration in Traumatic Brain Injury: A Systematic Review and Meta-Analysis- The systematic review lite methodA. Chung¹; S. Hand¹; C. Hogg¹; T. Lanerolle¹; C. Li¹; M. Steinruecke¹; P. Wahi-Singh¹; A. Jamjoom²; T. Anderson³; J. Rhodes⁴¹Medical school, The University of Edinburgh, Edinburgh, United Kingdom;²Department of neurosurgery, NHS Lothian, Edinburgh, United Kingdom;³Critical care, anaesthesia and pain medicine, NHS Lothian, Edinburgh, United Kingdom; ⁴Critical care, anaesthesia and pain medicine, University of Edinburgh and NHS Lothian, Edinburgh, United Kingdom**Correspondence:** J. Rhodes*Intensive Care Medicine Experimental* 2020, **8(2)**: 001056

Introduction: Pharmacological thromboprophylaxis (PT) may be effective in reducing the incidence of DVT following TBI (Carney *et al.*, 2017). However, there is a reluctance to commence it due to concerns about the risk of intracranial haematoma (ICH) expansion and contusion enlargement (Geerts *et al.*, 1996). PT is therefore often delayed, exposing patients to potential risks and complications of DVT. Appropriate timing to start pharmacological thromboprophylaxis (PTP) in TBI patients is unclear. Our aim is to conduct a systematic review to assess the safety of PTP administration before and after 72 hours.

Objectives: 1 -To produce an updated systematic review on the safety and efficacy of early versus late PTP in TBI.

2-To explore the feasibility of a rapid low-cost systematic review process, "systemic review lite" used to direct future research efforts.

Methods: This project was undertaken by medical students over a 10-week student selected module. PubMed and Embase were searched for cohort studies or randomised control trials comparing early versus late administration of PTP in TBI patients. "Early" was defined as < 72 hours and "late" as ≥ 72 hours. Primary outcomes were defined as VTE diagnosis and ICH progression.

In the first filter studies were excluded if full text or English translation were not available. Non-human studies and studies on neonates and children were excluded. Authors were not contacted for missing data and individual references were not individually hand searched and cross checked for relevant publications. In the second filter full text articles were assessed and excluded if they included alternate time frames or lacked appropriate comparators. Data was extracted to Review manager 5.3 (Cochrane Collaboration 2014). Quality was assessed by 2 independent reviewers using the Newcastle-Ottawa Scale.

Results: After the second pass filter full text articles were reduced to 10 after alternate time frames and lack of appropriate comparators were considered.

Meta-analysis revealed no statistically significant difference in either VTE diagnosis (Odds ratio 0.74 [95% CI 0.52, 1.05]) or ICH progression (Odds ratio 0.85 [95% CI 0.38, 1.89]) for early versus late PTP. Subgroup analysis of high-quality studies demonstrated a decrease in VTE diagnosis with early PTP (Odds ratio 0.63 [95% CI 0.42, 0.95] p=0.03). In studies of severely injured patients (GCS≤8 or AIS≥3), early PTP was associated with a decrease in VTE incidence (Odds ratio 0.53 [95% CI 0.39, 0.71] p=<0.0001. Mortality risk showed no difference between early and late groups.

Conclusion: This review suggests that early PTP can reduce the risk of VTE. However, possible the confounding effect of only administering early PTP to patients with stable brain injuries cannot be discounted. This systemic review lite format proved to be feasible, the student group delivering clear results in a short time frame that serves as a useful update to previous reviews (Chelladurai *et al.*, 2013; Jamjoom and Jamjoom, 2013).

Viscoelastic Coagulation Results: in Patients with Moderate to Severe Traumatic Brain Injury- early results from the Traumatic Brain Injury Associated Radiological Deep Vein Thrombosis Incidence and Significance (TARDIS) StudyM. Ulla¹; A. Gordon¹; J. Rhodes²¹Adult intensive care unit, St Mary's Hospital, Imperial College NHS Trust, London, United Kingdom; ²Critical care, anaesthesia and pain medicine, University of Edinburgh and NHS Lothian, Edinburgh, United Kingdom**Correspondence:** J. Rhodes*Intensive Care Medicine Experimental* 2020, **8(2)**: 001071

Introduction: Patients with traumatic brain injury (TBI) may present with several clotting abnormalities, both pro and anticoagulant, involving complex mechanisms such as the acute traumatic coagulopathy (ATC) and delayed coagulopathy secondary to hemodilution (Brohi *et al.*, 2003; Maegele *et al.*, 2017).

Viscoelastic testing of coagulation allows near patient assessment of coagulation profiles. However, there is a paucity of data specifically in patients with traumatic brain injury.

Methods: TARDIS is a prospective, multi centre, observational pilot study to investigate the incidence of deep venous thrombosis (DVT) after TBI, using compression ultrasound. Patients admitted to an intensive care unit within 72 hours of injury are eligible. As an additional sub study, viscoelastic testing performed using either rotational thromboelastometry (ROTEM) or thromboelastography (TEG) as per the manufacturers' instructions. These results were compared with conventional laboratory coagulation testing from the same day.

Data is described as mean (standard error of the mean) and median (interquartile range). Proportions were analysed by Chi square, p<0.05 being considered significant.

Results: 21 patients with moderate to severe TBI (mean GCS 6.2 SEM 0.6) had ROTEM INTEM (n=8) or TEG (n=13) data available. The mean age was 52.9 years (SEM 4.8). The majority were male (N=16, 76%). Marshal scores were 1, n= 1 (4.8%), 2, n=9 (42.9%), 3, n=1 (4.8%), 4, n=4 (19.1%), 5, n=5 (23.8%) and 6, n=1 (4.8%). Three (14.3%) patients were taking anticoagulant medication prior to injury. Two (9.5%) received coagulation factors and 8 (38.1%) were given Tranexamic acid.

The mean activated partial thromboplastin time was 31.8 seconds (SEM 1.1), within our normal laboratory range (26 - 36 seconds). Median prothrombin time (PT) was slightly prolonged at 14.8 seconds (IQR 14.0 - 16.1) compared with the laboratory range (10.5 - 13.5 seconds). Similarly, the fibrinogen concentration was slightly increased at 4.6 g/l (SEM 0.3) compared to the reference range (1.5-4.0 g/l).

We found evidence of abnormal viscoelastic parameters in 7 or 21 patients. Three (14.3%) had a Clotting Time/R prolonged and 6 (29.0%) had a prolonged clot formation time/K. Alpha angle was reduced in 4 (19.1%) and maximum clot firmness/maximum amplitude reduced in 3 (14.3%). None of the patients with ROTEM/TEG abnormalities were taking anticoagulants prior to injury. Two had been given Tranexamic acid and 2 coagulation factors. Comparing laboratory PT with viscoelastic parameters significantly more patients had a PT greater than

reference range than had an abnormal ROTEM or TEG profile, 18 (86.0%) versus 7 (33.3%) p=0.002.

Conclusion: Within 72 hours of TBI we found evidence of impairment of coagulation in conventional and a near patient viscoelastic tests of coagulation function. This abnormality was significantly more frequent in the PT than ROTEM/TEG profiles.

Impact of phosphatemia variability in neurologic outcomes in patients with spontaneous subarachnoid hemorrhage

R. Varudo¹; A. Mota²; E. Pereira³; C. Dias³

¹Intensive care department, Garcia de Orta Hospital, Almada, Portugal; ²Intensive care department, Central Hospital, Funchal, Portugal; ³Neurocritical care unit, intensive care department, São João University Hospital Center, Porto, Portugal

Correspondence: R. Varudo

Intensive Care Medicine Experimental 2020, **8(2)**: 001086

Introduction: Electrolyte disturbances, such as dysnatremia, hypokalemia and hypomagnesemia, are frequently observed during the acute period after spontaneous subarachnoid hemorrhage (sSAH). However, the data concerning hypophosphatemia after sSAH are scarce.

Objectives: To analyze the frequency of phosphate disturbance in sSAH patients (pts), daily phosphate repletion and to assess the influence on the outcomes comparing with pts with no sSAH.

Methods: All pts with sSAH admitted from January 2017 to December 2018 in the Neurocritical Care Unit were enrolled in our cohort. Control group includes critically ill non-neurologic pts admitted in a general ICU in the same ICU Department. Serum phosphate levels and daily phosphate repletion were collected on the first 10 days after admission. The primary endpoint was neurologic outcome, using Glasgow Outcome Scale at 6 months (GOS-6M) and Glasgow Coma Scale at ICU discharge (GCS-ICUd). Outcomes analysis were made using mean phosphate level during the first 10 days. We performed multiple linear regression, adjusted for age, GCS at admission, APACHE II, phosphate repletion (and Hunt-Hess and Modified Fisher scale for sSAH group) to assess the effect of phosphatemia in outcomes. Analysis were performed with SPSS® software v22.

Results:

83 pts with sSAH and 92 controls, with mean age of 56±12.1 and 64±13.1 years, respectively. Pts with sSAH had increased odds of having hypophosphatemia at admission as compared with controls (OR 3.2, 95% CI 1.1-8.9, p=0.029) and none presented with hyperphosphatemia. Mean phosphate level was lower in sSAH patients compared to controls (3.1±0.4 vs 3.9±1.3, p<0.001) as well as daily levels. Hypophosphatemia was more frequent in sSAH pts, mostly in the first 4 days (figure 1) and 52 pts (63%) had at least one day with hypophosphatemia (35 in control group, p<0.002). Median phosphate dose repletion was higher in sSAH pts [696 (1045) vs 100 (284), p<0.001].

Table 1. Multiple linear regression models for GCS at ICU discharge and GOS at 6 months in sSAH group

Independent variables	GCS-ICUd		GOS-6M	
	β _{std} (95% CI)	p value	β _{std} (95% CI)	p value
Age (years)	-0.53 (-0.06 to 0.03)	0.54	-0.11 (-0.03 to 0.01)	0.24
GCS at admission	0.64 (0.22 to 0.70)	<0.001	0.36 (0.000 to 0.196)	0.05
APACHE II	-0.44 (-0.33 to -0.09)	0.001	-0.31 (-0.10 to -0.009)	0.02
Hunt & Hess	0.38 (0.15 to 1.66)	0.02	-0.01 (-0.32 to 0.30)	0.95
Fisher	-0.01 (-0.61 to 0.56)	0.93	-0.12 (-0.39 to 0.09)	0.21
Phosphate level (mg/dL)	0.24 (0.43 to 2.87)	0.01	0.13 (-0.17 to 0.83)	0.19
Phosphate repletion (mg)	0.25 (0.000 to 0.002)	0.01	0.21 (0.000 to 0.001)	0.03

Table 2. Multiple linear regression models for GCS at ICU discharge and GOS at 6 months in control group

Independent variables	GCS-ICUd		GOS-6M	
	β _{std} (95% CI)	p value	β _{std} (95% CI)	p value
Age (years)	0.08 (-0.06 to 0.11)	0.49	-0.10 (-0.04 to 0.02)	0.36
GCS at admission	0.19 (-0.03 to 0.49)	0.08	-0.10 (-0.14 to 0.05)	0.33
APACHE II	-0.03 (-0.15 to 0.12)	0.80	-0.11 (-0.07 to 0.03)	0.38
Phosphate level (mg/dL)	-0.396 (-2.49 to -0.69)	0.001	-0.39 (-0.87 to -0.23)	0.001
Phosphate repletion (mg)	0.096 (-0.002 to 0.006)	0.42	0.08 (-0.001 to 0.002)	0.49

In sSAH pts, phosphate level and phosphate repletion (table 1) were independently associated with GCS-ICUd (R² 58%, R² adj 54%); pts with hypophosphatemia at admission had lower GCS-ICUd compared with pts with normophosphatemia (12.1±3.4 vs 14.1±2.4, p=0.005). sSAH pts with lower GOS-6M had hypophosphatemia at admission and those who died had lower mean phosphate level (2.8±0.8 vs 3.1±0.4).

In multivariable analysis, phosphate repletion was significantly associated (β 0.21, 95% CI 0.000-0.001) with GOS-6M (R² 52%, R² adj 47%), but not mean phosphate level (table 1). In control group, lower mean phosphate level was associated with higher GOS-6M (R² 27%, R² adj 22%) and higher GCS-ICUd (R² 25%, R² adj 21%); there was not an association between phosphate repletion and outcomes (Table 2).

Conclusion: Pts with sSAH had lower mean phosphate levels and required a significantly higher daily phosphate replacement to achieve normal values, compared with non-neurologic critically ill pts. sSAH pts need cautious phosphate repletion, as hypophosphatemia may be associated with poor neurologic outcomes. Further studies are warranted to better understand the role of phosphorus in the pathophysiology of sSAH, namely regarding brain metabolism, kidney-brain links and outcomes.

001106**Mechanical thrombectomy in acute ischemic stroke. Most frequent results and complications in our unit**E. Simón Polo¹; JM. Jimenez Vizuete¹; C. Palau Martí²¹Anaesthesiology, Complejo Hospitalario Universitario de Albacete, Calle Hermanos Falco, Albacete, Spain, Albacete, Spain; ²Anaesthesiology, Critical Care and Pain Therapy Service, Consorci Hospital General Universitari de València, València, Spain**Correspondence:** E. Simón Polo*Intensive Care Medicine Experimental* 2020, **8(2)**: 001106

Introduction: In developed countries, ischemic stroke is one of the leading causes of disability and the second leading cause of death, 85% of them being of cardioembolic or atherothrombotic origin. In recent years, endovascular treatment in this type of patient has shown superiority over systemic fibrinolysis.

Objectives: The objective of this study is to analyze the results and associated complications after endovascular treatment in patients with acute ischemic stroke admitted to our Reanimation Unit.

Methods: An observational retrospective study was carried out. All patients with acute ischemic stroke undergoing mechanical thrombectomy who were admitted to the Reanimation Unit in February 2015 and December 2018 were included. The following variables were selected as study variables: demographic (age and sex), clinics (NIHSS at admission, cardiovascular risk), type of anesthesia performed (general or sedation), neurological complications during your stay, and infectious complications (respiratory and urinary). Statistical analysis was performed using the SPSS 25.0 program. Continuous variables were described using the mean. Categorical variables are described by absolute and relative frequencies.

Results: A total of 224 patients were collected. 90% of the patients who underwent endovascular treatment remained admitted to the Reanimation Unit. The mean age was 69.3%. 43.3% were men and 56.7% women. Cardiovascular risk factors: Hypertension described in 73%, diabetes mellitus 32%, dyslipidemia 45%, personal history of ischemic heart disease 13.6%, intermittent claudication 5.7%, tobacco use 19%, history of SAHS 5%. 27.4% consumed oral anticoagulants and 28.1% had AF among their antecedents, de novo arrhythmia was diagnosed in the emergency room in 11%. In 91% of the cases described, there was no previous stroke. Stroke mechanism: cardioembolic 71%, atherothrombotic 22.8%, undetermined origin 22.3%, infrequent 6.7%. In 36% of cases, the artery predominantly affected was the middle cerebral artery in segment M1. The least frequently affected artery is the vertebral artery, with 2.3% of cases. The median time from clinical presentation to the start of endovascular treatment was 160 minutes. Neurological assessment was performed using the NIHSS scale: on arrival at the Emergency Department, the mean was 17 points, with no variations after the procedure. After 24 hours it is at 8 points. The mean at discharge was 9 points. The type of anesthesia performed was general in 96% while sedoanalgesia was performed in 4%. VTE was indicated for failure of fibrinolysis with IVr-t-PA in 8 patients (13.3%). Infectious complications: 38% of patients develop urinary tract infection; in 43% respiratory infections (pneumonia associated with mechanical ventilation, nosocomial pneumonia, tracheobronchitis). Percutaneous tracheostomy was required in 13%. The average stay in our unit is 3 days.

Conclusion: Ischemic stroke is a medical emergency that requires urgent intensive treatment and strict postoperative control. Bladder catheterization or orotracheal intubation prior to the procedure can be risk factors for the development of serious infections that can compromise the patient's life. Performing sedoanalgesia as an anesthetic procedure can be useful in minimizing these risks, reducing hospital stay, reducing costs and improving the patient's prognosis.

001153**The Risk of Stroke after Acute Myocardial Infarction in Patients with and without Atrial fibrillation**C.H. Chiang¹; W.T. Hung²; W.C. Huang³; K.C. Lin²; C.C. Cheng¹; F.Y. Kuo¹; G.Y. Mar²¹Critical care medicine and cardiovascular center, Kaohsiung Veterans General Hospital, Kaohsiung, Taiwan; ²Critical care medicine, Kaohsiung Veterans General Hospital, Kaohsiung, Taiwan; ³Critical care medicine and cardiovascular center, Kaohsiung Veterans General Hospital, Taipei, Taiwan**Correspondence:** W.C. Huang*Intensive Care Medicine Experimental* 2020, **8(2)**: 001153

Introduction: Both acute myocardial infarction (AMI) and atrial fibrillation (AF) are risks for stroke. The risk of stroke after AMI may be different in patients with or without AF. The aim of this study was to evaluate the impact of AF on stroke in patients after first AMI.

Methods: Setting Retrospective nationwide cohort study.

Participants: A total of 170,472 patients who had the primary diagnosis of first AMI between 2000 and 2012. Among them, 8,530 with AF was identified. Propensity score matching technique was used to match 8,530 patients without AF with similar ages and genders.

Primary and secondary outcome measures: All patients were followed until stroke or 31 December 2012, whichever occurred first. Kaplan–Meier cumulative survival curves were constructed to compare stroke between AMI patients with and without AF.

Results: Overall, 12-year stroke rate was higher in patients with AF than without AF (log rank P-value < 0.001), including in different genders, ages or intervention subgroups. In patients with AF, those with preexisted AF have higher stroke rates in male gender, age below 65 years, and with intervention subgroups than those with new-onset AF. In cox proportional-hazard regression analysis, AF was an independent risk factor for stroke after first AMI (hazard ratio, 1.67; 95% confidence interval, 1.5-1.87).

Conclusion: AF significantly increased stroke risks after first AMI. In patients with AF, those with preexisting AF have higher stroke risks in male genders, ages below 65 years, and with interventions than those with new-onset AF.

000288**Transcranial Doppler Emboli Monitoring for Infective Endocarditis**G. Huang¹; L. Johnson²; J. Peacock Jr.³; C. Tegeler²; K. Davis⁴; A. Sarwal²¹Internal medicine, University of California, Los Angeles, Los Angeles, United States of America; ²Neurology, Wake Forest Baptist Medical Center, Winston-Salem, United States of America; ³Internal medicine, Wake Forest Baptist Medical Center, Winston-Salem, United States of America; ⁴Pharmacy, Wake Forest Baptist Medical Center, Winston-Salem, United States of America**Correspondence:** L. Johnson*Intensive Care Medicine Experimental* 2020, **8(2)**: 000288

Introduction: Ischemic stroke can occur in 20-55% of patients with infective endocarditis (IE) with 75% occurring during the first 2 weeks of treatment. CT or MRI brain can diagnose the sequelae of stroke but transcranial Doppler (TCD) can document active embolization. We undertook a retrospective review of our patient cohort and a systematic review of literature to assess the role of TCD in early diagnosis and management of ischemic stroke in IE.

Methods: Retrospective chart review and literature review.

Results: We found 89 patients with stroke caused by IE at our institution from December 2011 to April 2018. TCDs were obtained on 26 patients; 16 were abnormal for cerebrovascular abnormalities. Only 4 patients had 30-minute emboli monitoring performed, of which one revealed emboli. We found 3 studies investigating the role of TCDs in IE that showed promise in its use as a predictive tool in stroke risk stratification.

Conclusion: Presence of embolization in the form of high intensity transient signals (HITS) detected on TCDs can be used for early diagnosis of IE, assessing efficacy of antibiotic therapy, and stratification of stroke risk in IE. This can aid further research into testing preventative interventions for reducing stroke burden in IE, such as earlier valvular surgery or vacuum-assisted vegetation extraction.

Intensive Care Medicine Experimental 2020, **8(2)**: 000304

Introduction: Neurocritical care is a subspecialty of critical care medicine that focusses on the evaluation, diagnosis, and management of patients with acute life-threatening central nervous system diseases. (1,2) Because of their complexity, neurocritical patients need specific continuous monitoring, to allow their recovery.

Objectives: 1. Characterize neurocritical Intensive Care Unit (ICU) patients admitted in 2019 and to correlate neurocritical care variables with Glasgow outcome Scale at ICU discharge and 6 months after discharge.

2. Finding the most significant variables in order to build a model that best predict outcome.

Methods:

An observational retrospective study included 105 neurocritical patients in our intensive care unit (ICU) during the year of 2019. Collected variables included age, gender, diagnoses, severity scores (APACHE, SAPS, initial SOFA), in local Glasgow coma score (GCS), hospital admission GCS, Marshall, Hunt & Hess scale, Fisher scale, National Institute of Health Stroke Scale (NIHSS), intracranial pressure (ICP) at ICU admission, time with ICP>24 in the first 72h after ICU admission, mean ICP during ICU stay, doppler variables in the first 24h of ICU stay (middle cerebral artery (MCA) blood velocity and pulsatility index) and Glasgow Outcome Scale (GOS) at ICU discharge and 6 months after discharge. We included also the time (minutes) between local to emergency department (ED) admission and time between ED and ICU.

We performed a Multiple Regression Analysis using Akaike's Information Criterion (AIC) to identify the most relevant variables that best explain outcome.

Results: One hundred and five neurocritical patients were included: traumatic brain injury (TBI) (61), aneurism (31) of which 27 had subarachnoid haemorrhage, stroke (11) and arteriovenous malformation (2). In patients with TBI 84,8 % were male, mean age of 45,7 years, 80,4 % present moderate to severe TBI, 68,4% present Marshall scores of 3 and above. 52% with initial sofa score of 7 and above.

In patients with aneurism, 72,4 were female, mean age of 57,8 years, mean hospital admission GCS of 10, 42% hunt&hess of 2 and above, 47 % with initial sofa score of 7 and above.

The best model for predicting GOS at ICU discharge included 5 variables: Sex, Age, initial SOFA Score (at admission), admission GCS, and Time between ED and ICU:

-Associated with best outcome : male sex, younger age, higher admission GCS, more Time ED-ICU.

-Associated with worse outcome :female sex, older age, lower admission GCS, high SOFA score.

The adjusted R² for this model was 40 % (accounts for 40% of variation in outcome)with a p- value < 1.6 x 10⁻⁹.

Conclusion: It was not surprise for us that high admission GCS and younger age were associated with best outcome. However we were not expected that more time between ED-ICU leads to better outcome. The male sex appears to perform better than female sex. Those facts will be a good discussion points.

The focus of this work was characterization of our neurocritical care population. The identification of a new predictive model presents an interesting hypothesis for future validation.

Intensive Care Medicine Experimental 2020, **8(2)**: 000314

Introduction: Reductions in heart rate variability (HRV) are associated with poor outcomes in patients with severe acute brain injury. However, it is unknown if the changes in HRV precede neurological

deterioration in such patients, as an early indicator of brain-heart network dysfunction.

Objectives: We examined the changes in HRV measured by electrocardiography (ECG) in patients who experienced neurological deterioration after severe acute brain injuries, and analyzed the correlation between HRV and the qualitative and quantitative variables of electroencephalography (EEG).

Methods: Thirteen EEG channels and one channel of simultaneously-acquired ECG were segmented in 120 s epochs and used to calculate ten HRV features (standard deviation of the normal-normal intervals, root mean square of the difference in successive intervals, very low frequency power, low frequency power, high frequency power, low frequency/high frequency power ratio, SD along the transverse axis of the Poincaré plot [SD1], SD along the longitudinal axis of the Poincaré plot [SD2], SD2/SD1 ratio, and approximate entropy) and three quantitative EEG features (suppression ratio, asymmetry index, and alpha/delta band power ratio). Raw EEGs of epochs were also reviewed using standardized terminology and graded according to its background activities and ictal-interictal continuum patterns.

Results: The neurophysiological features of 25 patients with severe acute brain injury due to various causes were analyzed. The HRV and EEG features showed progressive and significant changes in the 48-hour period prior to neurological deterioration. Notably, the suppression ratio and background severity grade of the EEG showed significantly negative correlations with all HRV features.

Conclusion: Integration of HRV monitoring with continuous EEG monitoring may enable timely identification of progressive secondary brain injury before the development of irreversible injury.

Intensive Care Medicine Experimental 2020, **8(2)**: 000501

Introduction: Increased intracranial pressure (ICP) is one of the major clinical complications of acute brain injuries (ABIs) and correlates with poor outcome. ICP monitoring (ICPm) is the most common neuromonitoring modality used in intensive care units (ICUs). However, no evidence-based recommendations on ICP management are present in the current literature. Practice about indications of ICPm is variable in high- (HICs) and in low-middle-income countries (LMICs), where data is scarce or inconsistent.

Objectives: Aim is to quantify practice variations in ICPm in HICs and LMICs and in TBI and non-TBI patients.

Methods: The SYNAPSE-ICU is a prospective, observational, international cohort study (NCT03257904) focused on describe the current practice of ICPm using a worldwide sample. Centre Data

Characteristics Form has been submitted to each center enrolled in the study to assess the standard intensive care practice in ABI patients. Information about the institution and ICP monitoring and management were indicated.

Results: Worldwide, 156 sites distributed in 41 countries participated in the study. The Center Form was completed by 97.4% of sites. Based on World Bank List of Economies Classification (2019-2020), 110 (72.4%) of centers were localized in HICs and 42 (27.6%) in LMICs. Over two thirds of the centers have an academic affiliation (69.7%). A specialist neurocritical ICU was available in 31.6% of centers, whereas in the majority of them (68.4%) ABI patients were admitted to other ICUs (mixed, surgical, medical). In 99.3% of sites patients were monitored 24/7 by medical staff, and the most represented nurse:patient ratio was 1:2 (54.0%).

Overall, 72.4% of centers routinely used ICPm in TBI patients, and approximately half of them routinely monitored ICP in SAH and ICH. A protocol/policy for ICP treatment in TBI, SAH and ICH was available in 63.8%, 49.3% and 48.0% of centers, respectively.

Regarding the availability of neuromonitoring devices, 95.4% of ICUs declared to have an intracranial catheter to monitor ICP. At least one additional non-invasive neuromonitoring technique (transcranial doppler, optic nerve sheath diameter ultrasound, EEG, pupillometry and NIRS) was available in most of centers both in HICs (91.8%) and in LMICs (90.5%), whereas an additional invasive neuromonitoring device (brain tissue oxygen and temperature, cerebral microdialysis, regional cerebral blood flow, deep/cortical EEG electrodes) was usable in 49.1% of HIC and in 26.2% of LMIC centers.

Neuroimaging modality most frequently used was CT scan (98.6% of ICUs), while an advanced technique (MRI, CT angiography, CT perfusion, and PET) was available in 59.3% of centers.

Conclusion: A great center variability in ICPm of ABI patients was observed worldwide. The results stress the need of evidence-based recommendations regarding ICPm, in particular in LMICs, where resource limitation may preclude ICPm utilization.

Intensive Care Medicine Experimental 2020, **8(2)**: 000682

Introduction: Does near-infrared spectroscopy (NIRS) is a reliable index of brain oxygenation? NIRS is generally used as a non-invasive tool to assess regional cerebral oxygen saturation (rSO₂) to prevent ischemic brain damage. Albeit its use is widespread in the neurocritical care field[1], its real role in accurately detect ischemic insults and low cerebral flow is still a matter of debate mainly because of a lack of information on the NIRS algorithm utilized by each manufacturer and the low-resolution depth of the elliptical path of the optical spectrophotometry [2-4,6].

Objectives: Our purpose is to detect the cerebral oxygen saturation of the forehead in a clinical model of a diffuse ischemic brain injury, such as brain-dead patients.

Methods: We retrospectively analyzed adult neurocritical care patients who evolved into brain death between January 2019 and March 2020. NIRS was sampled with the O₃TM (Masimo, Irvine, CA) and SensmartTM X-100 (Nonin Medical, Inc., Plymouth, Minnesota, US) system for the total duration of 20 minutes after the patient had been declared brain dead, according to the Italian national criteria/guidelines.

Results: A total of 40 brain dead patients were studied (median age 72 IQR[55-79], 35% intracranial hemorrhage, 35% traumatic brain injury, 15% ischemic stroke, 7% hypoxic brain injury post-cardiac arrest, 3% subarachnoid hemorrhage from brain aneurysm rupture, 5% others). Among them, despite the presence of clinical, neurophysiological and neuroradiological criteria of brain death (assessed with brainstem reflexes, electroencephalography, and CT angiography), we recorded a median rSO₂ value of 72% (IQR [63-75]). The 90% of the total series (36/40) have experienced a normal rSO₂ values (i.e., rSO₂ >50%) and only 10 % (4 patients) showed rSO₂ values below 50%, among whom two patients presented concomitant severe cardiac dysfunction. A left-sided decompressive craniectomy was performed in two patients, in which we observed the left rSO₂ value much higher than contralateral (i.e., both with delta rSO₂>20). Moreover linear correlation was found between rSO₂ and SaO₂ ($r = -0,393$; $p < 0,02$).

Conclusion: In the experimental model of global brain ischemia such as brain death, the current NIRS technology does not mirror the real state of the brain oxygenation; indeed a normal rSO₂ values were found in our analysis (72%, IQR[63-75]) These data sustain the low sensitivity of the NIRS monitoring in measure faithfully the correct oxygenation status beyond the forehead[5, 6]. More studies are needed to better understand the limits and reliability of NIRS algorithms in detecting brain ischemia.

Intensive Care Medicine Experimental 2020, **8(2)**: 000959

Introduction: Echography is becoming a diffuse, economic and non-invasive tool used in general ICU (Intensive care unit) while is less utilized for exploring the brain, protected by the skull. However, it could have multiple applications in the study of cerebral vessels anatomy

and from its important role in the diagnosis of acute intracranial pathologies (1). Skills to be acquired have been recently described in a Consensus (2). No information about the utility of practical training are available.

Objectives: The aim of this project is to evaluate the improvement in the use of ultrasonography and TCCD (transcranial colour-coded duplex) diagnostic methods after a dedicated training course.

Methods: In December 2019, 31 participants (3 intensivists and 28 residents) naive to the technique attended for two days the SONIC (Sonography in Neuro-Intensive Care) theoretical-practical course at University of Piemonte Orientale. Specialists in this field described the use of ultrasonography and TCCD in a large spectrum of clinical conditions, followed by practical hands-on sessions on volunteers and in ICU.

Before and after the training, all participants answered to a 51 multiple-choice online questionnaire and were required to evaluate a set of brain echographic images. A paired t-test was applied to evaluate the improvement.

Results: The median score obtained in the multiple-choice question was respectively 27 (pre) and 36 (post).

The paired t-test applied, showed a significant difference between the mean performance scores pre and post training course ($p < 0.001$). The mean difference, between pre and post scores, was equal to 10.19 points (95% confidence interval = 7.95–12.43).

The median score obtained in the images' evaluation was 4 (maximum score of 5).

Conclusion: The analysis conducted on the scores obtained before and after the theoretical-practical course showed how useful could be a targeted approach to the correct use of TCD ultrasonography improving personal skills about it.

According to the Consensus (2) we could consider an upgrade of the participants' level to basic-plus/pre-advance.

Brain Oxygen Tension Over the First 24 Hours of Monitoring, Predicts Intensive Care Survival in Adult Patients with Traumatic Brain Injury

K. Overend¹; T. Anderson²; J. Rhodes³

¹Medical school, The University of Edinburgh, Edinburgh, United Kingdom; ²Critical care, anaesthesia and pain medicine, NHS Lothian, Edinburgh, United Kingdom; ³Critical care, anaesthesia and pain medicine, University of Edinburgh and NHS Lothian, Edinburgh, United Kingdom

Correspondence: J. Rhodes

Intensive Care Medicine Experimental 2020, **8(2)**: 000969

Introduction: Optimal management and monitoring of traumatic brain injury (TBI) remains uncertain. Intracranial pressure (ICP) monitoring lacks high quality evidence and does not prevent cerebral hypoxia (Stiefel *et al.*, 2006; Carney *et al.*, 2017). Robust evidence for the use of brain oxygen tension (PbtO₂) monitoring is also lacking, but preliminary work is promising and suggests it may improve outcomes. In a prior study, we found that early PbtO₂ improvement, or low hypoxic load over the first 24 hours, were associated with ICU survival (Rhodes, Chandrasekaran and Andrews, 2016).

Objectives: In a second independent cohort of patients with moderate to severe TBI, to validate the observation that exceedingly early changes in PbtO₂ are associated with ICU survival.

Methods: A retrospective analysis was performed on prospectively collected data from a cohort of 60 TBI patients at a single centre focusing on the first 24 hours of monitoring. Minute-to-minute ICP, cerebral

perfusion pressure (CPP) and PbtO₂ values were recorded via an invasive cerebral monitor on to a bedside laptop running ICU pilot software (CMA, Sweden). The relationship of PbtO₂ vs. time was described as a Spearman correlation coefficient for each patient. The percentage of time that PbtO₂ was <20mmHg was calculated. Demographic and baseline characteristics were collected. The primary outcome was ICU survival.

Comparisons were made using paired or unpaired T tests and Wilcoxon signed rank test or Mann-Whitney U test. ICU survival was analysed using logistic regression.

Results: Demographics were well matched, except age, which was significantly higher in non-survivors (43 years [IQR 26.3 – 555.0] vs. 60 years [IQR 49.3 – 72.8] $p=0.01$). Survivors demonstrated significant increases in PbtO₂ over the first 24 hours, (18.9mmHg [IRQ 12.8 to 23.1] vs. 25.6mmHg [21.6 to 30.6], $p<0.001$, which was not seen in non-survivors (16.3 mmHg [IRQ 8.5 to 32.3] vs. 18.3 mmHg [16.9 to 21.8], $p=0.898$. Survivors experienced a significantly higher PbtO₂ over 24 hours than non-survivors (25.3mmHg [22.1 to 26.4] vs. 18.4mmHg [17.3 to 20], $p<0.001$). Age (odds ratio 0.95, [95% CI 0.90 to 1.00] $p=0.032$), the correlation coefficient between PbtO₂ and time (odds ratio 5.24 [95% CI 1.02 to 26.96] $p=0.047$) and percentage hypoxia in the first 24 hours (odds ratio 0.98 [95% CI 0.96 to 1.00] $p=0.033$ were significantly associated with ICU survival. When the data from this cohort were combined with the original cohort ($n=25$), these findings were preserved.

Conclusion: In patients with moderate to severe TBI undergoing invasive multimodality monitoring, data from PbtO₂ monitoring as early as the first 24 hours of monitoring is associated with survival. An improving PbtO₂ with time and low cumulative hypoxia were significantly associated with ICU outcome. The findings of the original observational study are upheld. What remains unclear is if this association with survival occurs spontaneously or is the result of goal directed therapy.

Intensive Care Medicine Experimental 2020, **8(2)**: 001064

Introduction: Few studies report the relation between functional brain alterations during and after ICU stay and abnormalities of CBF displayed on TCD. Using VTI as hemodynamic parameter is unusual for evaluation of CBF(1).

Objectives:

The purpose of this preliminary study is to compare the values of VTI of healthy Controls (C) versus ICU (P) with usual parameters (i.e systolic (Vs), diastolic (Vd) and mean velocities (Vm), resistance (RI) and pulsatility (PI) indexes.(2).

Methods: 50 C and 160 P were consecutively included during a 6 months period (August 2019 to May 2020). Velocities and VTIMCA were sampled using TCD at the middle cerebral artery (MCA, M1

segment). Left ventricular outflow (VTIAo) was assessed by transthoracic echocardiography.

Demographic data, reasons for admission in ICU, SAPS, sedative, vasopressor use and ventilator support were recorded as well MAP, Vs, Vd, Vm, PI, RI.

Data are shown as medians (interquartile:25-75).Ttest or non-parametric test (if appropriate) were use. $P<0,05$ was considered as significant.

Results: Sex ratio(M/F): 2,5 in P with SAPS II: 57 (41-69) and 1 in C. Age: 58 years (51-69) in P vs 40 years (30-52) in C.

Reasons for admission were sepsis: 71 (47 septic shocks), cardiac arrests: 19 cardiogenic shocks: 11, neurologic disorders: 12, others: 27. 210 measurements were realized respectively under: mechanical ventilation: 183, vasopressor support: 101 and sedative drugs: 116.Table1 shows relevant data.

	C (n=50)	P (n=160)	p
MAP mmHg	95,00 (89,00-98,00)	80,00 (73,00-92,00)	<0,001
VTIAo cm	21,50 (19,50-30,00)	18,00 (15,00-21,50)	<0,001
VTIMCA cm	51,75 (44,00-58)	34,80 (26,40-42,00)	<0,001
Vd cm/s	40,30 (35,38-46,20)	32,06 (23,52-44,00)	<0,015
Vm cm/s	58,50 (54,70-66,15)	52,00 (40,65-65,90)	<0,007
RI	0,55 (0,50-0,59)	0,63 (0,52-0,69)	<0,001
PI	0,86 (0,73-1,01)	1,09 (0,84-1,30)	<0,001
VTIMCA/VTIAo	2,52 (2,15-3,09)	1,90 (1,43-2,44)	<0,001
HF*VTIMCA/BSA	1876 (1712-2219)	1542 (1229,9-2044,4)	<0,001
HF*VTIAo/BSA	759 (682-919)	817 (639-1016)	NS

HF= Heart Frequency. BSA=Body Surface Area

There was a weak correlation between VTIMCA and VTIAo in P (not found in C).

However, VTIMCA and VTIAo were markedly dependent when VTIAMCA/ VTIAo ratio was <1,5 in P with marked PI and Vd abnormalities. (Spearman, $r=0,82$, $p<0,001$).

This ratio highlighted the coupling between VTIMCA and VTIAo. Low VTIAo correlated to low VTIMCA. P with vasopressors had higher VTIAMCA/ VTIAo ratio.

In addition, VTIMCA<35cm was more accurate than PI>1.3 and VD<25cm/s for the detection of abnormal neuropsychological behavior (respectively AUC: 0.81; 0.541; 0.345)

Conclusion: CBF could be estimate using VTIMCA and a hemodynamic index as HF*VTIMCA/BSA. The VTIMCA/ VTIAo ratio could be a tool to detect coupling. Low VTIMCA should do assess a VTIAo measurement. Further studies are needed to evaluate the clinical pertinence of the TCD in general ICUs.

Intensive Care Medicine Experimental 2020, **8(2)**: 001144

Introduction: Electroencephalography (EEG) is one of the most used non-invasive monitoring methods in critically ill patients. However, EEG interpretation requires the presence of an experienced

neurophysiologist and is time-consuming. The aim of this study was to evaluate whether automated pupillometer (AP)-derived variables might help to assess the degree of cerebral dysfunction in critically ill patients.

Methods: Prospective study conducted in the Department of Intensive Care of Hôpital Erasme in Brussels. Pupillary assessments were done using the AP in three subgroups of patients concomitantly monitored with continuous EEG: 1) Post-anoxic brain injury; 2) Primary brain injury; 3) Others (i.e. sepsis, liver failure ...). An independent neurologist blinded to patient's history and AP results scored the degree of encephalopathy and reactivity on EEG using a standardized scale. The mean value of Neurologic Pupil Index (NPI), pupillary size, constriction rate, constriction and dilation velocity (CV and DV) and latency for both eyes were reported using the NPI[®]-200 (Neuroptics, Laguna Hills, CA, USA).

Results: We included 214 patients (mean age 60 years, 55% male). EEG tracings were categorized in: mild (n=111, 52%), moderate (n=65, 30%) or severe (n=16, 8%) encephalopathy; burst/suppression (n=19, 9%) or suppression (n=3, 1%). A total of 38 (18%) EEG were classified as unreactive. We found a significant difference in all pupillometry variables among different EEG categories; an unreactive EEG was associated with lower NPI, pupil size, pupillary reactivity, CV and DV and a higher latency than reactive recordings. DV and sedation were independently predictors of unreactive EEG (OR 47.68 [5.65–402.76]; $p < 0.01$ and 6.67 [2.49–17.86]; $p < 0.01$, respectively). In particular, DV values had an AUC of 0.85 [0.78 – 0.91; $p < 0.05$] to predict the presence of unreactive EEG; in subgroups analyses, area under the curve (AUC) of DV to predict unreactive EEG was 0.70 [0.55–0.86; $p < 0.01$], 0.91 [0.82–1.00; $p < 0.01$] and 0.95 [0.88–1.00; $p < 0.01$] for post-anoxic, primary brain injury and others, respectively.

Conclusion: This study suggests that DV assessment via the AP might effectively identify unreactive EEG background, in particular in non-anoxic critically ill patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 001162

Introduction: Neurocritical care patients with acute brain injury (ABI) are at risk of developing intracranial hypertension which is associated with poor outcome. Monitoring of intracranial pressure (ICP) and other additional parameters, such as brain tissue pO₂ (PbtO₂), and brain oxygenation ratio (PbtO₂/PaO₂ ratio), can assess the severity of ABI and guide treatment. Thus, it may help predict and improve outcomes of these patients.

Objectives: To investigate the relationship between the type of outcome and parameters measured using an intraparenchymal monitoring catheter (PbtO₂ and PbtO₂/PaO₂ ratio) in patients with ABI.

Methods: An observational study was performed in a Greek ICU from July 2018 to May 2020, including 34 patients with ABI (13 Traumatic brain injury, 14 Subarachnoid hemorrhage, 5 Intracerebral hemorrhage, 2 Ischemic stroke) and ICP/PbtO₂ monitoring. GCS on admission, APACHE II score, ICP, PbtO₂ and PbtO₂/PaO₂ ratio during the first 24 hours were recorded. We ensured normal ICP (< 22 mmHg) with appropriate treatment measures in all patients. We considered as critical thresholds of PbtO₂ < 15 mmHg and PbtO₂/PaO₂ ratio < 0.15. Patient outcome was determined as favorable (patient had good recovery or moderate disability) or unfavorable (patient died, or was in a vegetative state or had severe disability) using the Extended Glasgow Outcome Scale (GOS-E) at 6 months after ABI. Simple logistic regression models were fitted to the data.

Results: Included 34 patients had a median age of 57 (IQR 15) years, median ICU admission GCS 7 (IQR 4.75) and mean APACHE II score 16.91 (SD ± 5.25). An external ventricular drain was inserted in 19

patients (55.9%) and surgery before ICU admission occurred in 20 patients (58.8%). A positive association of mean PbtO₂ on day 1 with type of outcome is detected. The odds for favorable outcome are 1.06 times higher or 6% increased for every mmHg that PbtO₂ is increased but this is not significant ($p = 0.149$, $p > 0.05$, 95%CI is 0.98–1.15 and includes 1) (Table 1). In our small sample, natural logarithm of mean PbtO₂/PaO₂ ratio on day 1 is positively related with type of outcome. Regarding 0.1 increments in natural logarithm of PbtO₂/PaO₂ ratio the odds for favorable outcome are 1.045 times or 4.5% higher. This relationship is not significant though ($p = 0.296$, $p > 0.05$, 95%CI is 0.68–3.55 and includes 1) (Table 1). Mean PbtO₂ and PbtO₂/PaO₂ ratio values for favorable and unfavorable outcome are recorded in Table 2.

Table 1. Association of outcome with catheter-based monitoring parameters.

Variable	OR (95% CI)	p-value
Mean PbtO ₂ on day 1	1.06 (0.98, 1.15)	0.149, >0.05
Mean PbtO ₂ /PaO ₂ on day 1	1.55 (0.68-3.55)	0.296, >0.05
	1.045 for 0.1 increments	

Table 2. Means of catheter-based monitoring parameters according to outcome.

Variable	Favorable outcome	Unfavorable outcome
Mean PbtO ₂ on day 1	18.6	12.58
Mean PbtO ₂ /PaO ₂ on day 1	0.158	0.112

Conclusion: In addition to ICP, monitoring and normalizing parameters, such as PbtO₂ and PbtO₂/PaO₂ ratio could help improve outcome in patients with ABI. Mean PbtO₂ and PbtO₂/PaO₂ ratio on day 1 had similar performance in these patients but PbtO₂/PaO₂ ratio was inferior to PbtO₂ alone in our small sample. There remains a need for more, high quality trials in patients with ABI.

In Situ Simulation for ITU Nursing Staff: No Haemorrhage Too Big; No Timeframe Too Small

L. Bezzina¹; A. Mohamed¹; S. Javier¹; P. Walker¹; C. Curtin¹

¹Medical education, Queen's Hospital, Romford, United Kingdom

Correspondence: L. Bezzina

Intensive Care Medicine Experimental 2020, **8(2)**: 000187

Introduction: The Barking, Havering, Redbridge University Trust (BHRUT) simulation team, ITU team and transfusion team collaborated in an attempt to improve knowledge among ITU nurses around local Massive Haemorrhage (MH) guidelines [1] through simulation, to great effect in a mere 1-hour whilst on ITU.

Methods: The simulation team ran a high-fidelity in-situ simulation of an unexpected massive haemorrhage in an ITU patient, on the intensive care unit. The doctor in the scenario managed the patient's airway during the ongoing massive haematemesis. The transfusion team were aware of the simulation and attended, when called, to simulate real life.

Questionnaires were administered pre and post simulation to gauge:

1. Knowledge about MH protocols in general [2]
2. Confidence levels with regards to MH guidelines specific to the Trust
3. Confidence levels around what constitutes a MH
4. Confidence levels around the key initial steps in escalating a patient with a MH

Results: A 5-point Likert scale was used to assess the key learning objectives for the session, where 5 was the most positive outcome and 1 was the least positive outcome:

1. Prior to simulation, ITU nurses had an average score 2.0 when asked about their general knowledge on Massive Haemorrhage protocols, this improved to 4.3 after simulation.
2. Perceived confidence levels with regards to following the Trusts' flow diagram on managing a MH improved from an average score of 1.8 to 4.0 after participants were involved in simulation.
3. ITU nurses felt much more confident in identifying a MH as a result of partaking in the scenario; 100% of nurses were able to identify a MH after simulation, compared with only 25% being able to name one parameter that constitutes a MH prior to the simulation.
4. 100% of nurses knew the two most important steps to take in the event of a MH before simulation, but valued the opportunity to take those steps in real-time during the simulation.

Conclusion: Haemorrhage following trauma is the leading cause of death in young adults in the UK [3], haemorrhage following childbirth remains the third leading cause of direct maternal death in the UK [4] and acute upper gastrointestinal bleeds (AUGIB), a common in-hospital emergency, and has a case mortality of 10%, according to the Joint UK Blood Transfusion and Tissue transplant Services [5]. Thus, it's not uncommon for our ITU staff to be faced with massive haemorrhage and hence it made this particular emergency an important target for simulation.

A mere 1-hour of in-situ simulation, centred around very specific massive haemorrhage learning objectives, proved an extremely effective way to impart learning during working hours to prepare ITU nurses for the inevitable day when they are faced with a real major bleed. Here we have demonstrated considerable improvements in knowledge and confidence with regards to management of massive haemorrhage following only 60 minutes of simulation.

Develop a removal of central access device label to standardize care in Intensive Care Unit

N.W. Chu¹; W.Y. Kwok¹

¹Intensive care unit, Prince of Wales Hospital, Hong Kong, Hong Kong

Correspondence: N.W. Chu

Intensive Care Medicine Experimental 2020, **8(2)**: 000297

Introduction: Many adult critical ill patients have central access devices (CAD) that includes central venous catheter (CVC), continuous renal replacement therapy (CRRT) catheter, or femoral arterial line during their acute phase of illness in the intensive care unit (ICU) for invasive monitoring of physiological status and treatment responsiveness. Bleeding is the most likely complication to occur after removal of the CAD when applied direct pressure to the puncture site is not adequate to achieve haemostasis. This kind of complication can be fatal especially if the larger size (such as 13FR) CRRT catheters are used.

Therefore, a Continuous Quality Improvement team has developed a removal of central access devices label aimed to provide quick clinical guide to bedside ICU nurses for the removal of CAD.

Objectives:

1. To deliver safe and standardize care to ICU patients during the removal of CAD
2. To prevent bleeding after removal of CAD

Methods: Wide staff consultations were made about the various kinds of method used to remind nurses on important clinical steps of the removal of CAD. Finally, a removal of central access device label was developed. The label reinforced the following critical actions for the removal of these line / catheter: 1. Application of direct pressure to the CAD exit site after the line has been removed for at least 10 minutes, 2. Re-checking of the removal site 5 minutes later after direct pressure was stopped for any bleeding / haematoma, 3. Removal of all central venous & arterial lines as early as possible while the patient was waiting to transfer out to general ward, 4. Checking the integrity of removed lines to avoid any retention of lines material, 5. Enhancement of nursing clinical handover through standardization of nursing documentation

Promotion of the project: 1. Staff education during briefing, 2. Eye catching smart point posted in the common staff areas of the unit, 3. Ad hoc compliance check during daily round

Results: The project was implemented in May 2016. Every year, the Intensive Care Unit of Prince of Wales Hospital has around 1800 admissions of which 450 CVC lines and CRRT catheters were removed. A regular surprise audit on removal of CAD and implementation of the label was 100% compliance. Moreover, there were no incidences of immediate bleeding.

However, there were 2 reported cases of delay bleeding after removal of CRRT catheters due to the patient's underlying illness in 2018. Therefore, a second check was made 15 to 30 minutes after direct pressure was stopped in order to close this loophole. As of December 2019, there were no immediate or delay bleeding cases reported.

To evaluate the effectiveness of the project, a staff survey was also conducted with questionnaires distributed to 80 ICU nurses (76%). Totally, 65 (81%) completed questionnaires were returned with the result analysed as follows:

Table 1. Result of the staff survey

Questions	Strongly Agree	Agree	Neutral	Disagree	Strongly Disagree
Q1. The removal of CAD label can provide quick clinical guide to prevent bleeding complication after removal of CAD	18.6%	69.5%	8.5%	3.4%	0%
Q2. The removal of CAD label can remind you to prevent bleeding complication after removal of CAD	18.6%	67.8%	10.2%	3.4%	0%
Q3. The removal of CAD label can help the prevention of bleeding complication	15.3%	55.9%	22.0%	6.8%	0%
Q4. The removal of CAD label can facilitate your documentation and clinical handover to nurses of next shift and general ward nurses	30.5%	62.7%	5.1%	1.7%	0%

Data in Table 1 shows that there was positive response on the project from the staff survey. Although there was 71.2% of the staff stated agree and strongly agree on the label which can help the prevention of bleeding complication, over 80% of the staff (88.1%, 86.4% and 93.2% respectively) agreed that the label can provide quick clinical guide and remind nurses to prevent bleeding complication after removal of CAD and also can facilitate their documentation and clinical handover. Hence, the result of staff survey showed that the removal of CAD label can provide quick clinical guide to prevent bleeding complication after removal of CAD.

Conclusion: Development of a removal of central access devices label has demonstrated its' effectiveness in preventing post removal bleeding complication in ICU. Nurses also feedback to enhance clinical documentation and handover as a biproduct of the project.

Effectiveness and Safety of Early Rehabilitation for Patients with Acute Brain Impairment in Intensive Care Unit

S. Andreichenko¹; M. Bychinin¹; T. Klypa¹

¹Intensive care unit, Federal Research and Clinical Centre, FMBA of Russia, Moscow, Russia

Correspondence: M. Bychinin

Intensive Care Medicine Experimental 2020, **8(2)**: 000422

Introduction: More data has been recently acquired about effectiveness of early rehabilitation in the Intensive Care Unit. However, the data on the safety of this technique for patients with acute brain impairment (ABI) is still being discussed [1, 2].

Objectives:

To assess the effectiveness and safety of early rehabilitation of ABI patients in the Intensive Care Unit (ICU).

Methods: The inclusion criteria were ABI following a brain infarction, intracerebral hematoma, or subarachnoid hemorrhage. Criteria of an exclusion were a short rehabilitation course (≤ 7 days), deeply decreased level of consciousness (≤ 7 points on Glasgow coma scale), multi organ decompensated failure. All patients ($n = 42$) were assigned to the Early Rehabilitation Group (ERG) if it started 1-2 day from ABI onset, or to the Delayed Rehabilitation Group (DRG) if it started after 2nd day. All patients were given a daily mobilization complex taking into consideration their mobility and tolerance of physical activity. Clinical and laboratory indicators were analyzed, including the frequency of depression and delirium, the length of hospital stay and the time of mechanical ventilation. The development of serious complications during mobilization and mortality were also recorded. The data is presented as absolute values (frequency in percent), average (standard deviation), or median (25-75th percentile) depending on the type and allocation of the data.

Results: In group ERG ($n = 15$) mobilization started on 2nd (1-2) day on average, while in group DRG ($n = 27$) only on 7th (4-12) day ($p < 0.001$). The groups were comparable in degree of consciousness disorder and organ dysfunction. All patients had severe disabilities (≥ 4 points on the modified Renkin scale). No differences in groups were found as for the duration of mechanical ventilation, hospital admissions and mortality. The frequency of both delirium ($p = 0.024$) and depression ($p = 0.040$) was lower in the ERG group. The length of hospital stay in the Intensive Care Unit was higher in the DRG group than in the ERG group (27 (21-34) and 19 (10-27), respectively; $p = 0.042$). At the time of discharge, the incidence of severe disability decreased in both groups (to 87% in group ERG and to 78% in group DRG, $p = 0.482$). There were no serious complications during mobilization in both groups.

Conclusion: Early rehabilitation can be effectively and safely applied for patients with ABI. The use of early rehabilitation for patients with acute cerebral deficiency reduces the frequency of mental disorders and the time in the Intensive Care Unit, which creates the basis for favorable long-term outcomes.

Intensive Care Medicine Experimental 2020, **8(2)**: 000439

Introduction: Italy was one of the most affected country at the beginning of COVID-19 pandemic with the highest number of deaths in Europe mostly concentrated in the Lombardy region. Critically ill patients with COVID-19 required intensive care unit (ICU) admission due to the development of acute respiratory distress syndrome (ARDS). Prone positioning as rescue therapy can support respiratory function in patients with severe ARDS although the feasibility of the extensive use depends from the personnel expertise.

Objectives: To report the experience with the respiratory management and extensive use of prone positioning in COVID-19 patients admitted to the ICU hub of a tertiary-level hospital in Lombardy region.

Methods: All patients with laboratory-confirmed SARS-CoV-2 infection and subsequently admitted to ICU of Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico (Milan), between February 23 and May 31, 2020, were enrolled in this retrospective consecutive case-series study. The recorded data included: age, sex, mode of respiratory support (non-invasive or invasive mechanical ventilation), use of prone positioning, mortality and ICU discharge.

Results: Of the 128 patients included, 121 required endotracheal intubation and prone positioning was used in 46% (59/128) as rescue therapy. The other results are summarized in the table.

Characteristics	All pts.	Age 20-39	Age 40-49	Age 50-59	Age 60-69	Age ≥ 70
N (%)	128 (100%)	11 (9%)	23 (18%)	36 (28%)	48 (37%)	10 (8%)
Median age (IQR)	59 (49-65)	34 (29-39)	46 (44-47)	55 (52-58)	64 (62-66)	74 (72-77)
Sex (male) (%)	96 (75%)	8 (73%)	17 (74%)	28 (78%)	37 (77%)	6 (60%)
Prone position	59 (46%)	5 (45%)	8 (35%)	17 (47%)	26 (54%)	3 (30%)
ECMO support	6 (5%)	2 (18%)	3 (13%)	1 (3%)	0 (0%)	0 (0%)
ICU discharge	92 (72%)	8 (73%)	20 (87%)	28 (78%)	32 (67%)	4 (40%)
ICU mortality	36 (28%)	3 (27%)	3 (13%)	8 (22%)	16 (33%)	6 (60%)
ICU length of stay (IQR)	14 (8-27)	13 (3-15)	27 (20-38)	17 (10-31)	18 (9-30)	11 (8-26)

Conclusion: Prone positioning is part of the strategies available to intensive medicine for ARDS treatment in COVID-19 patients. During COVID-19 pandemic era, extensive use of prone positioning as rescue therapy can be applied using a specific protocol to support the staff decisions, limit the occurrence of complications and avoid excessive nursing staff workload.

Intensive Care Medicine Experimental 2020, **8(2)**: 000523

Introduction: One output from the INACTIC collaboration (1) is a set of core competencies for advanced practice ICU nurses across Europe. Some European countries, such as the UK (2), have identified such competencies, however these roles are rare across the rest of Europe. The INACTIC competencies were developed with an expert panel of 184 ICU nurses from 20 countries; however it is important to verify these with patients and family members with experience of intensive care.

Objectives: The aim of the study was to examine the views of recovered ICU patients and relatives regarding the INACTIC core competencies.

Methods: Three Focus Groups were conducted in the UK (n=12 participants) and Greece (n=5 participants) to discuss a lay version of the competencies.

Results: The feedback from across the focus groups confirmed the inclusion of statements about personal attributes, such as 'patient advocacy' or 'having the confidence to defend your opinion about a patients' care' and described this as the 'essence of the expert role'. There was a cultural difference with the Greek focus group: because of very restricted family visiting relatives felt encouraging their participation in patient care was not possible.

Conclusion: The perspectives of patients and family members largely aligned with the professional consensus of the expert panel, in particular related to personal attributes of the expert ICU nurse. Cultural differences in ICU experience highlight the changes that some ICUs would need to make for the competencies to be embedded.

Intensive Care Medicine Experimental 2020, **8(2)**: 000588

Introduction: To provide insights into visiting policies of Intensive Care Units (ICUs), especially for children and adolescents, and family-centred care in German-speaking countries (Austria, Germany, Luxembourg and the German-speaking part of Switzerland).

Methods: Online survey with leading clinicians from all adult, age-mixed, or paediatric ICUs from German-speaking countries (n=1,943).

Results: In total, maximal 19.8% (n=385) of clinicians answered the survey. Most respondents were physicians (n=213, 57.3%). Open

visiting times were reported by 36.3% (n=117), with significant differences between paediatric ICUs (79.2%), adult (21.3%), and age-mixed ICUs (41.2%) ICUs (p<001). More than two thirds of clinicians stated that their ICUs had no age restrictions for children as visitors (n=221, 68.4%). Most frequently implemented family-centred care activities were open visitation times and information' dissemination. Clinicians reported concerns about children's traumatization, risk of infection, and workload as major barriers. Arguments for family-centred care were evidence, education, and communication.

Conclusion: One third of participating clinicians reported providing open visiting policies in their ICUs. Two thirds of the respondents' ICUs allow children as visitors without age restrictions, with even higher proportions in paediatric ICUs. The majority of respondents reported to offer family-centred care in their ICUs, although they stated concerns about risks and debatable benefits.

The Development Of A Teaching Package For Airway Pressure Release Ventilation (APRV)

N. Paver¹

¹Intensive Care, Royal Devon and Exeter Hospital (Wonford), Exeter, United Kingdom

Correspondence: N. Paver

Intensive Care Medicine Experimental 2020, **8(2)**: 000589

Introduction: APRV is a pressure controlled mode of ventilation that delivers an almost continuous positive pressure with intermittent, time-cycled, short releases at a lower pressure while spontaneous breathing is encouraged. It is based on the open lung approach (Stock and Down 1987). Few UK ICUs have a consistent experience of APRV as it is primarily used as a rescue mode of ventilation where others modes have failed (Zhou et al 2017; Swindon et al 2020). On our ICU APRV use has increased over the past 5 years, with a significant increase since 2017.

Critical care nurses play a vital role in the care and management of patients requiring mechanical ventilation. The Nursing and Midwifery

code of conduct specifies nurses must work within the limits of their competence and that the necessary training should be completed before carrying out any new role. Our ICU currently has no teaching package or written guideline for the setup and management of APRV.

Methods: A MDT working group was established to deliver the project. 5 ICU's around the region were surveyed and no unit had an APRV teaching package. A questionnaire regarding knowledge and confidence in the use of APRV was sent out to all members of nursing staff. A teaching package was designed starting with small pilots of teaching to a multi-disciplinary team on an adhoc basis. The teaching package will be cascaded via the Bath University Hospital Tea Trolley Teaching method (Hawkes 2018), enabling larger numbers of staff to be educated in a timelier manner. The efficacy of the teaching program will be assessed by a further questionnaire sent out after the teaching has been attended.

Results: The baseline questionnaire was sent to 77 members of staff and generated 46 responses (58.4%). 91% of staff completing had cared for a patient receiving APRV and 66% of those report no prior knowledge of APRV. Of the 46 responses 45 expressed the need for education in the free text section. 20 members of staff received teaching as part of the pilot, achieving 14 post teaching questionnaire responses (70%).

Conclusion: APRV use is increasing and the first survey showed a lack of knowledge or experience/confidence in its use. This has been addressed by the creation of a teaching package, and the pilot data has shown a positive outcome to both the delivery and content. Staff confidence/knowledge of APRV will be re-evaluated again once the teaching package has been delivered. The results of this will be available for presentation at the conference.

A National Evaluation of the Advanced Critical Care Practitioner Role within the United Kingdom

S. Diamond-Fox¹; D. Waeland²; C. Boulanger²; J. Poynter²; S. Gardner²; A. Platt³

¹Periops & critical care and faculty of health & life sciences, Newcastle upon Tyne Hospitals NHS Foundation Trust & Northumbria University, Newcastle upon Tyne, United Kingdom; ²Advanced critical care practitioner working group, The Faculty Of Intensive Care Medicine, London, United Kingdom; ³Department of nursing, midwifery and health, Northumbria University, Coach Lane Campus (East), Newcastle upon Tyne, United Kingdom

Correspondence: S. Diamond-Fox

Intensive Care Medicine Experimental 2020, **8(2)**: 000595

Introduction: Advanced Critical Care Practitioners (ACCPs) are now well integrated within critical care (CC) workforces across England, Scotland and Wales. As such, ACCPs have been acknowledged within landmark publications for their contribution to the delivery of CC services¹⁻³. There have been numerous key initiatives that have advanced the development of the role, including national curriculums/pathways for training and continued professional development 4-6. Despite now being well embedded within the CC workforce, only local quality-assurance datasets that have evaluated the perceived effectiveness and/or safety perceptions surrounding the introduction of the ACCP role have been published⁷⁻¹⁰.

Objectives: The study had several objectives: 1) Evaluate perceptions surrounding the ACCP role within the CC workforce; 2) Assess the level at which current qualified ACCPs were perceived to be working towards the expectations of the role described by the Department of Health (DoH) and the Faculty of Intensive Care Medicine (FICM)⁴⁻⁵; 3) Evaluate whether the introduction of the ACCP role had any negative impact on Medical, Nursing and/or Allied Healthcare Professional (AHP) training; 4) Identify areas of concerns regarding interprofessional working and 5) Assess the scope for further development of the role.

Methods: Previous work conducted at a local level informed the objective and design of this study⁷. We designed and distributed an online anonymous electronic survey via OnlineSurveys.com to multiple centres within England, Scotland and Wales via multiple CC networks. A link to the survey was hosted on the FICM website. All professional groups that had experience of working directly with ACCPs were eligible to take part in the survey. ACCPs were excluded from participating. Institutional ethical decision tools did not deem this project to require independent peer review.

Results: 591 clinicians responded to the survey during the 6-week period study period. The majority of respondents (n = 150, 25%) were Medical Consultants, followed closely by Staff Nurses (n = 141, 23.9%). Respondents ranged across all regions in which ACCPs are currently known to be in post. Results demonstrated overall positive outcomes for all objectives (Fig. 1). Qualitative analysis of free text data is ongoing, however initial thematic analysis identified several themes; improved workforce stability, enhanced patient safety, variations in level of training, deskill in other members of the workforce, limited career progression.

Conclusion: The ACCP role continues to develop across England, Scotland and Wales. This survey has identified that overall respondents perceive the introduction of the ACCP role to be positive and that current qualified ACCPs meet the expectations set by the DoH and the FICM, and should be given scope to develop their roles further. However, a number of areas have been identified amongst respondents which warrants further exploration to inform effective and sustainable future development of the ACCP role.

BUILDING AND SUPPORTING A TRAINEE NURSE PRACTITIONER PROGRAM. Grace Banks and Charlotte Tivy-Jones Great Ormond Street Hospital, Cardiac Intensive Care, Advanced Clinical Practitioners

B. Grace¹

¹Cardiac Intensive Care, Great Ormond Street Hospital, London, United Kingdom

Correspondence: B. Grace

Intensive Care Medicine Experimental 2020, **8(2)**: 000737

Introduction: The success of advanced nurse practitioners in intensive care is widely documented. Advanced Clinical practitioners (ACP) are highly skilled, experienced and competent practitioners. In Intensive Care (ICU) there is not only a need for university qualification and achievement but a specialist training program specific to ICU to run alongside. The ACPs on this CICU have set up an innovative program for training; obtaining and documenting competency and supporting trainee nurse practitioners. The ‘specialist core training’ program. This program runs parallel to university education, complementing learning but focusing on core ICU skills and development. Core training can be individualised to learner needs but has central achievement stages throughout the 3 year training period. This specialist core training includes; speciality skills and education, involvement in providing MDT teaching, leadership skills, research focus groups and competency/pathway document. The aim is to enhance care delivery, specialise ICU training, complement formal university training, cover the 4 pillars of ACP and support/improve the transition from training into ACP roles. Ultimately the goal, on completion of this specialist program, is a trainee who can function successfully as an ACP on a medical rotation, initiate and lead change projects, be innovative and forward focused.

Objectives: The aim of this PICU specialty core training is to complement general ACP training and allow PICU ACPs to have a sound foundation, knowledge and competence in their chosen specialist area. Our hypothesis is that the trainee experience, multidisciplinary team (MDT) experience and patient care and safety will be enhanced. We would consider this comprehensive program to be reproducible within other PICU environments.

Methods: PICU requires specialist knowledge and competence these skills can be taught alongside ACP training. Developing PICU specialist core training has required MDT collaboration including; trainee ACPs, anaesthetic consultants, ICU consultants, established ACPs and consideration of national guidance. We have developed a comprehensive program that runs alongside the formal ACP program that will map career progression from induction through to qualification. Thus providing a transparent vision/expectation as to how their career should progress.

Results: The project has been very successful. Feedback from current trainee ACPs highlights that this more robust program will help with training into such specialty ACP roles. The program covers 4 pillars of ACP, specialist skills, specialist education, MDT learning and clinical leadership and management training.

Trainee Feedback ‘The specialist training I would say is extensive, we have to be able to prove we can make reliable and safe judgements, planning our own caseloads and are also able to adapt swiftly to changing situations.’

Conclusion: This program has enhanced the training our trainee ACPs receive and supports the formal university learning. Has already enhanced the trainee ACP, MDT and patient experience. We would like to consider a national application for this program across UK PICU.

000807**Structural dimensions of the training needs of intensive care nurses**

Y.G. Santana-Padilla¹; M.D. Bernat-Adell²; L. Santana-Cabrera¹; T. Linares-Pérez³

¹Intensive care unit, Maternal and child Hospital, Las Palmas de Gran Canaria, Spain; ²Nursing department, Jaume I University, Castelló de la Plana, Spain; ³Cs cueva torres, Gerencia de Atención primaria de Gran Canaria, Las Palmas de Gran Canarias, Spain

Correspondence: Y.G. Santana-Padilla

Intensive Care Medicine Experimental 2020, **8(2)**: 000807

Introduction: Intensive care nurses develop specialized and specific care for which extensive and continuous training is necessary(1). Several scientific associations have developed different tools to standardize minimum training requirements. The European Federation of Critical Care association has developed a series of areas where the different competences of nurses are developed, these areas are: clinical, professional, management, educational and development (2). These competences, as different authors name, must be developed through specific training that must focus on the own needs of nurses throughout their professional continuum and the healthcare organization requires (3).

Objectives: Identify the different dimensions focused on the training needs of intensive care nurses in Spain and the nurses' perception of them.

Methods: Descriptive cross-sectional study by means of an electronic questionnaire to 84 intensive care units. The questionnaire was previously validated by a brain trust. The survey consisted of 66 items using a Likert scale from 1 to 10. Statistical analysis was performed by exploratory factor analysis (EFA) through polychoric correlations with the Factor Analysis 10.9.02 program and inferential statistics with the spss 20.0 program.

Results: The sample consisted of 568 nurses. The EFA determined 13 dimensions of care, which explains a total percentage of explained variance of 64,219 and a Cronbach's alpha of 0.934. The dimensions detected were: Skills in critical patient care, Communication and clinical safety, Nursing knowledge and clinical reasoning, Reception plans for novice nurses, Specific and continuous training of staff nurses, Excellence in care, Evaluation of critical patient, tools and technology, health management, application of support measures, decision-making and coping at the end of life, measures to improve care, motivation to continue training, impact of training. Significant differences were found in the assessment of these training needs among the nurses with the longest years of experience as a nurse ($p = 0.004$) as an ICU nurse ($p = 0.021$), the nurses with official postgraduate degree ($p = 0.001$) and the rest of the nurses.

Nurses with a higher academic degree and greater work experience as nurses value more positively the training needs and the need to have previous training requirements as the Jonckheere teppstra test ($p = 0.035$) and Chi-Square ($p = 0.016$) demonstrate.

Nurses from smaller hospital also value more positively 6 of the dimensions detected with p values between 0.002-0.036 compared to ICU nurses from large centers (> 500 beds).

Conclusion: The perception of the training needs of nurses are influenced by intrinsic and extrinsic factors. Among the intrinsic factors

the following stand out: the total work experience and in the ICU as a nurses and their own academic degree. Within external factors, the size of the hospital center influences more than the size of the intensive care unit itself.

000810**Multi-infusion with integrated multiple pressure sensing allows earlier detection of line occlusions**

F. Doesburg¹; R. Oelen¹; J. Xu²; M. Renes¹; M. Nijsten¹

¹Department of critical care, University Medical Center Groningen, Groningen, Netherlands; ²Institute of engineering, Hanze University Groningen, Groningen, Netherlands

Correspondence: F. Doesburg

Intensive Care Medicine Experimental 2020, **8(2)**: 000810

Introduction: Occlusions of intravenous (IV) tubing can prevent vital and time-critical medication or solutions from being delivered into the bloodstream of patients receiving IV therapy. At low flow rates (≤ 1 ml/h) the alarm delay (time to an alert to the user) can be up to 2 hours using conventional pressure threshold algorithms. In order to reduce alarm delays we developed and evaluated the performance of three new real-time occlusion detection algorithms that exploit the trend in pressure changes.

Methods: Bench-tested experimental runs were recorded in triplicate at rates of 1, 2, 4, 8, 16, and 32 ml/h. Each run consisted of 10 minutes of non-occluded infusion followed by a period of occluded infusion of 10 minutes or until an occlusion alarm. The first algorithm based on binary logistic regression tried to detect occlusions based on the pump's administration rate (Q(t)) and pressure sensor readings (P(t)). The second algorithm continuously checked whether the actual variation in the pressure (P-SD-actual) exceeded a threshold of 2 standard deviations (SD) above the baseline pressure. When a pump detected an occlusion using either the regression or SD algorithm, a third algorithm correlated the pressures of multiple pumps to detect the presence of a shared occlusion. The algorithms were evaluated using the six bench-tested single-pump occlusion scenarios and seven multi-pump co-occlusion scenarios (i.e. with flow rates of 1+1, 1+2, 1+4, 1+8, 1+16, and 1+32 ml/h respectively). Alarm delay (minutes) was the primary performance measures.

Results: In the single-pump occlusion scenarios the overall mean \pm SD alarm delay of the regression and SD algorithms were (1.8 \pm 0.8 min) and (0.4 \pm 0.2 min), respectively. Compared to our local alarm threshold of 400 mmHg (7.4 \pm 7.5 min) this corresponds to a mean time reduction of 52 \pm 34% ($p = 0.003$) and 90 \pm 6% ($p = 0.001$), respectively. In the multi-pump scenarios a correlation > 0.8 between multiple pump pressures after initial occlusion detection by the regression or SD algorithms had a mean \pm SD alarm delay of 0.4 \pm 0.2 min. No occlusions were missed in the single-pump and multi-pump scenarios by any of the algorithms.

Conclusion: Both the regression and SD algorithms were able to significantly reduce alarm delays compared to conventional pressure limit based detection. Coupled with a correlation algorithm co-occlusions could reliably be detected far more rapidly than with the conventional technique. The latter may be used to localize the segment of tubing in which the occlusion occurs.

000816**Mobilization in the evening to prevent and treat delirium in critically ill patients: the MENTAL random-ized, controlled trial**

P. Nydahl¹; D. McWilliams²; N. Weiler³; C. Borzikowsky⁴; F. Howroyd²; A. Brobeil⁵; R. Von Haken⁶; M. Kott⁷

Intensive Care Medicine Experimental 2020, **8(2)**: 000816

Introduction: Delirium is a common complication in patients on Intensive Care Units (ICU). Interventions such as mobilization are effective in prevention and treatment of delirium, but recommended during daytime.

Objectives: The objective of this study was to prove the effect of mobilization in the evening to prevent and treat ICU patients from delirium

Methods: The design was a multicentric, randomized, controlled trial in 5 mixed ICUs over a period of 2 weeks. Patients in the intervention-group were mobilized onto the edge of the bed or more between 9:00-11:00 p.m. Patients in the control group received usual care. Primary outcome parameter was the duration of a delirium. Secondary parameters were delirium incidence, mortality, duration of mechanical ventilation (MV) and stay for 28 days follow-up, feasibility, and safety

Results: In summary, n=69 patients could be analysed (intervention n=36, control n=33). Mobilization in the evening did reduce duration of existing delirium (Median (Interquartil Range) 1.5 (1-2.7) vs. 2 (1-2) days, albeit not statistically significant. Length of MV or days in ICU and hospital, and mortality were not significantly different. In an unplanned post-hoc analysis, mobilization in the evening prevented patients from delirium in the first four days (n=6 (16.7%) vs. n=13 (39.4%), p=0.032), with a number needed to treat of 5. The intervention was feasible in 71.7% of eligible patients, with 13.6% mobilization-related safety events.

Conclusion: In a mixed ICU population, mobilization in the evening did not show a reduction in duration of delirium, MV or length of stay, but a possible reduction in the incidence of early onset delirium.

Correspondence: Y.G. Santana-Padilla

Intensive Care Medicine Experimental 2020, **8(2)**: 000829

Introduction: The perspective of training needs is an element focused on daily clinical practice. The difficulties and opportunities detected in the day to day can be useful to assess and evaluate which elements of improvement are applicable. It is necessary to extract the experiences of nursing professionals in a field as specific as intensive care, to later develop elements that can help us generate training that provides safe and quality care by ICU nurses.

Objectives: Generate a questionnaire to analyze the training needs of nurses in the ICU.

Methods: Delphi technique modified with an extensive semi-structured pre-interview based on the recommendations of the European Federation of critical care nurse association and digitally recorded. The panel of experts consisted of 15 nurses with three or more years of experience as an ICU nurse in a polyvalent adult unit of the Complejo Hospitalario Insular Materno-Infantil. It took three rounds for the expert group to reach a consensus.

The scale used for its evaluation was a Likert of 10 points, where 1 were always unimportant values and 10 were very important values. Items with a mean score greater than or equal to 6.1 and a median greater than 7 were included. The diffusion of the questionnaire was telematic with a period of 15 days for each of the phases.

Statistical analysis was performed using the SPSS statistical program version 20.0

Results: In the preparatory round, 92 questions were developed by the research team from the interviews previously carried out with the expert panel.

In addition, text-type comments were allowed to assess the questions asked by the experts.

In the first phase, the 92 questions were sent and due to the experts' assessment, 14 items were withdrawn, leaving the assessment document at 78 items. In the second phase the 78 items were sent, and the text comments made in phase 1. In this second phase, text comments were not received on the questions or related to their drafting.

The questionnaire with 66 questions was forwarded for evaluation in the third phase. This questionnaire was distributed as follows: clinical setting (18 items), professional setting (14 items), management setting (16 items), educational and development setting (6 items), and training activities (12 items).

The third round was evaluated by experts and subsequently analyzed to assess the generated construct. The reliability of the scale was assessed by Cronbach's alpha, whose result was 0.908

Conclusion: The questionnaire generated following the steps of the Delphi technique allows us to reliably explore the training needs of nurses in the ICU. The experts included a large amount of care distributed throughout the questionnaire. The experts especially included questions aimed at maintaining a continuous and permanent training program

Continuity of care for ICU patients'

M. Ashkenazy¹

¹Icu, Hadassah Medical Center, Hebrew university, Jerusalem, Israel

Correspondence: S. Ashkenazy

Intensive Care Medicine Experimental 2020, **8(2)**: 000863

Introduction: The recovery from prolonged Intensive Care Unit (ICU) hospitalization involves physical and psychological sequela that influence patients' recovery from complicated illness. Patients and families deal with the transition from high dependency care of the ICU to a less intense environment of the regular ward where nurses cope with multiple complicated patients. A new function was suggested and implemented, dealing with the need for continuity of care for such patients. The function, "Follow up ICU" was implemented in various hospitals, each including varying specific roles and responsibilities. I discuss the implementation of immediate intrinsic follow up (during hospitalization) in Israel, addressing specific characteristics of the unique hospital environment and role distribution between the different wards. Special attention was given to patient-family centered care for the post ICU patient. Utilization and benefits were evaluated using surveys with medical staff

Objectives: Evaluate utility and gain from establishing intrinsic ICU follow up in an Israeli hospital, as implemented by a dedicated nursing function assisted with other medical services.

Methods: During 2019 – 2020 follow-up nursing was implemented, with additional medical support functions. A survey comparing pre and post-prior assessment of the quality of care by ward nurses was conducted. Services in hospital adopting the patient-family centered care for improving recovery from acute illness.

Results: ICU follow-up team, led by a nurse and assisted by a dietician, social worker, physiotherapist, and a physician created a patient-specific plan of care. The plan was implemented starting before releasing from ICU and continuing as the patient was transferred to the ward. During 2019 the process was implemented in support of 200 patients. A mean per-patient number of post ICU hospitalization was 3.5. 44% of the visits involved respiratory assessments, 34% involved mobility and wound care, and 39% post ICU syndrome caregiver-patient conversations. Survey with ward nurses indicated mainly that: post-ICU follow up support led to improved critical thinking and improved quality of care for post-ICU patients, as special attention was dedicated to unique treatment aspects. Dedicated guidance and support for the ward nurses led to significant improvement of specific needed nursing skills which in turn assist in increased quality of care. Two prominent examples include: care for tracheostomy patients and dealing with post-ICU syndrome. Overall 90% of interviews indicated high benefit due to improved communication between the ICU unit and the ward.

Conclusion: Following the establishment of an intrinsic post-ICU follow-up unit quality of care as evaluated by ward nurses improved significantly.

Preliminary findings from a qualitative study of nurses' experiences towards physical restraint use in Intensive Care Unit

S. Mattiussi¹; L. Ndroqi¹; D. Caruzzo¹; M. Danielis¹

¹Department of medical sciences, University of Udine, Udine, Italy

Correspondence: M. Danielis

Intensive Care Medicine Experimental 2020, **8(2)**: 000880

Introduction: The application of physical restraints remains a common and unchallenged practice in the Intensive Care Units (ICUs) in many countries worldwide. However, if on the one hand nurses consider physical restraints as an unavoidable practice in ICU, on the other some physical adverse effects, such as skin breakdown and functional decline, and psychological outcomes, such as delirium and post-traumatic stress disorders, have been documented. To date, there is little understanding of physical restraint use from the perspective of ICU nurses in Italy.

Objectives: To assess the knowledge, the attitudes, and the practice of intensive care nurses about physical restraints use.

Methods: A qualitative study following a phenomenological approach was carried out between September and October 2019. Semi-structured face-to-face and audio-recorded interviews were carried out in three general Italian ICUs. All interviews were audio-recorded and transcribed verbatim. Each interview lasted approximately 20 minutes. Data were analysed with a content analysis method.

Results: 11 nurses were interviewed, mainly female (n=6, 63.6%) and with an average age of 36 years. A preliminary data analysis produced 53 initial categories, 11 subthemes, and 3 main themes. The main themes included: a) The decision-making process (patients' characteristics, organizational features, decision maker's role, and nurses-specific factors); b) The use of physical restraints (rationale, methods, outcomes, and alternative approaches); and c) The experiences of nurses (nurses' lived experiences, and ethical dilemmas).

Conclusion: According to the findings, the antecedent for an almost routine use of physical restraints in ICUs is the need to ensure patient safety. Although known by nurses, the alternative approaches to limit this practice were not implemented.

Intensive Care Medicine Experimental 2020, **8(2)**: 000904

Introduction: King's College Hospital in South East London was one of the acute hospitals most affected by the SARS-CoV2 pandemic. The institution treated more than 2000 patients with COVID 19 pneumonia, 192 of whom required a critical care admission. The hospital expanded its critical care capacity from 69 to 196 ICU beds during the peak of the outbreak and was one of the busiest critical care services in the UK with COVID 19 critical illness. Patients in our institution also had high severity COVID 19 due to the high prevalence of acute renal failure in 50% of our ICU admissions.

A key component of the response of King's Critical Care was provided by the Advanced Critical Care Practitioners (ACCPs). The ACCP program, within King's Critical Care, was launched in 2017 using the Faculty of Intensive Care Medicine curriculum delivered over two years (FICM, 2008). This first cohort consisted of seven intensive care nurses,

two critical care paramedics, and two intensive care physiotherapists, with a combined total of over 100 years of intensive care unit (ICU) experience. 2 ACCPs were provided on each 12 hour shift. Here, we assess the contribution, performance and effectiveness of this team to the COVID 19 response through use of the Critical Care Informatics System and database. Specifically, the contribution of ACCPs to invasive interventions, proning (Gattinoni, 2020) and intra-hospital transfer were examined.

Objectives: To assess the utilisation and effectiveness of the ACCP group during the COVID 19 pandemic in a critical care service at the epicentre of the United Kingdom Outbreak.

Methods: Appropriate service improvement approvals were gained. The ICCA (Intellivue Critical Care & Anaesthesia, Philips HealthCare) database was queried for ACCP interventions (lines, intubations, proning procedures) during the COVID 19 pandemic. (Microsoft SQL Server Management Studio 17). The ICCA complications audit table was also queried. The ACCP active directory role was queried to ensure anonymity of healthcare professionals and no patient identifiers are reported.

Results: Within the ICCA dataset, the ACCP group were involved in the assessment and management of 177/192 patients admitted with COVID 19. They performed 86 central lines; 74 arterial lines; 29 vas-caths and assisted 59 intubations across the Emergency Department; Critical Care and acute medical wards within our institution during the pandemic response. Additionally the ACCP group were the main providers of PICC line insertion. No immediate adverse events were reported. The ACCP group were tasked with the challenge of setting up and delivering a prone service for patients with oxygenation failure due to ARDS. Throughout their training they had been signed off as airway competent and able to perform stable intubated transfers, empowering them to lead and orchestrate in total 64 prone positions with only 2 adverse events and zero events leading to immediate patient harm. The ACCP team independently performed 56 intra-hospital patient transfers, with only two adverse events and no direct patient harm. The interventional procedures performed by ACCPs had less complications recorded than those performed by physicians and higher documentation compliance (eg seldinger wire out confirmation/use of check-lists). Finally, the ACCPs played a key role in developing and delivering simulation training for the resuscitation (including rapid-sequence intubation, transfer and proning) of critically ill patients with COVID 19.

Conclusion: The 2020 COVID 19 pandemic confirmed the critical role that the ACCP group play within the critical care service at our institution. The inherent strengths of the ACCP team, such as geopolitical awareness; awareness of protocols; a willingness to follow protocols; longevity as a team (no rotation); high technical skills led to the ability of this team to rapidly adapt at a time of unprecedented operational and clinical strain. Specifically, the ACCP group were able to bridge the communications between strained medical and nursing teams, enabling structured and systematic task-based management of patients with severe COVID 19 illness in very difficult clinical settings with ad hoc organ support systems and critical supply chain pressures. Further work is planned, to use these operational and clinical observations from the ACCP response during the COVID 19 pandemic, to further develop this service. One key goal will be to explore independent working from ACCPs.

Early tracheostomies in COVID-19 patients: A retrospective case review of early rehabilitation effect on modified CPax score

C. Hellyar¹; E. Clibbens²; K. Dalby³

¹Anaesthetics, Princess Alexandra Hospital, Harlow, United Kingdom;

²Physiotherapy, Princess Alexandra Hospital, Essex, United Kingdom;

³Physiotherapy, Princess Alexandra Hospital, Harlow, United Kingdom

Correspondence: C. Hellyar

Intensive Care Medicine Experimental 2020, **8(2)**: 000912

Introduction: COVID-19 can cause acute critical illness requiring intubation and mechanical ventilation. Early rehabilitation in the Intensive care unit (ICU) may prevent some complications of critical illness such as ICU-Acquired Weakness (ICU-AW) and may lead to improved functional status[1]. In the United Kingdom (UK), tracheostomy for patients with COVID-19, is recommended to be considered 10-14 days after tracheal intubation[2]. However, earlier tracheostomy may be associated with reduced sedation, early rehabilitation and therefore improved functional outcomes[3].

Objectives: To assess whether rehabilitation outcomes were affected by early tracheostomy in patients with COVID-19 admitted to an ICU.

Methods: A retrospective review of all adults admitted in a single centre district general ICU in the UK with a diagnosis of COVID-19 who were mechanically ventilated and had a tracheostomy. Patients were excluded who were transferred to other institutions for ICU capacity reasons or who died during their ICU admission.

Data was collected from patient records and physical morbidity measured using a modified Chelsea Critical Care Physical Assessment Tool (CPAx) score[4]. This was calculated for each patient at the time of tracheostomy, when active rehabilitation commenced and on discharge to the ward and home.

A 2-tailed Mann-Whitney U test statistic assuming an alpha value of 0.05 was then calculated and data for tracheostomies performed before and after 7 days compared.

Results: Tracheostomies were performed on 11 mechanically ventilated patients within a median 5 days (IQR range 3.5-8.5). Median time to start active rehabilitation was 4 days (3.5-8.5) after tracheostomy. The median modified CPax score on the first day of active rehabilitation was 9/45 (8.5-10.5); on step-down to a ward it was 28/45 (15-35); and on discharge it was 45/45 (44-45). 10 patients (91%) were discharged from hospital directly to their home.

When comparing tracheostomies performed before and after 7 days, there was a statistically significant difference ($p < 0.05$) in: length of critical care admission (median 17 vs 31 days); days on sedation (median 5 vs 21.5 days); days on controlled ventilation (median 6 vs 23 days); total hospital length of stay (median 27 vs 53 days); and modified CPax score on step down to the ward (median 34/45 vs 12/45).

Conclusion: In this single centre case series early tracheostomy in COVID-19 patients who survived their ITU admission was associated with improved modified CPax scores and functional outcomes.

An Observational Pilot Study to Evaluate Predictors and Risk Factors Influencing Extubation Readiness

T. Lea¹; H. Wu²; P. Katy²

¹{street_address}, Birmingham, United Kingdom; ²Physiotherapy, Queen Elizabeth Hospital Birmingham, Birmingham, United Kingdom

Correspondence: T. Lea

Intensive Care Medicine Experimental 2020, **8(2)**: 000957

Introduction: Extubation failure is associated with 42% increase in mortality and doubles Intensive Care Unit (ICU) length of stay (Menon et al 2012). There is a 10-20% re-intubation rate despite a spontaneous breathing trial (Thille et al 2013). The current evidence base outlines key factors that predict risk of extubation failure, such as; rapid shallow breathing Index (Yang and Tobin 1991), suction frequency (Miu 2013) and respiratory secretion abundance (Salam et al 2004). Currently at a large West Midlands teaching hospital, physiotherapists are not involved in the decision making process for extubation readiness on ICU.

Objectives: 1. To evaluate if newly developed evidence based tool predicts extubation readiness
2. To evaluate risk factors that predict extubation failure.

Methods: Data was collected for all patients admitted to the adult ICU due for extubation from February 2019 until September 2019. Exclusion criteria were palliative patients and patients tracheotomised with no trial for extubation. Data was collected within one hour prior to extubation using an extubation readiness tool. This was devised using evidence based key factors that can help predict success or failure. Extubation failure was defined by the requirement for reintubation within one week or if the patient died.

Each risk factor from the assessment tool was categorised as high or low risk for extubation failure for each patient. Pass and failure rates for each risk factor were established. Data was analysed using the Fisher exact test.

Results: A total of 18 patients met inclusion criteria and were included in the analysis, of which 7 were scored as high risk based on the assessment tool. Patients deemed high risk were significantly more likely to fail extubation (43% vs 0%, $p < 0.05$), with no patients deemed low risk requiring reintubation. The most common risk factors associated with failure were respiratory rate, secretion load, MIP and P01:MIP ratio. (See Table 1)

Table 1: Results of significant risk factors

Risk Factors	N -number	Low risk (actual failure)	High risk (actual failure)
Ventilator days	18	9 (1)	9 (2)
Trauma	18	4 (1)	14 (2)
Respiratory rate	18	6 (0)	12 (3)
Secretion volume	18	9 (0)	9 (3)
Rapid shallow breathing Index (RSBI)	18	15 (1)	3 (2)
P01	18	10 (1)	8 (2)
Maximal Inspiratory pressure (MIP)	18	12 (0)	6 (3)
P01:MIP ratio	18	9 (0)	9 (3)
Peak cough flow	18	8 (1)	10 (2)
White blood cells	18	10 (1)	8 (2)
CRP	18	1 (0)	17 (3)
Pneumonia	18	14 (1)	4 (2)

Conclusion: The extubation readiness tool was effective in identifying patients at high risk for extubation failure. The tool demonstrated 100% successful extubation in patients identified as being in the low risk category. The four most significant risk factors that predict extubation success or failure are respiratory rate, secretion volume, maximal inspiratory pressure and P01:MIP.

Future projects will aim to recreate the tool using the factors that were deemed most significant and effective in predicting success or failure, and increasing the sample size. Limitations of this study were that the trial took a long period of time to recruit to secondary to balancing a clinical caseload alongside non-clinical work and difficulties in consistently identifying with the medical team which were the planned extubations each day.

Necessity and Invention During the COVID-19 Pandemic: Introducing Dedicated Family Liaison to Intensive Care

A. Carpenter¹; K. Dafter¹

¹Intensive Care, Royal Devon and Exeter Hospital (Wonford), Exeter, United Kingdom

Correspondence: A. Carpenter

Intensive Care Medicine Experimental 2020, **8(2)**: 000981

Introduction: CoVID-19 has severely challenged communication between intensive care unit (ICU) staff and patients' families, limiting information sharing, whilst also denying patients and their loved ones mutually supportive interaction.[1-3] Consequential reliance on less-effective telephone, video or e-mail communication.[2] is complicated by personal protective equipment and infection control requirements within clinical areas. Concurrently, many staff have been required to step back from direct patient contact due to risk to their own health. [4] Addressing these issues, our ICU introduced a new family liaison (FL) role. Two team members shielding from direct patient contact were utilized to establish this new service aimed at ensuring ongoing family centeredcare through regular, consistent contact between relatives, clinicians, and patients[3-5] and relieving pressures on direct care staff through reducing time burdens of family communication and associated administration. Key activities include facilitating video-calls, collating personal 'This is Me' information for new admissions, family updates and 'check-ins,' organizing 'garden visits' with a relative and coordinating bereavement support.

Objectives: To evaluate the impact and possible longer-term benefit of the reallocation of staff to a new family liaison role during the CoVID-19 pandemic.

Methods: We conducted a retrospective audit of documented family phone communications, direct visits and video-calls, for all patients on ICU for one week periods in February (prior to CoVID restrictions), March (during restriction, before FL introduction) and May (restriction in place, FL established). A web-based survey of was also conducted utilizing scaled, multiple-choice responses and free text comments.

Week	Total No. ICU Patients (with CoVID-19)	Patient-days (sum of days each patient on ICU during week)	Mean communications per patient		
			Phone	Visits	Video
9 th Feb	23 (0)	78	2.47	2.35	0
29 th March	15 (10)	55	4.8	0	0.13
3 rd May	18 (6)	56	5.72	0.06	1.56

Results: Of 109 ICU staff invited, 50 (45.9%) responded to the survey to date. 100% (n=50) indicated FL has improved consistency of family communication, 94% (n=47) reported it as helpful during end-of-life care and 84% (n=42) that FL reduced stress of communication. 54% (n=27) reported less telephone time and 98% (n=49) that video calls improved patient and family care. 42% (n=20) found FL made it easier to build relationships with families, 35% (n=17) no change, and 23% (n=11) found it harder (2 non-respondents). 84% (n=42) thought it would be valuable to continue the FL role beyond the current pandemic situation. The survey generated 137 comments (mean 15.2 per question) for further analysis.

Conclusion: Innovative use of staff at risk from direct patient to create a FL role appears to have increased volume of documented phone and video contacts with patients’ families. FL has been well received by colleagues, improving consistency of communication, helping end-of-life care, reducing stress and time on the phone. We hope to present further insight regarding impact and interest in continuing the FL through analysis of comments and further examination of evolving functions since the roles’ introduction.

Intensive Care Medicine Experimental 2020, **8(2)**: 001003

Introduction: Neonatal late-onset-sepsis occurs after 72 hours of life (1,2). The relationship between late-onset-sepsis and mortality can be confounded by other events that are part of NICU journey, thus the true effect on mortality of this complication is difficult to assess (3).

Objectives: The aim of this study was to assess the impact of late-onset-sepsis on mortality in critically ill infants.

Methods: Single-centre retrospective cohort study of neonates admitted to the NICU for ≥72 hours in a 10-year period (2002-2011). Late-onset-sepsis is defined according to National Institute of Child Health and Human Development criteria (2). Multivariate logistic regression analysis was used to assess risk factors for mortality.

Results: Of all admissions, 6.9% developed late-onset-sepsis (Table 1). Infants with late-onset-sepsis had higher mortality, lower gestational age, lower birthweight, longer NICU stay, spent more days mechanically ventilated and on parenteral nutrition. Furthermore, initiation of enteral nutrition was delayed by 7 days in infants who had late-onset-sepsis.

Independent risk factors for mortality included gestational age ≤28 weeks (OR=9.2, CI 3.8-22.3), periventricular leukomalacia (OR=4.3, CI 2.7-6.98), late-onset-sepsis (OR=2.6, CI 1.5-4.2), abdominal surgery (OR=2.3, CI 1.1-4.7) and chronic lung disease (OR 1.97, CI 0.966-4.0).

	No Late-onset-sepsis	Late-onset-sepsis	p-value
N / total (%)	4558/4928 (93.1%)	340/4928 (6.9%)	<0.05
Gestational age weeks	35 (32-38)	32 (28-38)	<0.05
Birthweight	2410 (1740-3200)	1715 (1100-2840)	<0.05
Gender (male)	2690 (58.6%)	195 (57.4%)	0.64
Length of NICU stay (in days)	13 (8-24)	42 (21-75)	<0.05
Mechanical ventilation days	0 (0-3)	4 (0-12)	<0.05
Respiratory Distress Syndrome	2546 (55.5%)	229 (67.4%)	<0.05
Chronic Lung Disease 28 days	254 (5.5%)	87 (25.6%)	<0.05
Systemic corticoids	308 (6.7%)	72 (21.6%)	<0.05
Total parenteral nutrition days	7 (1-12)	20 (12-32)	<0.05
Start enteral feeds	3 (1-7)	10 (5-17)	<0.05
Periventricular leukomalacia	229 (5%)	52 (15.3%)	<0.05
Mortality	232 (5.1%)	34 (10%)	<0.05

Table 1 - Demographics and risk factors when comparing infants who didn't develop late-onset-sepsis with infants who developed late-onset-sepsis. Continuous variables expressed in median (IQR) and dichotomous variables expressed in n(%).

Conclusion: Infants who developed late-onset-sepsis had a higher mortality and a longer, more eventful NICU stay. After adjustment for major risk factors, late-onset-sepsis appeared an independent risk factor for mortality.

001044**Introducing a physiotherapy follow-up service on transition from ICU to the ward: A pilot study (2020)**Fiona¹; A. Waqaar¹; J. Oldhams¹; D. McWilliams¹¹Critical care rehab team, Queen Elizabeth Hospital Birmingham, Birmingham, United Kingdom**Correspondence:** H. Fiona*Intensive Care Medicine Experimental* 2020, **8(2)**: 001044

Introduction: It is well recognized that the transfer from Intensive Care Units (ICU) to the ward is a high-risk transition which causes challenges for staff and anxiety for patients (1). National Guidance for rehabilitation after critical illness (2), recommends a structured handover process for patients and appropriate multidisciplinary follow-up on transition from ICU to the ward. A previous project identified ongoing rehabilitation on the ward is often inconsistent leading to delays in ongoing recovery.

Objectives: To assess the feasibility of a physiotherapy follow-up service for patients transitioning from ICU to the ward.

Methods: Patients admitted to a large UK based ICU between December 2018 and February 2019 were recruited to the study. Inclusion criteria included patients under the care of a specialist critical care rehabilitation team, discharged from ICU with a Manchester Mobility Score (MMS) of less than 5 (i.e. unable to mobilise) and considered to have rehab potential.

On transfer to the ward, patients were continued to be reviewed daily by the ICU physiotherapy team for one week. The physiotherapists provided ongoing structured rehabilitation and communication with the patient, their relatives and facilitated a gradual handover to the receiving ward therapy team during this transition period. Primary outcome was changes in MMS, with secondary measures of patient and staff satisfaction.

Results: 13 patients were included in the pilot. Rehabilitation was delivered consistently during the trial period, with patients reviewed by the ICU physiotherapy team for a mean of 6 days on transition to the ward.

During this time, the median MMS scores increased from 4 (i.e. able to stand with assistance) at ICU discharge, to 6 (i.e. mobilising up to 30 metres).

Patient feedback was extremely positive. Patients valued the continuity of care and felt supported during the step down in care from ICU. Positive feedback was also received from ward staff who felt more supported in the handover process and able to deliver seamless care. However, as the follow-up team was based in ICU, they did face practical challenges during the pilot; including coordination of rehabilitation sessions and communication across multiple wards.

Conclusion: Although a small pilot study, the results demonstrate that the physiotherapy ward follow-up service was feasible to introduce. The pilot study demonstrated an improvement in mobility scores with ongoing structured, physiotherapy rehabilitation. Patient and staff feedback was positive, although the service requires good lines of communication to support timetabling of rehabilitation and team working.

001060**The effect of guidelines implementation combined with simulation training on the course of complications during operation of central venous access devices**E. Beresten¹; E. Korneeva¹; U. Loaisa²; S. Averyanov¹; O. Pimenova³; V. Selivanov¹; V. Shchukin¹; A. Satsuk⁴¹Anesthesiology, Dmitry Rogachev National Research Center of Pediatric Hematology, Oncology and Immunology, Moscow, Russia; ²Methodological accreditation center, Dmitry Rogachev National Research Center of Pediatric Hematology, Oncology and Immunology, Moscow, Russia; ³Management, Dmitry Rogachev National Research Center of Pediatric Hematology, Oncology and Immunology, Moscow, Russia; ⁴General medical department, Dmitry Rogachev National Research Center of Pediatric Hematology, Oncology and Immunology, Moscow, Russia**Correspondence:** E. Beresten*Intensive Care Medicine Experimental* 2020, **8(2)**: 001060

Introduction: Providing a patient with a reliable venous access device is a key factor determining the effectiveness of therapy in pediatric oncology, hematology and immunology. In practice nurses resolve issues related to the usage of central venous access devices.

Objectives: The aim of the study was to determine the impact of implementation of central venous access devices (CVAD) guidelines combined with simulation training of nursing staff on the change in the numbers of infectious and occlusal complications in patients with central vascular access.

Methods: There was a retrospective and prospective analysis of the operational peculiarities of 3357 venous access devices installed to 2453 patients (1336 males, 1117 females) aged from 1 month to 18 years over a January 2018 to December 2020 period.

In 2017 the National Research Center of Pediatric Hematology, Oncology and Immunology approved and implemented guidelines for the operation of central venous access devices. In 2018 the record of all complications during the operation of central venous access devices was started. In 2019 simulation training for nurses was introduced; by the end of 2019 106 people had been trained. The main outcomes were the assessment of complications during the operation of vascular devices.

Results: In 2018 1618 central venous catheters were installed, in 2019 - 1739 ones. During the year after the implementation of the CVAD guidelines the following issues were recorded: infectious complications - 3.2% (n=52), lumen occlusion unrelated to thrombosis - 1.8% (n=30), catheter-related thrombosis - 12.2% (n=199), which in 7.4% (n=121) of patients led to catheter damage during attempts to restore patency. In 2019 given the additional simulation training the following issues were revealed: infectious complications - 2.6% (n=46), lumen occlusion unrelated to thrombosis - 1.72% (n=30), catheter-related thrombosis - 13.7% (n=239), catheter damage - 4.6% (n=81) of patients.

In the group of patients where the guidelines and simulation training were used, the frequency of catheter damage was statistically significantly lower, Pearson's chi-square test showed 11.791, p < 0.001, OR 1.654 95%, CI 1.238-2.211.

A total of 120,059 catheter-wearing days were recorded in 1203 patients in 2018, and 148,327 catheter-wearing days in 1250 patients in 2019.

Conclusion: An analysis of the data showed that the simulation training of nurses in conditions of compliance with the guidelines does not practically affect the frequency of thrombotic and infectious complications, which is most likely related to many additional factors in the pathogenesis of these complications. However due to the simulation training under our conditions the number of catheter damages when restoring catheter patency during the development of intraluminal thrombosis decreased.

The experience of the National Research Center of Pediatric Hematology, Oncology and Immunology has shown that the implementation of simulation training in addition to the usage of the guidelines had reliably reduced the number of damages of central venous access devices.

001120**Preliminary results from an observational study on the incidence of diarrhoea and constipation in Intensive Care Unit**

M. Danielis¹; C. Deana²; S. Veizi¹; P. Gazzola¹; T. Piani²; L. Capolicchio¹; F. Gigante¹; L. Castriotta³; E. Mattiussi¹

Intensive Care Medicine Experimental 2020, **8(2)**: 001120

Introduction: Gastrointestinal motility disorders are frequent events in Intensive Care Unit (ICU). A number of factors increase the frequency of diarrhoea and constipation among critically ill patients, and a number of interventions can prevent them. Given the relevance of these two phenomena, further epidemiological studies are needed.

Objectives: To determine the incidence of diarrhoea and constipation among critically ill patients in ICU.

Methods: An observational study was carried out in three general Italian ICUs with a total of 28 beds. The present investigation was prospective in design, with the analysis of medical records and the direct observation of patients admitted during the period from September and October 2019. Chi-squared and Wilcoxon tests were used to compare factors associated with diarrhoea and constipation. Statistical analysis was performed using the SAS[®] software. The study protocol was endorsed by the Regional Ethics Committee of the Friuli Venezia Giulia region (CEUR-2019-Os-170).

Results: Fifty-three patients were enrolled in the study, mostly males (n=37; 69.8%), with an average age of 66.6 years (SD 13.4) and a BMI of 26.8. For about a half of the sample (n=29; 54.7%) the main diagnosis reported at time of admission was organ failure (especially respiratory). Diarrhoea affected the patients in 10/53 (18.9%) cases within 72 hours after admission in ICU, and in 19/53 (35.8%) during the whole ICU-stay period. The incidence of diarrhoea in patients who received antibiotics and prokinetics was 18% and 37.5% respectively, with no differences with patients who received no antibiotics (p=0.37) and no prokinetics (p=0.78). Among patients who received laxatives, the incidence of diarrhoea was 100%, compared with those who received no laxatives (13.6%; p=0.001). Against, constipation occurred in 26/53 (49.1%) patients within 72 hours after admission in ICU, and in 4/27 (14.8%) on the sixth day. There was no difference between constipated and no constipated patients in terms of opiate and curare use, mechanical ventilation, and hypotension. Remifentanyl administration was associated with increased constipation (p=0.001).

Conclusion: Diarrhoea and constipation are very common among critically ill patients in ICU. Diarrhoea was associated with the use of laxatives, and constipation was associated with the use of remifentanyl.

001171**Critical patient Safety: transition of care in the Nursing Handover**

L. C. A. Leite¹; C. Carvalho¹

¹Serviço de medicina intensiva 1, Centro Hospitalar Universitário do Algarve, Faro, Portugal

Correspondence: L. C. A. Leite

Intensive Care Medicine Experimental 2020, **8(2)**: 001171

Introduction: The handover/handoff process takes place on a daily basis in all health care institutions, accounting for a significant portion of the work time of health professionals, moments and processes that are sometimes neglected and undervalued, although they are considered critical to patient safety.

Objectives: • Introduce a semi-structured approach, evidence-based, in the Nursing handover in a level III ICU.

Methods: Running between December 2017 and March 2018 in a level III UCI, based on project work methodology (1), a semi-structured evidenced-based approach was introduced, adapted to the context combining the ISBAR (Identification, Situation, Background, Assessment, Recommendations) with the primary approach of the critical patient ABCDE (Airway, Breathing, Circulation, Disability and Exposition). It was divided into mandatory items, mandatory reference in all handover moments, and optional items related to the specific clinical situation.

This strategy was assessed through direct observation of the Nursing Handover, with prior obtaining an informed consent, and applying a questionnaire to assess the perception of the Nursing team, after the implementation of the semi-structured evidenced-based approach, with regard to knowledge held on patient safety and the usefulness, satisfaction and sensitive and specific gains to the form.

Results: 100 Handover moments were observed. All nurses gave their consent for observation and records made during these moments. Conformity related to the items referring to the ISBAR mnemonic at the observed times was 89.5%, ranging from 100% (Identification and Evaluation) to 70% (Situation). The compliance related to items referring to the primary ABCDE assessment at the time observed varied from 84% (exposure) and 99% (Airway and Ventilation), with an average of 92.25%. An average of 75.65% of mandatory items was referenced, ranging from 50% (fluid balance) to 94% (Mechanical Ventilation/Oxygen settings)

With regard to the questionnaire, using a Likert Scale (1-10), a high perception of better organization and systematization (7,67) of the Nurse's Handover is notorious, more efficient (7,5) and of better quality (7,16), with the constructed semi-structured instrument being considered useful (7,7), contributing to the increase of satisfaction (7,4) of the Nursing team at this fundamental moment to providing excellent care. These results are transversal to the literature found, with regard to organization and systematization (2-4) efficiency and quality (3,5) and, finally, related to the global satisfaction and usefulness of structuring the care transition (3, 6-7).

Conclusion: There was little knowledge about the subject of patient safety, affected by a relative lack of knowledge in relation to the essential documents that guide this subject, highlighting the improvement of this knowledge after implementation. There was a high rate of compliance, based on the semi-structured tool built for this purpose, in relation to the mandatory reference items, the contents contained in the ISBAR mnemonic and included in the primary assessment, using the ABCDE approach. It is also clear a high perception on the part of the Nursing team, after the use of the semi-structured tool, with regard to improving the organization, systematization, efficiency, quality and satisfaction with the passage of the Nursing shift, with agreement on the part of the referred team the usefulness of the tool created and adapted.

Use of the vasoactive-ventilation-renal score in pediatric heart failure cases as a predictor of an extended intensive care unit stay

S. J. Choi¹

¹Asan Medical Center, Seoul, Republic of Korea

Correspondence: S.J. Choi

Intensive Care Medicine Experimental 2020, **8(2)**: 000052

Introduction: It has been reported that the vasoactive ventilation renal (VVR) score predicts the outcomes of cardiac surgery in children.

Objectives: We investigated whether the VVR score on admission predicts the length of stay (LOS) in the pediatric intensive care unit (PICU) in children diagnosed with heart failure (HF).

Methods: Medical records were reviewed for 96 pediatric HF cases between January 2010 and December 2016. A prolonged LOS (PLOS) was defined by a longer stay than the median duration for the surviving cases.

Results: The median LOS in our current patient series was 12 days. The VIS [14.1 [7.4, 24.3] vs 8.5 [5.0, 18.3], $p=0.018$], VVR [27.8 [11.6, 36.2] vs 11.1 [5.5, 20.7], $p<0.001$], lactic acid level (mmol/L) [2.8 [1.2, 5.3] vs 1.8 [1.1, 2.5], $p=0.020$], and B-type natriuretic peptide concentration (BNP, pg/mL) [2340.0 [1234.8, 6836.8] vs 1478.5 [529.8, 4532.8], $p=0.036$] were significantly different between the prolonged LOS versus the control group. The use of a mechanical ventilator and extracorporeal membrane oxygenation (ECMO) were associated with PLOS (odds ratios: 10.82 and 3.61, respectively). The AUCs of the VIS, VVR score, lactic acid level, and BNP for evaluating the association with mechanical ventilator or ECMO use were 0.682 ($p=0.006$), 0.823 ($p=0.000$), 0.683 ($p=0.006$), and 0.783 ($p=0.000$), respectively. In multivariable logistic regression analysis, the VVR score was the only parameter that was significant for predicting PLOS.

Conclusion: The VVR score on admission to the PICU is predictive for mechanical ventilator or ECMO use, which correlates with a PLOS. The VVR score at PICU admission in children with HF is therefore a useful LOS marker.

Anthropometric methods for assessing nutritional status in a child of one year old with viral diarrhea

Y. Erpuleva¹; M. Gadzhimaeva¹; D. Levina¹

¹Pediatrics and infectious diseases, Sechenov University, Moscow, Russia

Correspondence: M. Gadzhimaeva

Intensive Care Medicine Experimental 2020, **8(2)**: 000059

Introduction: Young children with viral diarrhea lose their body weight very quickly, and consequently their anthropometric indicators sharply decrease, and malnutrition increases up to cachexia. Thereby, it is necessary to perform a short-term assessment of the nutritional status of the child, in order to select nutritional support rationally. The purpose of our study was to assess the nutritional disorder in children on the first year of life with moderate to severe acute intestinal infection of viral etiology based on anthropometric research methods.

Methods: We examined 12 children with moderate to severe acute intestinal infection of viral etiology. Anthropometric methods for assessing nutritional status were used: mass-growth indicators, caliperometry with an assessment of the skin-fat fold of the triceps at baseline and a week after admission. Evaluation of the indicators was carried out according to the calculation formula: body mass index (BMI = Weight / Height² (kg / m²)), centile tables. Used tools: caliper, centimeter tape, table scales.

Results: The analysis of the data revealed that by the time of admission to the hospital 5 (41%) of 12 children showed a decrease in BMI by 10%, and 3 (25%) children showed a decrease in BMI by 20%. One week later BMI was restored to normal. When assessing the skin-fat fold of the triceps, it decrease was found to be 1-2 mm from the norm in all studied children (100%), and was regarded as a mild degree of malnutrition due to indicators less than the 50-th percentile. By the 5th day of the ongoing nutritional support, the fold was restored to the physiological norm (50th percentile).

Conclusion: Anthropometric methods for assessing nutritional status in children with viral diarrhea on the first year of life is found to be easy and helpfully.

Intensive Care Medicine Experimental 2020, **8(2)**: 000365

Introduction: Underweight on admission to the pediatric intensive care unit (PICU) has been associated with outcome. The Pediatric Sequential Organ Failure Assessment (pSOFA) score has been reported as predictor of outcome in critically ill children.

Objectives: The study aim was to assess the effect of organ dysfunction and nutritional status on outcomes of children admitted to PICU.

Methods: Retrospective study of children admitted to the PICU at Texas Children's Hospital (Jan-Dec 2016) with a length of stay (LOS) ≥ 3 days; nutritional status assessed by weight for age (WFA: underweight), z-scores by WHO and CDC. Malnutrition (MAL) defined as mild, and moderate-severe if z-scores were < -1 , < -2 , respectively. Hospital and PICU LOS, risk of mortality (ROM) by PIM2, need of

mechanical ventilation (MV) on admission to PICU, and mortality collected. Organ dysfunction (OD) was defined as a pSOFA score > 5, and collected on days 1 & 3.

Results: A total of 638 children (367 M/271 F) were included; age 2.8 yr. (0.6-11; median (25-75th IQR)). 513 (80.4%) children required MV on admission, had PIM2 ROM (%), 3.1 (0.9-4.7), PICU LOS, 6.4 days (4.4-11), Hospital LOS, 17 days (10-31); and pSOFA score on days 1 & 3 of 5 (4-7) and 5 (3-6) ($p < 0.0001$, Wilcoxon Signed Rank Test) for a prevalence of organ dysfunction of 45% and 38%, respectively. WFA z-score of -0.63 ± 1.97 (SD) and the prevalence of underweight was 35.6%; moderate to severe underweight was associated with organ dysfunction; odds ratio (OR) (95% CI) 1.62 (1.10-2.39) ($p < 0.05$). Children with malnutrition or OD and children with malnutrition and OD vs. normal children were associated with need of MV on admission to the PICU and with mortality; 2.29 (1.51-3.47) ($p < 0.0001$), 7.26 (3.04-17.35) ($p < 0.0001$); respectively; and 5.04 (1.73-14.69) ($p < 0.005$), 4.02 (1.15-14.04) ($p < 0.05$); respectively. A total of 36 children died for a hospital mortality rate of 5.64%.

	PIM2 ROM (%)	PICU LOS Days	Hospital LOS Days
Normal (n=229)	1.40 (0.80-4.07)	5.60 (3.87-8.82)	15 (10-27)
MAL or OD (n=304)	3.18 (0.91-4.98)	6.97 (4.72-11.2)	17 (11-34)
MAL + OD (n=105)	3.81 (1.19-6.39)*	7.87 (4.92-12.1)*	21(11-39)**

Values are median (25th-75th IQR); * $p < 0.0001$, ** $p < 0.05$ by Kruskal-Wallis

Conclusion: Organ dysfunction and underweight were commonly found on children admitted to the PICU. The presence of either or both conditions was associated with higher risk of mortality, need of ventilatory support, longer PICU and hospital LOS, and mortality.

Intensive Care Medicine Experimental 2020, **8(2)**: 000723

Introduction: A genome-wide DNA-methylation study previously identified *de novo* alterations in leukocyte DNA of critically ill children at paediatric intensive care unit (PICU) discharge, which offered a biological basis for the impaired long-term neurocognitive development of these patients. Early use of parenteral nutrition (early-PN) in the PICU, as compared with omitting PN in the first week (late-PN), explained the differential methylation of 23% of the affected CpG-sites. It remained unclear how fast these changes in DNA-methylation took place and how they evolved over time in PICU.

Objectives: We documented the time course of altered DNA-methylation in PICU and the impact hereon of early nutritional management.

Methods: We selected 36 early-PN and 36 late-PN patients, matched for age, type (admission diagnosis) and severity of illness (PeLOD score), infection upon admission, gender, height, weight and educational level of the parents and 42 age and gender matched healthy

children. We quantified DNA-methylation on day 3, 5 and 7 for the 147 CpG-sites of which methylation was normal upon PICU admission in this subset, and altered by critical illness at PICU discharge (EPIC Bead-Chip). For each time point, we determined how many of the CpG-sites were differentially methylated in critically ill as compared with healthy children, applying ANOVA and FDR 0.05. Next, for each CpG-site, we performed within-patients time course analyses of the methylation status, to identify any patterns within the time series based on paired t-test p-value and direction of change from admission to day 3 and beyond. For the CpG-sites affected by early-PN on the last PICU day, earlier changes in DNA methylation status -and patterns hereof- were compared for early-PN and late-PN patients.

Results: Methylation in patients differed from healthy children for 64.6% of the 147 CpG-sites on day 3, for 72.8% on day 5 and for 90.5% on day 7. Rapid demethylation from admission to day 3 occurred for 76.2% of the CpG-sites, of which 67.9% remained equally demethylated or partially remethylated and 32.1% further demethylated beyond day 3. From admission to day 3, 19.7% of the CpG-sites became hypermethylated, of which, beyond day 3, 34.5% remained equally hypermethylated or partially demethylated again and 65.5% further hypermethylated. For 4.1% of the CpG-sites, changes only appeared beyond day 3. Of the CpG-sites affected by early-PN versus late-PN at PICU discharge, 38.9% were already differentially methylated by day 3, another 25.0% by day 5 and another 13.9% by day 7.

Conclusion: Critical illness- and early-PN-induced changes in DNA-methylation occurred mainly within 3 days. Most abnormalities were at least partially maintained or got worse with longer time in PICU. Interventions targeting aberrant DNA-methylation changes should be initiated early.

Anaesthetic management of tracheo-oesophageal fistula with pulmonary atresia, pda with single ventricle with tetralogy of fallot

M. Singh¹; A. Kumar²

¹ANAESTHESIA AND CRITICAL CARE, London North West University Healthcare NHS Trust, London, United Kingdom; ²Anaesthesia and critical care, Lady Hardinge Medical College, New Delhi, India

Correspondence: M. Singh

Intensive Care Medicine Experimental 2020, **8(2)**: 000875

Introduction: Esophageal atresia (EA) with or without trachea-esophageal fistula is a common neonatal emergency which may be associated with major life incompatible cardiac abnormalities. Survival of such neonate depends on stabilization and proper resuscitation followed by postoperative care.

Objectives: Keywords- Esophageal atresia, trachea-esophageal fistula, single ventricle, PDA, VSD

Methods: Case Report:

We came across a 4 days old male baby, with diagnosis of EA and distal TEF, posted for right thoracotomy with primary repair under GA. On preoperative evaluation baby had respiratory distress, frothing from mouth & was hemodynamically unstable on dopamine with oxygen saturation (SpO₂) of 85% on room air. Intraoperatively surgery was uneventful but baby not able to maintain SpO₂ even after ligation of fistula. At time of reversal of neuromuscular blockade, he had active movements, was maintaining SpO₂ of 88% with 100% O₂ & on dopamine. After extubation he maintained SpO₂ of 85% on nasal prongs when shifted to PACU. But after 3 hours of surgery, his SpO₂ started falling & developed persistent cyanosis, so trachea was intubated with chest tube insertion on right side done suspecting pneumothorax or hemothorax or pleural effusion which were subsequently ruled out,

emergency 2 D echocardiography showed large VSD, pulmonary atresia, PDA, single ventricle with Tetralogy of Fallot. He was started on PGE1, Alprostadil & dobutamine because of worsening hemodynamic instability shifted to NICU but was not able to maintain SpO₂>75% with mechanical ventilation. His general physical condition deteriorated over next 2 days and died due to respiratory failure and cardiac arrest.

Results: Discussion and Conclusion:

EA-TEF is a major congenital anomaly and when it is associated with life incompatible anomalies like single ventricle along with PDA, VSD and Pulmonary atresia, it becomes a nightmare and a real challenge to both pediatric surgeon and anaesthesiologists. Success in survival of neonate with EA-TEF is attributed to improved neonatal care, anesthesia and better understanding of neonatal physiology. But unfortunately our institution is not well equipped with emergency cardiac back up which if would have been there, then after successful ligation of trachea-oesophageal fistula, our 4 days old neonate could have been saved, who died of respiratory failure and cardiac arrest.

Conclusion: This case emphasizes the importance of considering headache &/or visual changes developing during postpartum period - a prodrome for LPE even in normotensive patients. Early diagnosis with subsequent initiation of anticonvulsants & antihypertensive can prevent severe complications.

Intensive Care Medicine Experimental 2020, **8(2)**: 001045

Introduction: Longitudinal data on isolated pathogens and trends of antimicrobial resistance (AMR) in pediatric intensive care units (PICUs) are worldwide limited.

Objectives: To determine the most common microorganisms cultured from biological samples along with AMR trends over the years 2008-2019 in a university PICU.

Methods: Data from the Infection Control Committee electronic database were retrospectively exported and analyzed.

Results: Out of 2,127 positive cultures, 1,598 were analyzed (529 duplicates). Overall, Gram (-) microorganisms (972, 60.8%) predominated, mainly represented by *Pseudomonas aeruginosa* (365, 37.6%). Out of Gram (+) pathogens (475, 29.7%) coagulase-negative Staphylococci (CoNS) (280, 58.9%) were most commonly found. Fungal positive cultures were infrequently reported (151, 9.5%). CoNS increased markedly over the years, compared to other Gram (+) pathogens ($p=0.003$) and were the most consistently identified isolates in blood cultures ($p<0.001$). Gram (-) bacteria resistance rates are shown in Table 1.

Antibiotic	Resistance (%)												
	2008	2009	2010	2011	2012	2013	2014	2015	2016	2017	2018	2019

Pip/Taz, piperacillin/tazobactam; Amp/Sulb, ampicillin/sulbactam; C3G, cephalosporins third generation

Conclusion: Gram-negative bacteria were the most commonly cultured pathogens, mainly represented by *Paeruginosa*. Although their incidence did not change over a decade, the high carbapenem and third-generation cephalosporin resistance rates stress the need for strict implementation of infection control bundles and AMR stewardship interventions.

Patent ductus arteriosus (PDA) management: a therapeutic strategy in newborns on vv- ECMO support

S. Bianzina¹; R. Tedeschi²; S. Pezzato¹; S. Buratti¹; A. Moscatelli¹
¹Neonatal and Pediatric Intensive Care Unit, G. Gaslini Hospital, Genoa, Italy; ²Anesthesia and intensive care, University of Bari, Bari, Italy

Correspondence: S. Bianzina

Intensive Care Medicine Experimental 2020, **8(2)**: 001167

Introduction: There is some evidence supporting the manipulation of DA patency in newborns affected by pulmonary hypertension, but choosing the appropriate timing for PDA closure is still a challenge.

Objectives: Aim of our study was to evaluate the haemodynamic effects of PDA closure during vv-ECMO support.

Methods: We evaluated newborns affected by severe acute respiratory failure secondary to pulmonary hypertension on vv-ECMO and with PDA, admitted to our ICU between May 2017 and July 2018. We collected haemodynamic parameters (MAP, HR, SpO₂, NIRS, urinary output), blood gas analysis, biochemical data, respiratory and inotropic support at 24 hours pre and 48 hours post-PDA closure (documented by echocardiography).

Results: We analyzed 7 newborns (2 males and 5 females), with mean gestational age of 36.4 weeks and mean body weight of 2.9 kg. 5 out of 7 patients were affected by congenital diaphragmatic hernia, 1 by meconium aspiration syndrome and 1 by hemolytic disease of the newborn with hydrops. In 3 cases we obtained pharmacological PDA closure (with ibuprofen iv), while 4 patients underwent surgical approach. Comparing post vs pre-PDA closure parameters, we found

a significant reduction ($p < 0.05$) in lactate levels (14 ± 7.8 vs 20.5 ± 13 mg/dl) and epinephrine dose (0.05 ± 0.1 vs 0.08 ± 0.1 mcg/kg/min). We also detected a trend in increasing of MAP (58.7 ± 11.8 vs 53.3 ± 15.2 mmHg) and decreasing of milrinone (0.4 ± 0.33 vs 0.44 ± 0.32 mcg/kg/min) and iNO (9.3 ± 6.1 vs 12.2 ± 6.9 ppm) support, but with no statistical significance. There were no differences, instead, in SpO₂ (95.6 ± 2.1 vs 92.4 ± 9.7 %), NIRS (61.8 ± 9.1 vs 61.9 ± 8.1 %) and urinary output (6.3 ± 2.7 vs 7 ± 4 ml/kg/h).

Conclusion: During the early phase of severe pulmonary hypertension, PDA is important to ensure the unloading of right ventricle and a better systemic perfusion. With the progressive lowering of pulmonary vascular resistances, instead, PDA closure leads to an improvement of systemic perfusion indexes (lactates) and a reduction of inotropic drugs.

Intensive Care Medicine Experimental 2020, **8(2)**: 000134

Introduction: Stroke after coronary artery bypass surgery (CABG), is a serious complication with an incidence of 1.3% and a reported mortality of 20%. Identification of intraoperative and early postoperative pathogenetic mechanisms is important for developing preventive strategies

Objectives: To evaluate perioperative factors related to postoperative stroke in coronary artery bypass surgery (CABG)

Methods: All patients who underwent CABG procedure with the use of cardiopulmonary bypass from June 2012 to February 2020 and were complicated with postoperative ischemic stroke, were retrospectively evaluated. The following perioperative factors were compared between stroke patients-Group A, and control group B: Female gender, history of stroke, current smoking, asymptomatic carotid disease(>50% stenosis), diabetes mellitus, cardiopulmonary bypass time(CPB),low cardiac output syndrome(LCOS) and postoperative atrial fibrillation

Chi square test was used for statistical analysis

Results: From a total of 2339 CABG patients (37 off pump procedures were excluded), 43 were complicated with postop ischemic stroke Results are shown in Table 1

	Group A n=43	Control group n=2296	p
Age	65,6±9	64,9±9.5	
Female (n,%)	11(25,6%)	320(13,9%)	0,04
History of stroke	8(18,6%)	214(9,3%)	0,06
Smoking	12(27,9%)	834(36,5%)	0,28
Carotid disease	10(23,7%)	286(12,5%)	0,04
Diabetes	22(51,2%)	889 (38,7%)	0,11
CPB>120 min	13(30,2%)	406(17,7%)	0,03
LCOS	7(16,3%)	142(6,1%)	0,03
Post-op AF	24(55,8%)	670(29,2%)	<0,01

Conclusion: Female gender, carotid disease, CPB time > 120 min, LCOS and postoperative atrial fibrillation are factors with statistical significant relationship with postoperative ischemic stroke after CABG

Intensive Care Medicine Experimental 2020, **8(2)**: 000136

Introduction: Surgical revascularization is the only therapeutic choice in many patients with coronary artery disease. The optimal timing of coronary artery bypass grafting(CABG) after myocardial infarction (MI) remains unclear

Objectives: To investigate if time interval between myocardial infarction and elective CABG has any impact on early postoperative morbidity and mortality

Methods: All patients with a history of myocardial infarction, who underwent CABG procedure with the use of cardiopulmonary bypass from June 2012 to February 2020, were retrospectively evaluated. Exclusion criteria were : Rescue CABG and off pump procedures. Based on time distance from myocardial infarction(MI) patients were divided in : MI < 1 month (Group A) and MI > 1 month (Group B) The following factors were compared between the groups: post-op use of Intra-aortic Balloon Pump (IABP), use of Levosimendan for inotropic support, atrial fibrillation (AF), acute kidney injury(AKI), prolonged mechanical ventilation (>24 hours), perioperative myocardial infarction (PMI) and mortality. We also compared patients with MI < 1week (Group C) with the rest of the cohort (Group D). Age, gender, Euro score II were similar between the groups. Chi square test was used for the statistical analysis

Results: Results are shown in Tables 1 and 2

	Group A n= 467	Group B n= 635	P value
Use of IABP (n,%)	57 (12,2%)	45 (7,1%)	0,004
Levosimendan (n,%)	49 (10,5%)	43 (6,8%)	0,03
AF(n,%)	150 (32,1%)	201 (31,7%)	0,87
AKI(n,%)	50 (10,7%)	94 (14,6%)	0,1
Prolonged ventilation (n,%)	17 (3,6%)	20 (3,1%)	0,65
PMI(n,%)	5 (1,1%)	8 (1,3%)	0,8
Mortality (n,%)	13 (2,8%)	8(1,3%)	0,07

Table 1

	Group C n= 81	Group D n= 1021	P value
Use of IABP (n,%)	14 (17,3%)	88 (8,6%)	0,01
Levosimendan(n,%)	11(13,6%)	81 (7,9%)	0,08
Prolonged vent (n,%)	9 (11,1%)	28 (2,7%)	<0,01
PMI(n,%)	4 (4,9%)	9 (0,9%)	0,01
Mortality (n,%)	4 (4,9%)	17(1,7%)	0,04

Conclusion: In patients who underwent CABG during the first month from myocardial infarction IABP and Levosimendan were more common required. Patients with time interval of 1 week had higher mortality, while use of IABP was more frequent. Perioperative myocardial infarction and prolonged mechanical ventilation were also more frequent

Introduction: Postoperative atelectasis after cardiac surgery with median sternotomy, occurring 32 to 68% [1] [2] [3], is commonly considered as a cause of postoperative hypoxia. On the other hand, re-expansion pulmonary edema (RPE), rather than atelectasis, is frequently considered as a cause of postoperative hypoxia after minimally invasive cardiac surgery (MICS) with right mini-thoracotomy although the reported incidence of RPE is only 2.1% [4]. There is no previous study reporting the incidence of postoperative atelectasis in patients who had MICS with right mini-thoracotomy.

Objectives: The aim of this study is to assess the incidence rate of postoperative atelectasis in patients who underwent a right mini-thoracotomy MICS.

Methods: We retrospectively investigated the incidence rate of postoperative atelectasis in patients who underwent a right mini-thoracotomy MICS between January 2017 and December 2018 in our hospital. Postoperative chest X-rays were reviewed by two independent doctors and diagnosis of atelectasis was made only when two doctors agreed. We included only atelectasis defined by collapse or incomplete expansion of the right lung or part of the right lung and excluded pulmonary edema without volume loss of the lung field.

Results: One hundred fifty patients underwent right mini-thoracotomy MICS during the period. We excluded 3 patients who had reoperation on the same day because of complications of the first surgery and we included total of 147 patients. The mean age was 59.1 years and 57% were male. 48 patients (32.7%) were diagnosed with atelectasis on the operated side. Cohen's kappa inter-evaluator reliability was 0.637. Most conducted surgery was mitral valve surgery (82 patients, 55.8%). RPE was detected only in six patients (4.1%).

Patients with postoperative atelectasis were older (mean age; 64.8 vs 58.9, $P = 0.035$) than patients without postoperative atelectasis. There was no statistical difference in the incidence of atelectasis between aortic valve surgery and mitral valve surgery (37.2% vs 30.5%, $P = 0.29$).

Conclusion: We detected about 30% postoperative atelectasis on the operated side after right mini-thoracotomy MICS. Atelectasis is a common postoperative complication not only in cardiac surgery with median sternotomy but also in MICS with right mini-thoracotomy. Atelectasis should be included in the differential diagnosis for postoperative hypoxemia after MICS with right mini-thoracotomy because postoperative atelectasis can be rapidly improved with active physical therapy.

000167**SIM, RECORD, REPLAY, REPEAT Model: Putting lessons from simulation & simulation debrief into practice within 15 minutes**

P. Walker¹; S. Peck¹; L. Bezzina¹; A. Mohamed¹; C. Curtin¹

Correspondence: L. Bezzina

Intensive Care Medicine Experimental 2020, **8(2)**: 000167

Introduction: The literature, qualitative feedback and personal experience tells us that simulation provides a highly effective platform for learning owed to its' fully immersive design which aims to replicate substantial aspects of real life for a medical professional [1] but without putting patients at risk. Yet it is hard to quantify if it is more effective than the traditional didactic equivalents and if it *is*, as we suspect it is, to what degree [2]. Secondly, it remains almost impossible to evaluate whether the clear technical and non-technical learnings, that take place during a full day of simulation, are put in to practice upon an individual's return to work.

Here we describe a simulation design which enable the learning from simulation and the simulation debrief to be put into practice immediately within an individuals' workplace, with their usual colleagues, in the same morning. This is likely to be a superior model for in-situ simulation going forward. Barking, Havering and Redbridge University Trust (BHRUT) hold anaesthetic and theatre clinical governance meetings on a monthly basis and thus, all theatre activity is stopped across site for an entire morning. On these mornings theatre staff are asked to come in as normal and hence this presents a perfect opportunity for training.

Objectives: We aim to demonstrate that learning and knowledge through the proposed SIM, RECORD, REPLAY, REPEAT process is more likely to be retained as a result of making errors and correcting errors in consecutive simulations, respectively, within their work environment and with their usual team.

Methods: The simulation team, the junior on-call anaesthetist, the consultant anaesthetist on-call and a full cohort of theatre staff including, ODPs, scrubs nurses and anaesthetic nurses were involved in an in-situ simulation scenario of anaphylaxis on induction.

The simulation was recorded on the 'SMOTS™ In-Situ System' cameras with playback SMOTS technology [3]. The simulation ran for 10-minutes in a functional theatre and the debrief that followed took place immediately afterwards in the neighbouring empty theatre. Staff first watched their performance back and then debriefed their performance, stating which technical and non-technical factors they felt they underperformed in and how these could be corrected. Staff were then given the opportunity to take part in an identical simulation, retaining the same roles, in an endeavour to improve aspects of their performance that they identified as suboptimal.

Results: Result collection is ongoing at time of writing: Through this work we hope to demonstrate that a second playback and debrief of a second consecutive identical in-situ simulation will provide evidence of significant improvements in performance. More importantly, we hope to demonstrate that learning and knowledge through this process is more likely to be retained as a result of making errors and correcting errors in consecutive simulations, respectively.

Conclusion: We put the 'SIM, RECORD, REPLAY, REPEAT' process described here forward as a superior model for in-situ simulation training because of the obvious advantages of the conditions (no theatre lists, same workplace, same team) together with being able to action both technical and non-technical learnings with immediate effect. We postulate that learnings in these conditions are more likely to make it into the working environment as a result of the usual team being involved and bearing witness to improvements over a short period of time.

We believe this model can be extrapolated to ITU and other areas of medicine and we would encourage staff and managers to look to create space for this model of learning owed to the clear benefits for patient safety.

Intensive Care Medicine Experimental 2020, **8(2)**: 000210

Introduction: Vitamin C has been investigated for a wide variety of uses within intensive care due to its anti-oxidative properties (1, 2, 3). Research regarding its potential for the prevention of postoperative atrial fibrillation (POAF) after cardiac surgery is ongoing but results remain inconsistent (4, 5, 6). Due to a broad intracellular anti-oxidant effect, several postoperative pathological effects might be mitigated. Taking into account the low cost of vitamin C, it might be more valuable to investigate a pharmaco-economic benefit in addition to an effect on POAF.

Objectives: Our primary goal was to investigate the pharmaco-economic impact of perioperative supplementary oral ascorbic acid intake in patients undergoing coronary artery bypass graft surgery (CABG). Secondary endpoints were the effects on the length of stay in both the intensive care unit (ICU) and the hospital and the incidence of POAF.

Methods: After IRB approval, patients planned for CABG who met the inclusion criteria (in cardiac sinus rhythm preoperatively and not taking supplementary vitamin C independently) were randomized into a placebo group and an intervention group. The medication was given orally, 1 gram twice a day, starting from 5 days preoperatively until 10 days postoperatively. The used medication, length of hospital and ICU stay and development of POAF in ICU were recorded. We report the preliminary results with a calculated target sample size of 75 patients. Significant differences were assessed using an independent T-test and a Mann-Whitney U test.

Results: Of the 119 screened patients, 68 patients completed the study. Except for BMI (p=0.029), there was no statistically significant difference in baseline characteristics. (Table 1) The median pharmaco-economic cost was significantly lower (P=0.009) in the vitamin C group (€ 1636) than in the placebo group (€1687). There was no significant difference in the incidence of POAF or length of stay. (Table 2)

Table 1. Demographics

	Vitamin C	Placebo
Age (Mean; Standard Deviation)	66 (10)	66 (8)
Male/Female (Count)	24/6	31/7
BMI (Mean; Standard Deviation)	25,9 (3,1)	28,0 (4,5)

Table 2. Results

	Placebo	Vitamin C	P-value
Pharmaco economic expenditure (median; min-max)	€ 1687 (€ 1299- € 3662)	€ 1636 (€ 663 -€ 1892)	0.009
Length of hospital stay (days) (Median; min-max)	7 (5-14)	7(5-9)	>0.05
Length of ICU stay (hours) (Median; min-max)	36 (8-93)	28 (21-68)	>0.05
POAF incidence	7/38 (18.4%)	7/30 (23.3%)	>0.05

Conclusion: In this preliminary analysis, Vitamin C had a small pharmaco-economic benefit when used in the perioperative period of CABG surgery. No effect was found on the length of stay or the incidence of POAF. However, we should acknowledge the fact this is preliminary data and further inclusion is warranted. Potential benefits in other types of cardiac surgeries should also be investigated.

Introduction: Cardiac surgery patients receive large amounts of fluid perioperatively. Some studies demonstrated that an intraoperative liberal infusion of fluids was associated with increased morbidity.

Objectives: The aim of this study was to evaluate the impact of intraoperative excessive fluid balance in relation to early acute kidney injury and mortality in patients undergoing off-pump coronary artery bypass graft surgery.

Methods: A prospective cohort study during 1 year in two tertiary hospitals. The study included consecutively patients aged 18 years or more who required postoperative ICU after undergoing off-pump coronary artery bypass graft surgery. Patients were compared intraoperatively to those who received excessive fluid balance (EFB) or not (non-EFB). The primary endpoint was early acute kidney injury.

Results: After matching, 180 patients remained in each group. The percentage of acute kidney injury was 31.7%. The intraoperative fluid balance from non-survivors was higher. Patients with fluid balance above 2500 mL intraoperatively had a higher incidence postoperatively of composite cardiovascular complications, intra-aortic balloon pump requirement and mortality, but not early acute kidney injury. During the study period, 586 surgical patients were enrolled (329 excessive fluid balance and 257 non-excessive fluid balance)

The postoperative complications are shown Table 1. Although no differences were observed in acute kidney injury between the EFB and non-EBF ($P = 0.36$), the cardiovascular complications postoperatively were higher in EFB group. Also, mortality rates were statistically different in EFB (10%) and in non-EBF (3.9%) groups $P = 0.02$.

Table 1. Postoperative outcomes

	Original Cohort		P	Matched Cohort		P
	Non-EBF (n=257)	EBF (n=329)		Non-EBF (n=180)	EBF (n=180)	
On ICU postoperatively						
Composite cardiovascular, n (%)	190(34.4%)	270(45.7%)	0.0063(35.0%)	96(53.3%)	0.000	
intra-aortic balloon pump requirement, n (%)	12(2.2%)	39(6.6%)	0.003(1.7%)	11(6.1%)	0.02	
Acute kidney injury (%)	209 (37.9)	207 (35%)	0.3261(33.9)	53 (29.4%)	0.36	
ICU LOS (d), median (IQ 25–75)	2 (1–4)	2 (1–4)	0.593 (1–4)	2 (1–4)	0.29	
Hospital LOS (d), median (IQ 25–75)	17 (11–26)	16 (9–25)	0.30 ¹⁵ (9–23.75)	22 (13–30.75)	0.01	
Hospital mortality rate	53(9.0%)	66(12%)	0.107(3.9%)	18(10.0%)	0.02	

Legends: EFB - Excessive fluid balance. ICU – intensive care unit. All values between parentheses represent percentile 25–75 values observed.

Conclusion: Patients undergoing off-pump coronary artery bypass with excessive intraoperative fluid balance have more complications and higher hospital mortality, but the same incidence of early acute kidney injury.

Intensive Care Medicine Experimental 2020, **8(2)**: 000308

Introduction: Acute kidney injury (AKI) is a significant complication in the care of patients with end-stage liver disease (ESLD) after liver transplantation (LT). In the present study, we addressed the question of whether those with AKI had a greater difference (deficit) between pre-morbid and within-ICU hemodynamic pressure-related parameters compared to those without AKI.

Methods: Prospective observational study including all patients admitted to the ICU after liver transplantation over a 3-years study period. Demographic variables (sex, age, cause of transplantation and severity scores), hemodynamic variables, and those related to graft function and postoperative complications were recorded. Patients were classified according to the development of AKI.

We obtained pre-morbid and ICU, time-weighted average values for hemodynamic pressure-related parameters (systolic [SAP], diastolic

[DAP], and mean arterial pressure [MAP]; central venous pressure [CVP], mean perfusion pressure [MPP], and diastolic perfusion pressure [DPP]) and calculated deficits in those values.

Data statistical analysis was done using SPSS software. Quantitative variables are expressed as mean with standard deviation (SD) and qualitative variables as absolute and relative frequencies. The statistical significance of the proportion comparison was addressed by the chi-square test, Mann Whitney U test or Student's t-Test with a statistical significance $p < 0.05$.

Results: During the study period, 100 patients were admitted to the ICU after a liver transplantation (80% male) with a median age of 56 (IQR 50–61). The main causes of the liver transplant were alcoholism (58%), hepatocellular carcinoma (45%) and hepatitis C virus infection (43%). Median MELD score was 13 (IQR 9–19); Median ICU stay was 5 days (IQR 4–9), with an overall ICU mortality of 8%.

Fifty nine patients presented AKI, which was associated with a significantly higher ICU stay (4 vs 6, $p=0.005$), higher hospital stay (13 vs 20, $p=0.005$) and higher ICU mortality (0 vs 8, $p=0.001$).

All achieved pressure-related values were similar between patients with or without AKI progression. However, a significantly greater increase in CVP was observed in patients with AKI (0 vs 27%, $p=0.039$).

Conclusion: Acute Kidney Injury after liver transplantation is a frequent complication which is associated with worse outcomes. The hypervolemia defined as an early increase in CVP could be a modifiable factor.

Correspondence: J.C. Lopez-Delgado

Intensive Care Medicine Experimental 2020, **8(2)**: 000387

Introduction:

Nutritional status influences perioperative outcomes in patients with heart failure and cardiac surgery

Objectives: The aim of our study was to assess the influence of nutritional status on the results and prognosis of patients undergoing cardiac surgery.

Methods:

Prospective observational study from 2011 to 2015. Preoperative nutritional status was assessed using the Prognosis Nutritional Index (PNI). PNI was calculated as $10 \times \text{serum albumin (g/dL)} + 0.005 \times \text{total lymphocyte count (per mm}^3\text{)}$. Preoperative and intraoperative variables, postoperative complications, and hospital and long-term mortality were collected in a local database.

Results: 1279 patients were included: mean age 67 (59–73.43) years; 68.49% (876) were men; BMI: 27.3 (24.9–30) Kg/m²; APACHE II: 12 (9–15). 54.03% (691) were valve surgeries and 40.27% (515) bypass surgeries. Hospital mortality was 6.8% (87). The patients were classified according to the nutritional status based on PNI values in three subgroups:

Normal 64.8% (829), Moderate 20% (256) and Severe 15.2% (194).

Univariate analysis between subgroups identified higher postoperative complications and mortality in the subgroups with the worst PNI. The multivariate analysis showed a longer mean hospital stay (24 (16-33) vs 29.5 (21.75-41) days; OR: 1.015; 95% CI: 1.006-1.024; $P=0.001$) in the moderate subgroup when compared to the normal one. Likewise, a higher degree of renal dysfunction was observed (93 (77-115) vs 113 (83-169) $\mu\text{mol/L}$ of creatinine; OR: 1.003; 95% CI: 1.001-1.005; $P=0.005$), a greater mean hospital stay (24 (16-33) vs 33 (24-49) days; OR: 1.022; 95% CI: 1.009-1.034; $P<0.001$) and a longer time in mechanical ventilation (14 (8-20) vs 18 (10-68) hours; OR: 0.998; 95% CI: 0.996-0.999; $P=0.01$) in the subgroup of patients with severe PNI compared to the normal subgroup.

Conclusion: A higher PNI may be associated with greater postoperative complications (i.e., renal and respiratory) after cardiac surgery, as well as a longer hospital stay in our population.

Blood volume and preload responsiveness; a post hoc analysis of a randomized controlled trial

A. Lindén-Søndersø¹; S. Statkevicius²; J. Bonnevier²; P. Bentzer¹

¹Department of anaesthesiology and intensive care, Helsingborg Hospital, Helsingborg, Sweden; ²Department of intensive and perioperative care, Skåne University Hospital Lund, Lund, Sweden

Correspondence: A. Lindén-Søndersø

Intensive Care Medicine Experimental 2020, **8(2)**: 000579

Introduction: Signs of inadequate cardiac output in the post-operative phase after major surgery is often treated with fluid in order to optimize preload [1]. Given that overly aggressive fluid treatment is likely to worsen outcome, prediction of fluid responsiveness by dynamic indices should be used in patients with circulatory instability to identify those likely to respond to fluid therapy with an increase in cardiac output [2]. However, preload is dependent not only on blood volume but also on venous tone meaning that fluid responsiveness may be related to a lower than normal venous tone rather than hypovolemia [3]. If so, this could imply that a pharmacological increase in venous tone can be a more rational approach to increase preload in some preload responsive patients.

Objectives: To assess the prevalence of hypovolemia in a cohort of patients likely to be preload responsive.

Methods: Data from the randomized controlled trial AIR was analyzed [4]. The AIR trial included post-operative patients after major abdominal surgery and was approved by the regional ethical vetting board in Lund, Sweden.

Inclusion criteria for the present analysis were post-operative patients with signs of hypoperfusion: a) $\text{ScvO}_2 < 70\%$, b) lactate $> 2 \text{ mmol/L}$, c) urine output $< 0.5 \text{ ml/kg}$ in the hour prior to inclusion or d) systolic BP $< 100 \text{ mmHg}$ or MAP $< 55 \text{ mmHg}$. In spontaneously breathing post-operative patients the passive leg raising test appear to be the most useful predictor of preload responsiveness [5,6]. A positive passive leg raising test was used to identify patients likely to be preload responsive and was defined as an increase in pulse pressure (ΔPP) of $> 9\%$, measured through an arterial line [7].

Plasma volume (measured using 125I-albumin) and hematocrit (measured spectrophotometrically) was used to calculate blood volume (BV). Normal BV was estimated based on length, weight and gender [8,9]. Patients were considered hypovolemic if the measured BV was at least 10% lower than the predicted normal BV, as previously defined

[10]. We defined hypovolemia as at least 10% higher BV than the predicted normal value. Data are presented as median (interquartile range) or as proportions.

Results: A total of 40 patients were included in the analysis. Baseline characteristics can be seen in Table 1.

Median blood volume in the cohort was 4051 (3373-5275) ml or 55 (49-64) ml/kg. A total of 43% (17/40) of the patients were hypovolemic, 32% (13/40) were euvolemic and 25% (10/40) were hypervolemic (Figure 1). A correlation analysis showed no correlation between blood volume and ΔPP after PLR (Spearman, $R = -0.109$ [95% CI -0.414-0.219, $P=0.505$]).

Table 1 - Patient demographics

Age, yrs	67 (54-73)
Weight, kg	71 (62-85)
Height, cm	167 (163-176)
ASA	2 (2-3)
POSSUM physiology score	15 (13-17)
Revised Cardiac Index Score	1 (1-1)
Duration of surgery, min	402 (329-480)
Duration of anesthesia, min	506 (439-585)
Peroperative bleeding, ml	600 (263-1000)
Peroperative diuresis, ml/kg/h	0.6 (0.4-1.0)
Peroperative crystalloids, ml	4325 (3963-5250)
Peroperative colloid, ml	725 (500-1000)

Conclusion: A large fraction of hemodynamically unstable post-operative patients likely to be preload responsive are not hypovolemic and in these patients a pharmacological increase in venous tone may be a more rational approach to increase preload than further intravenous fluid administration.

Intensive Care Medicine Experimental 2020, **8(2)**: 000679

Introduction: Most important problem of early post-operative period post major abdominal surgeries is Intestinal Failure (IF) which if unmanaged properly might lead to Abdominal Compartment Syndrome, ultimately causing Multiorgan Failure. Postoperative IF is suppression of motor-evacuation function, alteration of small bowel digestive, food intake capability, developing critical water-electrolyte imbalance, circulatory hypoxia of bowel wall, dysbacteriosis with proximal microbial colonization of bowels, accompanied by changes in acid-base balance. Main reason is inadequate infusion therapy during perioperative period. Liberal infusion therapy might aggravate visceral edema of ischemic bowels, while as insufficient infusion therapy might aggravate splanchnic ischemia

Objectives: Improving result of surgical treatment of patients post emergency abdominal surgery with selection of perioperative infusion therapy strategies, optimal for postoperative restoration of intestinal function

Methods: Research work included 60 patients (28 male, 32 female, average age 56.5 ± 14 years) post emergent abdominal surgeries, divided into 2 groups. In group 1 (n=29) perioperative infusion therapy included balanced ionic solutions. 2nd group (n=31) balanced ionic solutions was combined with synthetic colloids. For investigation of intestinal function in postoperative period, complex assessment of gastrointestinal tract condition, including physical examination, measuring of intra-abdominal pressure (IAP), ultrasound visualization of condition of intestinal wall as well as absorptive function of gastrointestinal tract, laboratory monitoring, perioperative infusion therapy was recorded, monitoring of vital functions

Results: The correlation reviewed was strong significant ($r=1.000$, $p=0.01$) between the amount of infusion therapy and stage of IF. Day 1 & subsequent two days, patients in both groups showed IF 3rd stage. Signs of bowel function recovery were observed by Day 4. Correlation analysis, strong significant correlation between stage of IF and lumen diameter of small bowel ($r=0.931$), intestinal wall thickness ($r=0.940$), IAP ($r=0.998$, $P=0.01$). The IAP as parameter with highest r compared to other parameters was considered prognostic index for the IF dynamics, used to determine tactics of infusion therapy. In group 2, significant correlation was found between intraoperative infusion volume

and IAP ($r=0.417$), demonstrating that both excessive & insufficient infusion load results in increased IAP on Day 1. Investigation of influence of infusion therapy quality on intestinal failure stage discovered that inclusion of a third generation hydroxyethyl starch infusion solution (patients of group 2) lowered infusion therapy influence on the bowels condition. Analysis of influence of infusion therapy quality on IAF and IF severity did not find significant differences between use and non-use of colloids as a part of infusion therapy; nevertheless, a trend towards more favorable course of IF in patients of group 2 was noted. Hence, the presence of colloids as a part of infusion therapy can be considered influence on IF severity

Conclusion: The amount of intraoperative infusion therapy has direct effect on postoperative intestinal function. Optimization and administration of oriented infusion therapy in postoperative periods leads to early regression of intestinal failure

Intensive Care Medicine Experimental 2020, **8(2)**: 000692

Introduction: Arterial hypotension following spinal anaesthesia is a common issue in clinical practice, possibly leading to major complications in emergency settings [1]. To prevent this, standard administration of intravenous fluids is usually performed. Inferior vena cava (IVC) ultrasound [2] and passive leg raising test (PLRT) [3] are effective methods in guiding fluid therapy in non-critical patients.

Objectives: Aim of the study was to evaluate IVC ultrasound and PLRT guided volaemic optimisation compared to standard of care in patients undergoing spinal anaesthesia, in order to decrease post-anaesthesia hypotension rate and excessive fluid administration.

Methods: This prospective, controlled, randomised trial included 474 consecutive patients, allocated in a block of six into a *control group*, an *IVC-ultrasound group* and a *PLRT group*. Inclusion criteria were adult patients of both sexes, evaluated as American Society of Anaesthesiology (ASA)-risk class I to III 4, undergoing an elective intervention under spinal anaesthesia. Patients from the three groups received the same standard non-invasive monitoring.

Control group: According to standard of care, volaemic filling status was not checked prior to the procedure. Post-spinal anaesthesia hypotensive patients were treated according to standard protocol and clinical situation with crystalloid replacement and vasoactive drugs.

IVC-ultrasound group: IVC collapsibility index (IVC-CI) of 36% was chosen as the cut-off level to differentiate *responsive* (with IVC-CI >36%) or *unresponsive* patients (IVC-CI <36%) to fluid administration. In case of *responsive* pattern, 500 ml of crystalloid infusion over 20 minutes was administered.

PLRT group: Before and after the PLRT, etCO₂ analysis was performed; patients with an etCO₂ increasing more than 12% from baseline were interpreted as *responsive* and received crystalloid infusion.

Primary outcome was the hypotension rate reduction after spinal anaesthesia. Secondary outcomes were fluid amount administered, the amount of vasoactive drug used and the time needed to perform the whole anaesthetic procedure.

Results: An 11% reduction rate in hypotension ($p = 0.047$) was observed between the IVCUS group and the control group. A 2% reduction rate in hypotension ($p = 0.428$) was observed between the PLRT and the control group. Total fluid amount administered was greater in the IVCUS than in the control group (593 ml versus 453 ml, $p = 0.014$), but selectively administered, according to patient's volaemic status. Total amine consumption was 36% in control group, 16% in IVCUS group and 22% in PLRT group. Procedure time was increased in the IVCUS group (48 min) compared to control group (46 min) and PTLR group (40 min), $p = 0.35$.

Conclusion: IVCUS-guided fluid replacement was a method able to generate a significant reduction in post-spinal arterial hypotension rate.

Central venous to arterial CO2 difference (DCO2) assisted goal directed hemodynamic management during major surgery- a randomized controlled trial

L. Kumar¹; PK. Das²; S. Tripathy³

¹Anesthesia & critical care, AIIMS, Bhubaneswar, India; ²Assistant professor, anesthesia & critical care, AIIMS, Bhubaneswar, India; ³Md,dnb,edic. additional professor, dept. of anesthesia and critical care, All India Institute of Medical Sciences, Bhubaneswar, Bhubaneswar, India

Correspondence: S. Tripathy

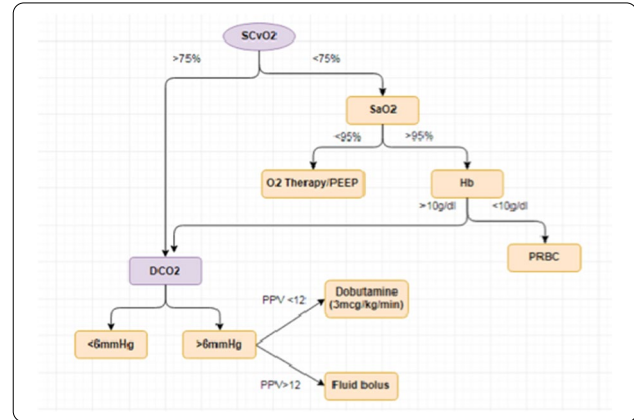

Intensive Care Medicine Experimental 2020, **8(2)**: 000859

Introduction: Conventional goal-directed therapy(GDT) as used in perioperative & critical care to optimize resuscitation, has had mixed outcomes. (Gelman 2020) The venous-to-arterial partial pressure of CO2 difference (DCO2) reflects oxygen supply to demand adequacy and has been suggested to improve resuscitation in sepsis. (Mallat et al. 2016)(Nassar and Mallat 2019) We hypothesized that a DCO2 guided GDT protocol would decrease morbidity after major surgeries.

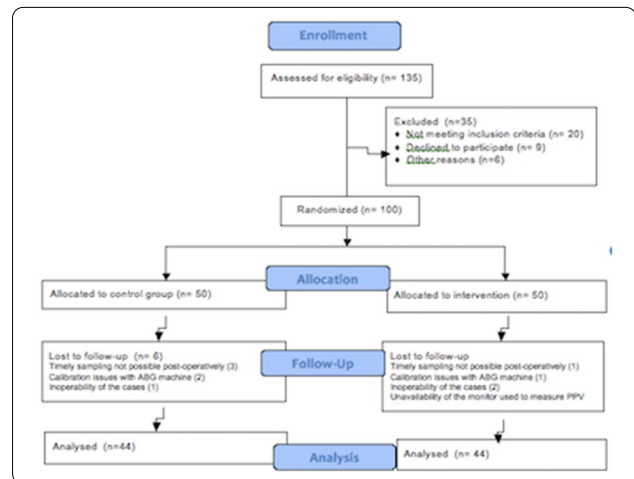

Objectives: To compare the incidence of postoperative organ dysfunction, length of ICU, and hospital stay in patients undergoing major surgeries when managed by a goal-directed DCO2 aided protocol versus usual care.

Methods: This was a double-blind randomized controlled trial (RCT), permitted by the institutional ethical committee and registered prospectively (CTRI/2018/07/014987). Conducted from July 2018 to May 2020 in an 800 bedded university teaching center with 16 multispecialty theatres and 14 bedded intensive care unit. 100 ASA1/2 patients undergoing elective major surgeries and planned for arterial and central venous catheters were randomized (computer-generated random numbers) and allocated (sealed opaque envelopes). In both groups, arterial and venous blood samples were collected second hourly (or earlier in the intervention group (I) if changes were made). Fluid management was based on a prespecified protocol that used pulse pressure variation (PPV), central venous saturation (SCVO2), hemoglobin

(Hb), and DCO2 levels to guide GDT in group I. Dobutamine infusion was started if DCO2 was > 6mmHg, other parameters being normal. (Figure1). Control group C was provided care as per unit protocols. Patient demographics, details of the surgery, duration, hemodynamics, fluid balance, vasopressors and inotropes used, blood gas reports, and ICU parameters like APACHE and S071OFA scores were noted for 48 hrs after surgery. Organ dysfunction was defined as an increase in SOFA score from the preoperative value. Appropriate statistical tests were applied for sample size calculation and comparing the outcomes.

Results: Data were analyzed from 44 patients in each group. Patients were similar between the groups. The majority of the patients underwent oncosurgery (64%), followed by neurosurgery (16%) and urosurgery (10%). Length of ICU stay in group I (M= 1.52, SD 0.82) was significantly less than group C (M= 2.18, SD= 1.08, t= 3.21, p= .002). The incidence of complications and the length of hospital stay were comparable between the groups.

Conclusion: Conclusion- In this RCT a protocolized approach of DCO2 guided goal-directed therapy in patients undergoing elective major surgery, resulted in a significantly decreased length of ICU stay. The concept of using DCO2 seems both elegant and cost-effective in major surgeries (where arterial and central lines are already planned) and may prove of benefit in the era of enhanced recovery after surgery. Better powered multicentric studies in patients with comorbidities may demonstrate a difference in organ dysfunction and other outcomes in the future.

Intensive Care Medicine Experimental 2020, **8(2)**: 000894

Introduction: MDR colonization is a major issue for perioperative and intensive care medicine frequently resulting in life-threatening infections.

Objectives: Within our ICU admissions, the aim of this study was to evaluate MDR colonized patients undergoing surgery and their post-operative course compared to non colonized patients.

Methods: We retrospectively analyzed all consecutive patients undergoing surgery in our hospital for a period of 21 months (July 2017–April 2019) that required ICU admission on POD 0. We then compared MDR colonized (rectal and/or pharyngeal swab) patients (MDR+) to non colonized patients (MDR-) for post operative complications, ICU and hospital LOS and mortality. We also investigated the impact of targeted perioperative antibiotic therapy compared to empiric antibiotic prophylaxis (<https://www.save.veneto.it/home-sanitari/>).

Results: 540 patients were included in the study (352 men, 65%), mean age 68±12 years; they underwent either elective (n=477, 88%) or emergency (n=63, 12%) surgery; 234 (44%) were submitted to pancreatic surgery, 137 (25%) to hepato-biliary surgery, 100 (19%), to intestinal resection and the rest to other abdominal/vascular surgery; they were admitted to ICU on POD 0 for scheduled (n =461, 85%) or unscheduled intensive PO monitoring.

143 pts were pre operatively MDR+ (27%), 54 (38%) of whom were either Klebsiella Pneumoniae Carbapenemasis Producer or Enterococcus Faecium VRE colonized and 115 (80%) were ESBL colonized. ICU LOS was significantly higher in MDR+ compared to MDR- (8.02±13.8 vs 2.39±3.4 days, p <0.05). Hospital mortality occurred in - patients, - were MDR+, - of them in the ICU. Complication rate and type were significantly higher in MDR+ patients (97, 68%) compared to MDR- (118, 30%).

88 MDR+ patients (52%) received targeted pre-operative antibiotic therapy compared to standard prophylaxis but, despite a trend, this did not influence their outcome significantly.

Conclusion: Pre-operative surveillance swab positivity correlates with both ICU LOS and post-operative mortality. Targeted perioperative antibiotic prophylaxis may modify patient's outcome and this should be routinely evaluated. More studies are needed to further investigate the possible therapeutic options in MDR+ patients undergoing surgery.

000910**Goal Directed Fluid Therapy Post Orthotopic Liver Transplantation: A Systematic Review**

T. Joseph¹; F. Froghi¹; D. Martin¹; B. Davidson¹

¹Ucl division of surgery and interventional sciences, Royal Free Hospital, London, United Kingdom

Correspondence: T. Joseph

Intensive Care Medicine Experimental 2020, **8(2)**: 000910

Introduction: Orthotopic liver transplantation (OLT) is the only effective treatment for end stage liver disease (ESLD) [1]. Advanced liver cirrhosis has numerous pathophysiological consequences that leads to difficulty in controlling fluid balance. The OLT procedure also has significant haemodynamic consequences [2]. Goal-directed fluid therapy (GDFT) has been shown to reduce postoperative complications in the general surgical population [3] but the value of post-operative GDFT has not been established in patients with liver cirrhosis undergoing OLT.

Methods: A systematic review was conducted on GDFT post OLT by searching EMBASE, MEDLINE and PubMed databases. Human studies from 01/01/1980 to 10/06/2020 investigating goal directed fluid therapy in the post-operative period after OLT were included. We excluded animal experimental studies, those not reported in English language, and non-OLT studies (eg living donor hepatectomy) and studies that did not directly investigate a haemodynamic variable.

Results: Of the 533 studies identified by the search terms 522 were excluded for lack of relevance or were duplicates. Of the remaining 11, 9 were excluded (non-OLT surgery (1), no haemodynamic variable monitored (7) and one transfusion study). One RCT and one cohort analysis evaluated GDFT in the immediate (0-72 hours) postoperative setting of liver transplantation (110 participants).

Of the two studies Martin et al (2019) reported a randomised, controlled feasibility trial of GDFT post OLT. In this study GDFT was based on SV optimisation in the first 12 hours post operatively. Controls received standard of care without the use of cardiac output measurement. SV optimisation was achieved by repeated boluses of 250ml crystalloid until a <10% increase in SV was seen. It was demonstrated that delivering GDFT immediately post-OLT is safe and feasible. The GDFT group had significantly higher volumes of crystalloid infusion. Although there were signals of reduced length of ICU and hospital stay the study was not powered to demonstrate a clinical benefit. [4]

Reydellet et al (2014) conducted a retrospective analysis of patients undergoing OLT before and after introduction of a GDFT protocol. The GDFT protocol was based on several haemodynamic parameters. Haemodynamic optimisation intraoperatively and in the first 48 hours postoperatively was achieved with drugs or fluids. A transfusion protocol with Hb >8 g/dl or ScvO₂ >70 % as the targets was also used. The control was physician guided fluid therapy prior to introduction of the protocol. Contrary to the COLT study, the protocol group in this cohort received significantly less crystalloid volume. The study also

demonstrated a significant reduction in post-operative ileus and duration of mechanical ventilation in the protocol group. [5]

Conclusion: The two studies suggest clinical benefit but were not adequately powered to demonstrate efficacy. An adequately powered effectiveness study of GDFT following liver transplant is required.

Intensive Care Medicine Experimental 2020, **8(2)**: 000941

Introduction: The management and safety of the airway during general anesthesia or in a critical environment is one of the most important skills of an anesthesiologist or an intensive care physician. Inadequate airway protection or insufficient oxygenation of the patient is associated with an overall increase in mortality and morbidity. The primary goal is the early identification of the Difficult Airways (DA) to reduce or eliminate potential risks linked to incorrect management. The identification of DA is, generally, based on clinical-anamnestic evaluation with low sensitivity and specificity. Ultrasound evaluation has been recently proposed as a useful, non-invasive, and cost-effective tool. Many ultrasonographic parameters have been studied to identify a diagnostic tool to predict difficult laryngoscopy, but no useful cut-off range was at present validated to define a standard parameter, mainly due to the lack of a systematic scan approach in ultrasound neck examination. Among sonographic parameters, the increased thickness of soft tissues anterior to the epiglottis (STTe) was emerging as one of the most reliable independent predictors of difficult laryngoscopy and mask ventilation. In our usual clinical practice, we have highlighted that the anteroposterior and longitudinal scanning allows us to obtain a systematically standardized and reproducible measurement of STTe.

Objectives: This study aimed to analyze the use of a standardized ultrasound approach to identify a DA with specific research of predictive parameters of difficult intubation (DI) and difficult ventilation (DV) combined with clinical-anamnestic evaluation. The aim was, therefore, to verify whether these parameters are useful in order to help creating an airway plan in the operating room, but also a critical care setting. Another possible use of these tools could be the selection of patients who need a protection extubation.

Methods: Prospective, observational, cohort, single-blind study. The study was conducted at the University of Bologna S.Orsola-Malpighi Hospital and approved by the Independent Ethics Committee. Eligibility criteria were consenting adult patients requiring general anesthesia and orotracheal intubation. The patients were consecutively enrolled (from September 2017 to October 2018) during the preoperative anesthesia evaluation. Exclusion criteria were emergency surgeries, rapid-sequence induction, uncooperative or pregnant patients, patients with a history of difficult intubation, or with difficult laryngoscopy and/or with indication to bronchoscopy. The clinical design is divided into two different phases: the preoperative phase (phase 1) and the intraoperative phase (phase 2). Evaluations carried out in phase 1 and in phase 2 were performed by different anesthesiologists at different times (blinded study). In phase 1 clinical-anamnestic evaluation and ultrasound were performed. The intraoperative phase was conducted by expert anesthesiologists (more than 5 years of experience). General anesthesia was conducted according to a standard protocol. DI was evaluated using the Cormack-Lehane score.

Results: As statistical estimation, 253 patients were enrolled (50% male, range 18-88 years old). Direct laryngoscopy was classified as difficult (CL >3) in 15 patients (6%), 10 were predicted by the preoperative clinical evaluation, while the remaining 5 cases (2,1%) had not been anticipated. The ultrasound parameter predictive of DI was the thickness of the soft tissues anterior to the epiglottis in hyperextension of the head and protrusion of the tongue (STTe). The ROC curve analysis identified a cut off of STTe equal to a value of 2.50 cm above which we can predict difficulties in intubation (specificity 55.9%, sensitivity 73.3%; AUC 0.649, CI 0.537 - 0.762; p=0.05). This cut-off value is confirmed even better in the group of patients with difficult laryngoscopy (Cormack-Lehane ≥ 3 even after BURP) in which it results the same specificity (55.9%) but greater sensitivity (87.5%; AUC 0.726; p=0.03). In addition, we verified the predictive role of the US in identifying the borderline difficult laryngoscopy (CL 2e). We found 23 having a CL 2e: STTe was verified both before (p= 0.001) and after BURP (p=0.001). No statistically significant differences were found between the two groups (easy vs difficult) for other US parameters for DI. STTe was, also, the best predictor for DV.

Conclusion: The use of ultrasound has found in recent decades a wide application as a diagnostic and a therapeutic tool, specifically at present airways ultrasound evaluation is an important tool to predict a DI. Standardized ultrasound assessment of the STTe may be useful to predict "complex difficult" direct laryngoscopy and difficult intubation and to identify a DI not foreseen by the conventional clinical parameters (clinically unexpected or unexpected DI). Preoperative identification of DA permit to better organize patient's management in the perioperative and the pre-procedure identification of DA permit to better choose the airway strategy. Further studies are necessary to validate the parameters found and correlate them to the preoperative clinical evaluation, improving patient safety, and allowing the best use of resources. US airway evaluation could find a place in scores for DA prediction.

Introduction: In patients who have undergone a radical cystectomy, delayed return of bowel function is to be expected. However, a cohort of patients (10-40%) go on to develop the complication of post-operative paralytic ileus (POI), which can negatively impact outcomes. Although the causative factors of POI are often complex, identification of potential risk factors could prove useful in the management of these patients in order to improve patient outcomes.

Objectives: To:

- * establish the incidence of ileus in patients having radical cystectomies
- * compare length of stay and mortality between those that had and did not have ileus
- * identify features that correlate with developing ileus.

Methods: This was a single-centre retrospective, observational study carried out at the Royal Surrey County Hospital. We reviewed the electronic and paper medical records, drug charts, anaesthetic charts and operative notes of all patients who had radical cystectomies and ileal conduits in 2018.

Results: 72 patients were identified from a surgical registry. The incidence of ileus was 34% (24/72). Full notes including intra-operative notes were only available for 61 patients.

	Delayed return to normal bowel function and ileus	Normal post-operative bowel function	Statistical significance
Hospital length of stay	8.5 (6 – 21)	6 (5-7)	p<0.0001
Mortality n (%)	6/24 (25%)	0/47 (0%)	p<0.0001
Intrathecal diamorphine (mcg)	700 (500-1000)	800 (500 – 800)	p=n.s.
First 48 hrs post-op morphine equivalent dose (mg)	61 (37-108)	45 (25-114)	p=n.s.
Intra-operative iv fluids (ml)	2000 (2000 – 2500)	2000 (1688 – 2500)	p=n.s.
Highest intra-operative lactate (mmol/L)	2.75 (1.7 – 4.1)	2.1 (1.7 – 3.15)	p=n.s.
Parenteral nutrition, n (%)	6/24 (25%)	0/47 (0%)	p<0.0001

Conclusion: Delay to return to normal bowel function including post-operative ileus was associated with a significant increase in hospital length of stay, increased requirement for parenteral nutrition and significantly increased mortality rates. This is a complex, multifactorial post-operative complication and we were unable to find any factors that were associated with ileus in this study. Further prospective research is required to establish if there are causative factors which may be optimised to prevent this post-operative complication.

Intensive Care Medicine Experimental 2020, **8(2)**: 000069

Introduction: Major changes occur in central hemodynamic during early postpartum period: redistribution of fluid from the interstitial space into the bloodstream, which increases the blood volume circulating and cardiac output. All these changes are aimed at stabilizing the patient in the postpartum period with blood loss. However, blood volume circulating during pregnancy and postpartum period remains unknown and studies on its results come to the conclusion about its great variability. The aim of this study was to evaluate the postpartum

volume status of puerperas with blood loss 10-20% of blood volume circulating.

Methods: Thirty puerperas after a elective cesarean section with spinal anesthesia, underwent ultrasound evaluation of the heart and inferior vena cava immediately after surgery, 3 and 6 hours.

Results: The volume of blood loss measured by the gravimetric method was 914 ± 410 ml, which amounted to 10 to 20% of the blood volume circulating, calculated by the formula $100 \text{ ml} \times \text{weight before pregnancy (kg)}$. The ejection fraction of the left ventricle, measured immediately after surgery, 3 and 6 hours, was 55.5% (95% confidence interval 51.9 - 61.6), 58.2% (95% CI 59.4 - 61.2) and 55.4% (95% CI 53.5 - 59.9), respectively. The Friedman test (χ^2) showed the absence of a statistically significant difference of the ejection fraction ($p = 0.692$). Inferior vena cava collapsibility index showed a statistically significant decrease in the measurement periods: 35.5% (95% CI 22.5 - 44.8), 20.5% (95% CI 14.6 - 28.5), 14.4% (95% CI 12.2 - 25.6), respectively, the Friedman test (χ^2) $p = 0.036$. A statistically significant increase of the end-diastolic volume of the left ventricle was also noted: 73.0 ml (95% CI 66.3 - 76.7), 81.2 ml (95% CI 72.9 - 87.3), 89.8 ml (95% CI 80.4 - 96.7), respectively, the Friedman test (χ^2) $p = 0.021$.

Conclusion: Blood loss 10-20% of blood volume circulating or more than 1000 ml does not always require replacement fluid management, redistribution of fluid volume from the interstitial space increases blood volume circulating within 3-6 hours after delivery. Further studies of the volume status are needed.

Fluid responsiveness assessment in Cardiac Surgery patients.

Superior Vena cava respiratory variability vs Mini fluid challenge

B. Chekroud¹; C. Gandon¹; P. BURTIN¹; JY. Bigeon¹; A. Roussiaux¹; N. Ducrocq¹

¹Anesthésie et réanimation, Clinique du Millénaire, Montpellier, France

Correspondence: P. BURTIN

Intensive Care Medicine Experimental 2020, **8(2)**: 000752

Introduction: Fluid responsiveness assessment is the cornerstone of fluid therapy in both the ICU and the operating room (1,2). The use of dynamic indices (fluid challenge or the cardiopulmonary interaction) has proved to be the most effective method and these tests have been included in guidelines (3). Nevertheless, fluid responsiveness in cardiac surgery (CS) patients is weakly investigated. A recent study has reported that in ICU patients the respiratory variability of the superior vena cava (SVC) performed better than other tests (4).

Objectives: The routine use of a TEE probe in all our CS patients allowed us to investigate in a prospective observational study the performance of the respiratory variation of the VCS (Delta VCS) and mini fluid challenge (FC100) as a predictive indice for fluid response.

Methods: All patients were included after CPB and chest closure while still under general anesthesia. A fluid infusion was performed in all patients by infusion of the CPB residual volume treated by a cell saver (500-600 ml; hematocrit > 50%). The cell saver bag was infused sequentially and hemodynamic measures were obtained after 100 ml (FC 100), 250 ml (FC250) and 500 ml (FC 500). We recorded demographic and procedural data. At baseline and at each stage of the FC we recorded: SV, VTI, HR, BP, E/A ratio, E/E' ratio, S'Ann wave, the diameter of SVC during inspiration and expiration. SVC diameter was measured during QRS and T wave of the ECG. We calculated the respiratory variation index (%) of SVC as $(\text{Exp VCS Diam} - \text{Insp VCS Diam}) / \text{Exp VCS Diam}$ for QRS wave, T wave and absolute variation. Patients were classified as Fluid responders (RESP) if SV increased by +15% after FC500 or Non Responders (NRESP). Groups were compared by KH12 and Student t tests. ROC curves were built for FC 100, Delta VCS QRS, Delta VCS T and Delta VCS absolute ($p < 0.05$).

Results:

Fig 1: ROC curves comparisons for the 4 dynamic indices tested ($p < 0.036$)

49 patients were included: M 39 (79.6%), CABG 51%, AVR 27%, MVR 8%, Other 14%; mean age 67 ± 11.5 ; mean Euroscore $2.348 / 3.16\%$; mean LVEF 53.9 ± 11.4 . 31 patients (63.3%) were NRESP and 18 (36.7%) were RESP. There was no difference for RESP / NRESP groups for LVEF (RESP: 51.2% vs NRES: 56.6%) CPB duration (RESP: 71.2min vs NRES: 68.6min), Cross clamp time (RESP: 57min vs NRES: 54.4min), baseline E/A (RESP: 1.49 ± 0.24 vs NRES: 1.19 ± 0.19), baseline E/e' (RESP: 7.86 ± 1.28 vs NRES: 8.54 ± 1.37). Delta SVC QRS and delta SVC T were higher in the RESP group but the difference did not reach significance: (RESP: 13.67% vs NRES: 7.84% and RESP: 13.89% vs NRES: 9.91% respectively). Groups were significantly different only for delta SV after FC100 (RESP: $11.4 \pm 3.08\%$ vs NRES: $2.54 \pm 0.57\%$; 95CI 0.05918 to 0.21458). ROC curves are shown in fig 1. The highest AUC is obtained by FC100 (AUC 0.829; 95CI 0.677 to 0.929) and significantly higher than the SVC derived indices ($p < 0.036$).

Conclusion: The main findings of our study are: First, in CS up to 63% of the patients may be unresponsive to FC and this is similar to septic shock patients. Second, the SVC derived indices perform poorly in predicting fluid responsiveness and that is not consistent with the results obtained in shock patients (4). The influence of the specificities of CS patients (type of anesthesia, cardioplegia and CPB, chest drainage system) are discussed. Third, the good performance of the mini fluid challenge (FC100) makes it a method of choice in post CPB CS patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000820

Introduction: It has been demonstrated that persistently decreased microvascular blood flow is associated with mortality in the critical care population.^{1,2} Microvascular blood flow is a potentially important therapeutic target, that may diverge from macrovascular parameters leading to a loss of haemodynamic coherence.³ In our centre we use a low central venous pressure (CVP) anaesthetic for liver resection surgery to decrease intra-operative blood loss⁴ with subsequent goal-directed fluid therapy (GDFT). This can be considered as a model of shock and resuscitation. These patients were studied to assess peri-operative microvascular flow and relation to macrovascular parameters.

Objectives: To establish:

- changes in microvascular blood flow peri-operatively in liver resection surgery
- relationship between microvascular blood flow and macrovascular parameters
- relationship between microvascular blood flow following GDFT to post-operative complications

Methods: This was a single-centre prospective observational study (REC 14/NE/1150) enrolling patients undergoing elective liver resection surgery. Microvascular blood flow, measured using the MicroScan device (MicroVision Medical, Amsterdam) and physiological measurements were taken at pre-specified time points throughout the peri-operative period (T1, awake on day of surgery pre-operatively, T2 following induction of anaesthesia, T3 on exposure of the liver, T4 completion of liver resection prior to fluid resuscitation, T5 arrival at ICU, T6 completion of goal directed fluid therapy (GDFT)). Mortality rates, post-operative morbidity survey (POMS) and Clavien-Dindo classification were used to assess post-operative complications.

Results: A total of 55 data sets were included in the analyses, 28 male and 27 female, mean age was 58 years (S.D. 13) and BMI 28.1 kg/m² (S.D. 5.4), 18% were smokers, 13% were diabetic and 76% had neoadjuvant chemotherapy.

CVP was decreased successfully during anaesthesia from 7mmHg (IQR 4.7-10) at T2 to 3 mmHg (IQR 0.7-5) at T4 (p<0.0001). There was a statistically significant decrease in mean arterial pressure (MAP); 74 mmHg (IQR 65 – 88) at T2 to 64 mmHg (58 – 74) at T4 (p=0.0002). This was accompanied by a rise in heart rate from a median of 67 bpm (IQR 60-77) to 73 bpm (IQR 64-87) at T4 (p=0.013). A subset of 18 patients had records of cardiac output measured by oesophageal doppler, this was not suitable for use in awake patients so was only recorded at T2, T3 and T4. There was no significant difference between cardiac index (CI) at time 2 and time 4; median CI 2.55 L/min/m² (1.88 – 3.48) and 2.00 L/min/m² (1.80 – 2.30) respectively.

Following completion of GDFT (T6) there was no significant difference in heart rate compared to baseline (T1). However, MAP at T6 remained significantly lower than baseline (T1); 100mmHg (88-110) vs 77 (73-89), p<0.0001.

Microvascular flow measurements decreased post-operatively and this fall was sustained after completion of GDFT as detailed below.

Table 1 – Microvascular flow (results displayed as median (IQR). Kruskal-Wallis was used to determine significance of variation between groups)

Parameter	T1	T5	T6	p
MFI	2.78 (2.42-2.98)	2.5 (1.94-2.75)	2.58 (2.08-2.83)	p<0.0001
sPPV	95.6 (87.4-99.8)	66.6 (58.5-66.7)	65.1 (61.3-66.8)	p<0.0001
sPVD	4.85 (3.69-5.9)	5.9 (4.4-7.8)	5.77 (4.91-7.2)	p<0.0001

There was an increase in proportion of perfused large blood vessels (IPPV); 66.7 (34.1-90.9) at T1 vs 99 (91-100) at T6, p<0.0001 density (tPVD).

There was no significant correlation between MAP and the microvascular parameters MFI, sPPV or sPVD at any time point using Pearson and Spearman correlation coefficients as appropriate. There was no association with microvascular flow and post-operative morbidity or mortality.

Conclusion: Microvascular blood flow decreased post-operatively and this was sustained despite completion of GDFT and restitution of macrovascular parameters. There was evidence of shunting with a decrease in small perfused blood vessel density and increase in large perfused blood vessel density from baseline to completion of GDFT. GDFT was insufficient to restore post-operative sublingual microvascular perfusion.

Intensive Care Medicine Experimental 2020, **8(2)**: 001018

Introduction: High blood glucose levels are frequently shown in patients post-cardiac surgery patients that might affect prognosis.

Objectives: To evaluate postoperative blood glucose trend levels and predisposing risk factors in cardiac surgery patients, during their stay in intensive care unit (ICU).

Methods: 210 consecutive post-cardiac surgery patients, admitted to ICU, participated in this prospective clinical study. Blood glucose levels were measured by patients' admittance to ICU and afterwards every 2-3 hours daily, until their discharge or for up to seven days (if discharged later). An existing ICU protocol for blood glucose control was applied. Patients were classified by mean blood glucose level during their stay in ICU.

Results: 56% of the patients had mean blood glucose levels 140 – 180mg/dl, 25% above 180mg/dl and 19% below 140mg/dl. 36% of the participants had mean blood glucose levels above 180mg/dl during the first and second day of ICU treatment and 30% during the third day. Multivariate logarithmic regression analysis has shown history of Diabetes mellitus, Euroscore II and pre-operative white blood cells count as independent predictors of post-cardiac surgery mean blood glucose levels above 180mg/dl. Patients with mean blood glucose levels above 180mg/dl post-cardiac surgery had greater duration of mechanical ventilation support (p=0.019).

Conclusion: According to our study, a high percentage of cardiac surgery patients admitted to ICU exhibit blood glucose levels >180mg/dl, at the immediate postoperative period despite standard treatment protocol. Diabetes mellitus, Euroscore II and pre-operative white blood cells count were independent predictors of hyperglycemia. Appliance of a further bundle for optimization of blood glucose levels is deemed necessary.

Incidence Pattern of Neurological Diseases after Carbon Monoxide Poisoning: Retrospective Longitudinal Study in South Korea from 2012 to 2018

H. H. Kim¹; C. Sangchun¹

¹Emergency Medicine, Ajou University Hospital, Suwon, Republic of Korea

Correspondence: H.H. Kim

Intensive Care Medicine Experimental 2020, **8(2)**: 000006

Introduction: Neurological sequelae after carbon monoxide (CO) poisoning has recently become a critical issue. Epidemiologic data of delayed neurological sequelae such as incidence, time of development, and duration vary widely in the literature.

Objectives: We aim at analyzing nationwide claims data from South Korea for incidence patterns of neurological disorders in survivors of carbon dioxide poisoning.

Methods: A national cohort was abstracted from database that includes the patients diagnosed with carbon monoxide poisoning from January 1st, 2007 to December 31st, 2018. We investigated the whole diagnostic codes for nervous system diseases. The codes were retrieved from the claims data generated during the patients' initial visits to an inpatient or an outpatient after the diagnosis of T58, carbon monoxide poisoning.

Results: Among the total of 26,778 patients, 18,720 (69.9%) patients were diagnosed with nervous system diseases after the carbon monoxide poisoning. The most common disease was disorders of sleep initiating and maintaining (n = 701, 3.74%), followed by tension-type headache (n = 477, 2.55%), and anoxic brain injury (n = 406, 2.17%). Admission to the intensive care unit after carbon monoxide poisoning was associated with subsequent development of nervous system diseases. The cumulative hazard ratio was 2.25 (95% CI, 2.07 to 2.44, p<0.05).

Conclusion: In poisoned patients with carbon monoxide, it needs to consider that nervous system diseases followed after carbon monoxide poisoning have relatively early peak incidence patterns. Nervous system diseases after carbon monoxide poisoning had different patterns of incidence depending on whether the patient had been admitted to intensive care unit or not.

Inorganic arsenic suppresses human neutrophil extracellular traps in vitro

M. M. Islam¹; N. Takeyama¹

¹Emergency and Critical Care Medicine, Aichi Medical University School of Medicine, Nagakute, Aichi, Japan

Correspondence: M.M. Islam

Intensive Care Medicine Experimental 2020, **8(2)**: 000057

Introduction: Arsenic, a group 1 carcinogen classified by International Agency for Research on Cancer, is a major environmental toxicant and pollutant, which has caused health concern all over the world. The Agency for Toxic Substances and Disease Registry also enlisted arsenic as number one in their ranking of substance priority list 2017. Neutrophils are the vanguard of host innate immune system against invading microbial pathogens and several diseases. Neutrophil extracellular traps (NETs) have been disclosed as an essential aspect of human innate immunity. NETs are comprised of meshwork of chromatin fibers decorated with antimicrobial proteins like myeloperoxidase (MPO), neutrophil elastase (NE) and cathepsin G [1]. The function of NETs is to capture, immobilize and kill intruding gram negative and gram positive bacteria, fungi, parasites as well as invading microorganisms extracellularly [1]. The influence of arsenic on human NET formation, however, was not well established.

Objectives: This study aimed to evaluate the effects of acute low dose (20 ng/ml) NaAsO₂ exposure on innate defense mechanisms regarding NETs and phagocytosis *in vitro*.

Methods: Isolated polymorphonuclear neutrophils (PMN) from peripheral blood of healthy human volunteers were incubated with NaAsO₂ for 12 h and phorbol myristate acetate was used to induce NET formation. Effect of arsenic exposure on PMN functions including NETs release, phagocytosis, bacterial killing and reactive oxygen species (ROS) production were assessed. NETs formation was quantified by measuring cell-free extracellular DNA (cf-DNA), MPO-DNA and NE-DNA which are characteristic of NET. Cell-free DNA (cf-DNA) was measured using the Quant-iT PicoGreen dsDNA assay kit. MPO- and NE-DNA were measured by sandwich ELISA. ROS production was measured in live cells by a technique that converts 2', 7'-dichlorofluorescein diacetate which was oxidized to a fluorescence dye 2', 7'-dichlorofluorescein. Extracellular killing of bacteria by NETs was evaluated by co-culture of *Escherichia coli* and neutrophils in the presence of a phagocytic inhibitor cytochalasin D.

Results: *In vitro* inorganic arsenic exposure to human PMN significantly dampens the release of cf-DNA, MPO-DNA and NE-DNA which are the main components of NETs. Either capacity of phagocytosis and bacterial killing were also reduced after acute arsenic exposure.

Conclusion: We conclude that low dose of inorganic arsenic will disturb PMN function including NETs and phagocytosis. Our results open new doors for understanding the detailed mechanisms of arsenic intoxication on human innate immunity.

Comparison between mask oxygen therapy and nasal high-flow oxygen therapy using tracheal oxygen concentration measurement modelT. Taira¹; K. Kota²; T. Kouji²; F. Tetsuya²; F. Tastuma¹; K. Ichiro¹; K. Manabu²¹Intensive care medicine, emergency medicine, University of the Ryukyus Hospital, Nishihara, Japan; ²Intensive care medicine, anesthesia, University of the Ryukyus Hospital, Nishihara, Japan**Correspondence:** T. TairaIntensive Care Medicine Experimental 2020, **8(2)**: 000138

Introduction: An effective treatment for carbon monoxide poisoning is the elimination of blood carbon monoxide by the administration of high oxygen concentration. Hyperbaric oxygenation therapy has the highest concentration of oxygen; however, medical institutions without hyperbaric oxygenation chambers also often treat patients with carbon monoxide poisoning. If hyperbaric oxygenation therapy is unavailable, the first-line treatment is a 100% oxygen mask; of late, another oxygen administration method in use is the nasal high-flow (NHF) therapy. However, no previous study has verified the type of oxygen administration method that can deliver higher oxygen concentration to the body. Here, we present a comparison of 100% intratracheal oxygen administration by oxygen mask or by NHF, using an original tracheal oxygen concentration measuring model.

Objectives: To compare the tracheal oxygen concentration of 100% oxygen administered by mask or by NHF using a special intratracheal oxygen measuring model.

Methods: A Michigan Instruments artificial lung was connected to a Hamilton ventilator C1 and a human model of intubation practice. The measuring device of oxygen concentration with INOflo, manufactured by Mallinckrodt pharmaceuticals, was inserted into the trachea of the human model to measure the oxygen concentration. The lung tidal volume and the minute volume were adjusted by the Hamilton C1. The minute volume was set to 5 L and 10 L; the flow rate of the oxygen mask was set to 6 L, 10 L, and 15 L; and the flow rate of the NHF was set to 10 L, 20 L, and 40 L. For each of these, the measurement was performed four times.

Results: The model tracheal oxygen concentration results were as follows. Under the 100% oxygen by mask and 5L of minute ventilation conditions, when the oxygen flow rates were set to 6L, 10L, and 15L, the average oxygen concentrations were 58.75%, 63.75%, and 68.75%, respectively. When the minute ventilation was set to 10 L, these values were 39.75%, 46.5%, and 53.75%, respectively. In NHF, 5L of minute ventilation, when the oxygen flow was 10L, 20L, and 30L, the average oxygen concentrations were 96.5%, 97%, and 97.5%, respectively; and for the 10L of minute ventilation, for the 10 L, 20 L, and 30 L flow rates, the average values were 91.75%, 95%, and 97%, respectively.

Conclusion: The oxygen concentration in the human model's trachea was higher with NHF oxygen administration, regardless of the ventilation minute volume and oxygen flow rate. These results suggested that for patients with carbon monoxide poisoning, NHF may reduce carbon monoxide in a shorter time than oxygen administration via a mask.

Acute brain lesion on magnetic resonance imaging as predictive factor of delayed neurological sequelae in carbon monoxide poisoningS. Nah¹; S. Han¹¹Emergency Department, Soonchunhyang University Bucheon Hospital, Bucheon, Republic of Korea**Correspondence:** S. NahIntensive Care Medicine Experimental 2020, **8(2)**: 000190

Introduction: Carbon monoxide (CO) is a colorless, odorless toxic gas produced by incomplete combustion of carbon-based fuel and material. Because of these characteristics, many patients cannot recognize that they are poisoned and in mild cases, diagnosis and treatment are often delayed because symptoms do not appear immediately. In CO poisoning, the brain and heart which are vulnerable to ischemia are damaged due to the decline of oxygen transport. Development of delayed neurological sequelae (DNS) defined as any neurological symptoms that newly developed within 6 weeks after CO poisoning. Preventing DNS is a major goal of treating acute CO poisoning, but to our knowledge there are no reliable tools for assessing the probability of these sequelae.

Objectives: To find out whether acute brain lesions on diffusion-weighted imaging are relevant to subsequent development of DNS after acute CO poisoning.

Methods: This registry-based observational study was conducted at a university hospital in Korea, between January 1, 2017, and December 31, 2018. Of 254 patients (aged ≥ 18) with acute CO poisoning, 154 patients (60.63%) who underwent diffusion-weighted imaging were considered for the study. Patients who refuse magnetic resonance imaging (MRI) (n=40), discharge against medical advice (n=6), follow up loss (n=32), persistent neurological symptoms at discharge (n=8) and refuse hyperbaric oxygen therapy (n=14) were excluded. Patients were scheduled for MRI within 2 days of visiting hospital. If two or more of the univariate factors retained in the multivariate analysis were highly correlated, then only one factor was selected for further modeling to avoid collinearity before modeling. (Table 1).

Table 1. Factors associated with the development of delayed neurologic sequelae

	Univariable analysis		Multivariable analysis			
	OR (95% CI)	P-value	Model 1		Model 2	
	OR (95% CI)	P-value	OR (95% CI)	P-value	OR (95% CI)	P-value
Headache	0.438(0.096-1.992)	0.285				
CRP	1.055(0.964-1.155)	0.245				
Troponin I	1.164(0.894-1.516)	0.259				
GCS	0.853(0.771-0.944)	0.002	0.864(0.760-0.983)	0.026	0.849(0.745-0.967)	0.014
Exposure time, min	1.001(1.000-1.002)	0.038	1.002(1.001-1.004)	0.010	1.003(1.001-1.004)	0.005
Abnormal MRI	3.804(1.624-8.911)	0.002	2.242(0.864-5.821)	0.097		
White matter lesion	8.057(2.448-26.516)	0.001			6.741(1.843-24.660)	0.004

OR, odds ratio; CI, confidence interval; CRP, C-reactive protein; GCS, glasgow coma scale; MRI, magnetic resonance imaging

Results: Of the 154 included patients, acute brain lesions on diffusion-weighted imaging were observed in 49 patients (31.8%). Among 154 patients, DNS occurred in 30 patients (19.5%). In the multivariable logistic regression analysis, abnormal MRI was associated with DNS in model 1 (odds ratio [OR], 2.24; 95% Confidence interval [CI]), 0.864–5.821; $P = 0.097$). In model 2, the acute brain lesions on MRI in white matter was notably associated with development of DNS (OR, 6.741; 95% CI, 1.843–24.660; $P = 0.004$). And Glasgow coma scale and exposure time were also related to subsequent development of DNS after CO poisoning in model 1, 2.

Conclusion: Acute brain lesions on MRI in white matter was notably associated with the development of DNS. Diffusion-weighted imaging during the acute phase of CO poisoning may predict the risk of developing subsequent neurologic deficit.

Intensive Care Medicine Experimental 2020, **8(2)**: 000442

Introduction: Selenium, an essential micronutrient incorporated into antioxidant 'selenoproteins', has been extensively trialled as a putative therapy in critical illnesses. However, when administered in its oxidised form, selenite, it exhibits varying degrees of success [1]. Importantly, the ability of any molecule to undergo 'redox' reactions depends on its oxidation status. We previously showed that the reduced form of selenium, selenide, acts both as an antioxidant and a metabolic modulator via transient inhibition of mitochondrial cytochrome C oxidase [2]. Here we assessed the effects of a basic selenide salt (NaHSe) against oxidative stress in human hepatocytes.

Methods: HepG2 human hepatocytes were grown to 80% confluence under standard cell culture conditions. Sodium hydrogen selenide (NaHSe) was synthesized as described [3]. Cells were incubated with 0.3 or 1 μM NaHSe (as therapeutic concentrations) for 1 hour. Oxidative stress was initiated by addition of hydrogen peroxide (H_2O_2 ; 500 μM); cells were incubated for a further 24 hours. Cell viability (in tetrazolium chloride [1% w/v] stained cells) or mitochondrial membrane potential (MMP; in tetramethylrhodamine methyl ester [TMRM] incubated [25 nM for 30 min] cells) were measured using spectrophotometry and flow cytometry, respectively.

Results: H_2O_2 decreased cell viability and mitochondrial membrane potential and these could be reversed by NaHSe treatment (Fig 1).

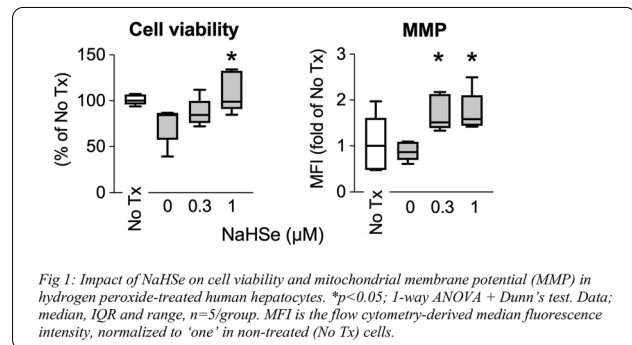

Fig 1: Impact of NaHSe on cell viability and mitochondrial membrane potential (MMP) in hydrogen peroxide-treated human hepatocytes. * $p < 0.05$; 1-way ANOVA + Dunn's test. Data: median, IQR and range, $n = 5/\text{group}$. MFI is the flow cytometry-derived median fluorescence intensity, normalized to 'one' in non-treated (No Tx) cells.

Conclusion: Treatment with the reduced form of selenium, hydrogen selenide, protected against oxidative stress in human hepatocytes. This was associated with a clear elevation in mitochondrial membrane potential. The ability of selenide to confer protection against oxidative pathologies via a mitochondrial mechanism of action (and the importance of its oxidation status) will be subject to further investigation.

Selenium Therapy: Impact of Oxidation Status on Antioxidant Selenoprotein Expression

W. Smith¹; M. Kuganesan¹; R. Tidswell¹; M. Singer¹; A. Dyson¹

¹University college london, Bloomsbury Institute of Intensive Care Medicine, London, United Kingdom

Correspondence: A. Dyson

Intensive Care Medicine Experimental 2020, **8(2)**: 000444

Introduction: Selenium, an essential micronutrient, is incorporated into numerous 'selenoprotein' oxidoreductase enzymes that impact on cellular redox status in health and disease. As a putative antioxidant therapy in critical illness states, selenium has been administered solely as the oxidised form, selenite, with varying success [1]. However, the ability of any molecule to undergo 'redox' reactions depends on its oxidation status, and this may impact on its utility as a therapy [2]. We assessed the ability of both the oxidized selenium product, selenite, and the reduced form, selenide, to modify selenoprotein expression in human hepatocytes.

Methods: HepG2 human hepatocytes were grown to 80% confluence under standard cell culture conditions. Cells were plated and incubated with either sodium hydrogen selenide (NaHSe; 30 nM, synthesized as described [3]), sodium selenite (Na_2SeO_3 ; 30 nM) or no treatment (cell medium) for 24 hours. L-cysteine (0.1 mM) was used as a positive control (to decrease selenoprotein synthesis) as it interferes with selenocysteine, a crucial intermediate. Protein expression of glutathione peroxidase-1 (GPX-1) and thioredoxin reductase-1 (TxR-1) was determined by Western blot analysis. These selenoproteins were chosen as they are ubiquitously expressed, readily abundant, and

crucially involved in the detoxification of inorganic and organic peroxides, respectively.

Results: The oxidized selenium form, selenite, used in critically ill patients as an antioxidant therapy, negatively impacted on antioxidant selenoprotein expression (Fig 1). By contrast, exposure to the reduced form, selenide, showed increased abundance of the two enzymes studied.

Fig 1: Impact of oxidation status of selenium on selenoprotein expression in human hepatocytes. * $p < 0.05$; 1-way ANOVA + Dunn's test. Data: scatter plot; line at median, $n = 3-6$ /group. GPX-1; glutathione peroxidase-1, TxR-1; thioredoxin reductase-1.

Conclusion: The oxidation status of selenium-based therapies on selenoprotein expression revealed divergent results. This demonstrates that oxidation status can impact on efficacy, and suggests that targeted administration of reduced selenium forms may yield more favourable results.

Organ and system substitution techniques to treat poisonings

C. Palau Martí¹; S. Moliner Velázquez¹; R. Rubio Haro¹; C. Ferrer Gómez¹;
E. Mateo Rodríguez¹; J. De Andrés Ibáñez¹

¹Anaesthesiology, Critical Care and Pain Therapy Service, Consorci Hospital General Universitari de València, València, Spain

Correspondence: C. Palau Martí

Intensive Care Medicine Experimental 2020, **8(2)**: 000948

Introduction: 3-14% ICU admissions are due to poisonings. The mortality rate is 2,1%. The treatment for acute poisonings requires: precociousness, vital functions support, metabolic support and symptomatic treatment, reducing or stopping the absorption of the poison, an antidote-based treatment and measures to increase the elimination of the toxic (intestinal and renal excretion as well as extracorporeal techniques).

Objectives: The aim of this review is to establish the organ and system substitution techniques currently available and how they were used to treat poisonings in our ICU during the 2015-2018 period.

Methods: Study authorized by the ethics committee in the centre. In the 2015-2018 period there were 7941 admissions to the ICU. 31 of these were poisonings (0,39%). The organ and system substitution techniques consist in: 1. Renal replacement techniques (hemodialysis, continuous renal replacement techniques and peritoneal dialysis),

2. Plasmapheresis and plasma exchange, 3. Hemoperfusion and 4. Exchange transfusion. The following extracorporeal organ support techniques are also available: 1. Extracorporeal liver support (MARS: molecular adsorbent recirculating system), and 2. Extracorporeal membrane oxygenation (ECMO).

Results: In our series, 64% were men and the average age was 44 years old. The most common cause was medication-related poisoning (benzodiazepines). Ethanol was the main addictive drug. The measures taken in our ICU have been continuous renal replacement therapy in one occasion (lithium poisoning).

Conclusion: In spite of the fact that the ICU admissions rate is low, it is necessary to be familiar with the organ and system substitution techniques in order to apply the best one in each case. It is equally important to know about the pharmacokinetic characteristics of those toxics that can be expelled using these extracorporeal techniques.

A QIP on Naloxone Administration: Do Staff Need a Push to Give a Bolus in an Emergency?

D. Wirth¹; C. Briggs¹; P. Beddoes¹; T. Smith¹

¹Anaesthetics department, Whipps Cross University Hospital, London, United Kingdom

Correspondence: D. Wirth

Intensive Care Medicine Experimental 2020, **8(2)**: 001079

Introduction: Naloxone, an opioid antagonist, is used for the management of opioid toxicity, presenting with respiratory depression, miosis and/or decreased consciousness. This is a medical emergency occurring in different settings: theatre recovery, maternity or general surgical wards. Urgent naloxone administration is vital and can be given IV, SC or IM at an initial dose of 400mcg(1). Naloxone is initially given as a push bolus, and locally is prepared as 400mcg in 1ml ampoules (2). We recognised that familiarity with naloxone at our institution was low. Lack of knowledge and familiarity is a known contributor to drug error(3). Use of cognitive aids can facilitate timely implementation of treatment in emergencies such as opioid toxicity(4).

Objectives:

- To assess staff familiarity and confidence with naloxone.
- To assess knowledge regarding naloxone administration.

Methods: An anonymous staff survey was designed to assess familiarity and confidence with naloxone use and was distributed to theatre recovery, surgical wards and maternity. Later a poster (Figure 1) was designed and placed on control drug (CD) cupboards to serve as an accessible cognitive aid in an emergency. A safety alert was emailed to guide staff on how to manage suspected opiate toxicity. We re-surveyed to assess improvement in knowledge and confidence of naloxone use.

27/05/2020

NHS
Barts Health
NHS Trust

NALOXONE FOR SUSPECTED OPIATE TOXICITY

SUSPECT IF:

- Pinpoint pupils
- Decreased conscious level
- RR <8

ACTION:

- Give naloxone
- Give 15L 02 NRB
- Call doctor
- Consider 2222 call

NALOXONE ADMINISTRATION:

- Undiluted 400 mcg (1ml) bolus
- IV preferable (same dose SC or IM if no IV access)

Results: Our initial survey found low confidence in naloxone administration with 79% of respondents either unwilling or needing a nomogram to administer it. This was unsurprising as most had not used naloxone in the preceding year. On re-survey, we found improved confidence, with an increase in those either confident or very confident from 20% to 40% and fewer people unwilling to use naloxone (17% to 12%). Staff selecting the correct dose as per trust protocol increased by 31%, from 41% to 72% ($p=0.02$ CI 4.5%-51.9%).

Conclusion: Use of naloxone is rare and staff at our institution are unfamiliar with it, demonstrated here by a lack of confidence and knowledge of correct dose. 30% of medication errors relate to gaps in knowledge or application of knowledge of a drug(3). However, in opiate toxicity, prompt, accurate administration of naloxone is imperative, yet human factors such as stress and communication breakdown in an emergency scenario may further inhibit ability to correctly administer treatment.

A simple and low-cost cognitive aid positioned on CD cupboards combined with a safety alert via email improved accuracy and confidence with naloxone use.

In critical care, doctors drill for rare emergencies though simulation (sim), but key members of the MDT such as nurses and midwives receive less sim-based training. We have demonstrated an increase in confidence and accuracy of naloxone administration with simple, cost-effective measures. Further work could examine the sustainability of these improvements and implement sim-based training to further improve MDT performance.

Post-discharge psychological symptoms in critical care survivors who had been difficult to sedate

D. Gil Castillejos¹; L. Rico Rubio²; C. Ferre Grau²; MA. De Gracia Ballarín¹; M. Bodí¹; A. Sandiumenge³

¹Intensive and Critical Care Unit, Hospital Universitari de Tarragona Joan XXIII, Tarragona, Spain; ²Department of nursing, Rovira i Virgili University, Tarragona, Spain; ³Medical transplant coordinator, Vall d'Hebron University Hospital, Barcelona, Spain

Correspondence: D. Gil Castillejos

Intensive Care Medicine Experimental 2020, **8**(2): 000004

Introduction: Patients admitted to an intensive care unit (ICU) have a potentially fatal physical condition which also has an intense psychological impact

The emotional impact of this experience can have negative repercussions during the patient's recovery, as evidenced by the fact that anxiety, depression and post-traumatic symptoms are more prevalent among critical care survivors than in the general population.

The use of analgesia-based sedation, or analgo-sedation, is therefore a common and necessary practice in ICUs, the aim being to achieve an optimum level of comfort and pain relief for patients, to reduce their anxiety and disorientation, and to allow them to rest and sleep without interfering with medical and nursing care. However, the use of analgo-sedation is not free of complications, not least as its over-use can hamper the conscious processing of events experienced in the ICU. In addition, patients who undergo prolonged sedation may become difficult to sedate and require increasing doses, a scenario that has been associated with longer ICU stays and more complications during admission. In this respect, analgo-sedation may increase the likelihood of severe psychological sequelae among critical care survivors. Moreover, patients who prove difficult to sedate during an ICU admission experience more periods of over- and under-sedation as it is a challenge to keep them within the target range of conscious sedation (Richmond Agitation-Sedation Scale score of -2, -1, 0).

Objectives: The aim of the present study was to determine the incidence of anxiety, depression and PTSD among critical care survivors and to explore the impact of difficult sedation on the frequency and intensity of these symptoms.

Methods: Descriptive and prospective analysis of analgo-sedation and psychological symptoms in patients who required >24 h of mechanical ventilation during their ICU admission. We compared complications, clinical outcomes and psychological sequelae according to whether or not patients had been difficult to sedate. Descriptive analysis and multivariate logistic regression were performed.

Results: Data were obtained for 195 patients, of whom 30% experienced difficult sedation. Difficult to sedate patients were younger (52.2 ± 16.4 vs. 61.4 ± 14.1 years; $p=.001$), less critically ill (APACHE II score 22.1 ± 9.9 vs. 26.4 ± 8.7 ; $p=.002$) and more likely to engage in harmful use of alcohol ($p=.001$) and to have used psychoactive/psychotropic drugs during the previous three months. They also spent longer in the ICU (28.1 ± 25.8 vs. 17.6 ± 15.4 days; $p=.001$) and a greater percentage of time on mechanical ventilation (61.1 ± 15.4 vs. 51.4 ± 18.8 ; $p=.001$). At 1-month follow up, 87.7% of difficult-to-sedate patients reported anxiety (vs. 45.4%; $p=.001$), with the corresponding figures at 3 and 6 months being 75.4% (vs. 29%; $p=.001$) and 70.8% (vs. 23.7%; $p=.001$). Depression was reported by 82.4% (vs. 43.1%; $p=.001$), 66% (vs. 33.9%; $p=.001$) and 60.4% (vs. 27.2%; $p=.001$) of difficult-to-sedate patients at 1, 3 and 6 months, respectively. At 1 month, 28.1% of these patients (vs. 11.5%; $p=.007$) reported symptoms of PTSD.

Conclusion: Critical care patients who undergo prolonged analgo-sedation may become difficult to sedate, and this can have a negative impact on their subsequent emotional wellbeing. It is therefore crucial to implement multidisciplinary sedation protocols based on

algorithms that encourage collaborative sedation and weaning. The early identification of patients who are likely to experience difficult sedation, coupled with strategies for preventing it, are essential for minimizing the impact of this complication, both in the short and long term. It is also important to ensure that adequate attention is paid not only to the physical but also the psychological needs of critical care patients, since both aspects will impact their subsequent recovery process.

Delirium after on-pump cardiac surgery: a single centre descriptive study

H. Stragier¹; D. Mesotten¹; M. Vander Laenen¹; W. Boer¹; T. Fivez¹

¹Department of anesthesiology, intensive care and pain therapy, Ziekenhuis Oost-Limburg A. V., Genk, Belgium

Correspondence: H. Stragier

Intensive Care Medicine Experimental 2020, **8(2)**: 000120

Introduction: Cardiac surgery requiring cardiopulmonary bypass (CPB) has been associated with neurocognitive impairment, called the postperfusion syndrome. Delirium is the most common form of neurocognitive impairment and has been linked with increased morbidity and mortality. It has been suggested that micro-emboli during CPB cause this postperfusion syndrome

Objectives: We aimed to assess whether the duration of CPB is the major factor in delirium after cardiac surgery.

Methods: This single centre retrospective study included 235 patients, admitted to the ICU after cardiac surgery with CPB between 01-01-2019 and 31-12-2019. Delirium was defined as patients having been administered the antipsychotic drugs haloperidol or quetiapine, either intravenously or orally, at least once during ICU-stay. Patient characteristics and drugs were retrieved directly from the electronic medical records. Risk factors for delirium after cardiac surgery were analysed: age, type of surgery, Euroscore, APACHE-II score. Data were presented as median and IQR.

Results: Patients underwent arcus (n=10), CABG (n=85), CABG/valve (n=36), valve (n=51), mitral valve (n=44) and multiple valve surgery (n=9). 24/235 (10%) received antipsychotics during ICU-stay. ICU-stay and hospital stay were longer in patients with delirium (median 5, IQR 4-7.5 and median 17.5, IQR 11-40.5) than in patients without (median 3, IQR 3-5 and median 11, IQR 9-17) (both p<0.004). Median duration of CPB did not differ between patients with delirium (135.5, IQR 105.75-203) and those without (150, IQR 115-193) (p=0.90). Age, type of surgery, Euroscore, APACHE-II score also did not differ between patients with or without delirium.

Conclusion: In our centre, duration of CPB was not associated with incidence of delirium. However, both length of stay at the ICU and in the hospital were significantly prolonged in cardiac surgery patients with delirium. This findings underline the clinical importance of delirium both on short term and long term outcome.

Intensive Care Medicine Experimental 2020, **8(2)**: 000290

Introduction: Critically ill patients experience pain during Intensive Care Unit (ICU) stay, which must be assessed by valid scales since it affects various outcomes.

Objectives: To evaluate painful procedures in critically ill patients and to investigate their effect as well as the role of analgesia in the outcome.

Methods: We included 28 mechanically ventilated patients who were subjected to 5.71 ± 4.29 painful (turning, endotracheal suction, physiotherapy, central venous catheter placement) and non-painful (oral care, dressing change) procedures. We measured their pain level before, during and after the stimuli by using the Behavioral Pain Scale (BPS) and the Critical care Pain Observation Tool (CPOT). We also recorded their vital signs (systolic and mean blood pressure, heart rate and respiratory rate) at the same timepoints. We analyzed the correlation of our measurements as well as the use of bolus analgesia with the duration of mechanical ventilation, the ICU stay and the survival of the patients.

Results: There were statistically significant differences in the pain scores and vital signs between the different timepoints (before-during and during-after) for all procedures. The differences in the values of BPS and CPOT scales in the aforementioned timepoints were significantly correlated with the respective differences in the values of vital signs. Regarding the type of the procedure, it was shown that physiotherapy influenced more than the others the change of both pain scales. The use of bolus analgesia during the procedure compared to the non-use predicted both less days of mechanical ventilation (17.94 ± 12.73 vs 25.02 ± 21.19 , $p = 0.015$) and less days of ICU stay (18.54 ± 12.82 vs 25.56 ± 20.92 , $p = 0.016$). The higher difference in the BPS before and during the stimuli was correlated with more days of mechanical ventilation [B (95%CI) = 3.640 (1.001 – 6.280), $p = 0.007$] and more days of ICU stay [B (95%CI) = 3.645 (1.035 – 6.254), $p = 0.006$]. As far as the outcome, the higher difference in the CPOT during and after the stimuli and the non-use of bolus analgesia related to increased chance of death [OR (95%CI) = 1.492 (1.107 – 2.011), $p = 0.009$ and OR (95%CI) = 2.626 (1.013 – 6.806), $p = 0.047$ respectively].

Conclusion: Increased level of patients' pain during various procedures in the ICU, as assessed by the BPS and CPOT scales, is related to worse outcomes while the use of bolus analgesia during these procedures might improve the outcomes.

Introduction: While procedures and treatments are performed, sedation is undergone not only for reducing patient's anxiety and pain but also for facilitating the performance. Although there are various sedatives in pediatrics, most of them are not officially approved. The choice and doses of drugs are different case by case and also the responses of them are inconsistent with expectation. For this reason, careful management are particularly necessary. Usually, until the early recovery period in post-anesthetic care unit (PACU) after sedation, adverse events can be observed through careful monitoring. However, it is difficult to identify delayed complications (after 2 hours) and also few studies introduced.

Objectives: In this study, we investigated the delayed adverse events that may occur in pediatrics after sedation. We would like to find out the most common adverse reactions and their period. And based on these evidences, how to deal with delayed responses takes a message in the future.

Methods: The subjects were pediatric patients (3 to 18 year-old) who had undergone sedation for procedures related to hemato-oncology examinations such as bone marrow biopsy, aspiration, spinal tap or both. The adverse events were consisted of 20 categories and they were recorded after sedation by their parents. Patients were divided in two groups; patients who were visited to day care center (DCC) (group A) and admitted in ward (group B). They had repeated these procedures periodically. With Fentanyl 1.5mcg kg⁻¹ as analgesics, three type sedatives were used in order; propofol; ketamine 3:1 combination (type A), 4:1 combination (type B) and propofol single use 1.5mg kg⁻¹ (type C). The occurrence time interval was set at two hour intervals including 30 minutes recovery room period as session one, total 13 sessions. The beginning and ending time of adverse events were also recorded. These categories were based on adverse event of sedative drugs and others specific events were recorded separately.

Results: A total of 168 Patients were participated, group A was 103 patients and group B was 65 patients. Adverse symptoms were showed mostly within 24 hour; group A was 34.95% (36/103) and group B was 51.56% (33/64). Among 20 items, most common adverse events were nausea (13.59%, 14/103) in group A and drowsiness (26.56%; 17/64) and dizziness (23.44%; 15/64) in group B. The incidence was not related to the type of procedure or the combination of sedatives. For hemostasis and intrathecal chemotherapy, during this time, patients were lying down on recovery and intensively monitored, adverse events in group A were showed distribution of various time session (32.8%; 21/64 in recovery room) but those of group B were mostly occupied in this period (74.4%; 32/43). More than 50% of adverse events occurred within 6 hours. In particular, group B rarely occurred after 12 hours (2%; 1/43). Adverse events were disappeared within a day except four cases in group A (6%; 4/64). All adverse events were not required any treatment, refusal of next sedation or need for change of sedatives.

Conclusion: Although there are various sedatives in pediatrics, most of them are not officially approved. The choice and doses of drugs are different case by case and also the responses of them are inconsistent with expectation. The overall trend and degree of risk could be predicted through this study on delayed adverse reactions to sedatives. Though various adverse responses were developed, most of them disappeared within 24 hours spontaneously.

Based on these results, we could consider that sedation with propofol and ketamine should be safe sedatives to reduce anxiety and facilitate sedation safely even when continuous intensive monitoring and management is impossible. Apart from studies of delayed adverse responses in pediatric patients, future studies seek to identify and address how to reduce the adverse reactions and related variables.

Intensive Care Medicine Experimental 2020, **8(2)**: 000392

Introduction: Delirium is a severe neuropsychiatric disorder of organic origin characterized by the appearance of alterations in both consciousness and cognitive functions. The development of delirium is associated with multiple complications: increased mortality, longer duration of mechanical ventilation, higher rate of reintubation, and increased hospital stay. Since effective treatment has proven troublesome, prophylactic strategies become paramount.

Objectives: Analysis of the risk factors associated with the development of delirium in a polyvalent ICU.

Methods: Prospective observational study on a cohort of ICU patients admitted from 1/10/2016 to 1/05/2019; those requiring transfer to another centre were excluded. Patients were classified into two groups, according to whether they developed delirium or not, and the following variables were analysed: sex, age, frailty, reason for admission, comorbidities, SAPS 3, SOFA, specific management measures and development of organic failure(s) (OF). Statistical analysis between subgroups was carried out: Pearson's Chi-square test or Mann-Whitney's U to find significant differences, and uni- and multivariate logistic regression analysis to quantify existing associations.

Results: 1534 patients were admitted during the indicated time, 72 excluded. Ninety-three developed delirium (incidence 6.3%). After obtaining the initial data, we performed a multivariate analysis (table 1) including significant variables of the univariate analysis (with $p < 0.1$), and finally, recursive partitioning using Chaid tree, observing (a) a higher incidence of delirium in patients who presented more than 2 OF (20.4%) and, (b) in patients with less than 2 OF, higher incidence in patients above 74 years (8.6%). Patients who developed delirium had longer ICU and hospital length-of-stays and a higher rate of readmission, without differences in mortality.

Table 1. Multivariate analysis

VARIABLE	OR (CI 95%)
Age (>74)	2,1 (1,3-3,5)
Coma as reason for admission	2,5 (1,07-5,8)
More than 2 OF	4,9 (2,9-8,2)
Invasive mechanical ventilation	1,9 (1,1-3,3)
Confirmed isolation	2,4 (1,2-4,6)
Continuous neuromuscular blockade	7,2 (2-26,3)

Conclusion: The highest risk observed for developing delirium clustered in patients who presented more than 2 OF and patients over 74 years old. The detection of patients at high risk for developing delirium could imply a change in management and an improvement in the quality of care.

Intensive Care Medicine Experimental 2020, **8(2)**: 000396

Introduction: Delirium is a common often misdiagnosed, unrecognised and misunderstood condition in the critical care setting (Page et al,2009) that has been associated with increased mortality, morbidity and cognitive dysfunction (Leutz et al, 2010) . Delirium has implications for increasing cost to the National Health Service as it is linked to prolonged ventilation, and ICU stay which exposes the patient to associated risks as well as increased hospital stay (Mehta et al, 2015, Zhang et al, 2013, Gleason et al 2015).

Objectives: The aim of this study was to identify our prevalence of delirium in our critically ill patient population and assess our compliance with using CAM-ICU (Confusion Assessment Method for the Intensive Care Unit), the gold standard screening tool for identifying patients with delirium in the critical care setting (Gelinas et al, 2018, NICE, 2010).

Methods: A prospective cohort study was undertaken in a 75 bedded UK critical care unit, between August 2018 to December 2018. Patients were reviewed consecutively for 2 weeks between 14:00 and 16:00hrs in which a Richmond Agitation and Sedation Score (RASS) was completed. For patients that were found to have a RASS score > -1, CAM-ICU was completed. 106 Patients were excluded (106 patients) due to a length of stay less than 2 days, a previous known cognitive dysfunction, non-English speaking or were <18 years old.

Results: 217 patients were identified in the 2 week period. A RASS score was completed on 111 patients, of which 24 percent of patients were found to be CAM-ICU positive at least once during their critical care stay, 61% were had a negative CAM-ICU and 14% were unable to be assessed for delirium as remained with a RASS <1 throughout the study. Higher rates of CAM-ICU positive were found in patients admitted to the neuro and cardiothoracic speciality areas, 50% and 32% respectively. CAM positive score were more likely to be seen in males and in emergency admissions. No differences in ICNARC or APACHE II scores were identified between the 2 groups. The compliance with CAM-ICU was poor, out of 311 opportunities identified; CAM-ICU was only completed on 52 occasions (19%). Of the CAM positive group, only 14 percent had been screened for delirium. Patients that were found to be CAM-ICU positive had long lengths of ITU stay and longer lengths of hospital stay. This cohort was less likely to be discharge back to their usual place of residence.

Conclusion: Delirium in critical care is effecting a quarter of our patients yet continues to be under diagnosed. Further work is required to increase compliance with CAM-ICU screening in an effort to identify patients at risk and implement intervention to minimise the long-term effects associated with ICU delirium.

Intensive Care Medicine Experimental 2020, **8(2)**: 000558

Introduction: Delirium is a common condition in the intensive care unit (ICU), notably among the elderly, and is associated with poor outcomes. Pharmacological therapy is often used for its treatment, however, its efficacy has not yet been established.

Objectives: To investigate whether pharmacological therapy is effective in reducing delirium-related outcomes among ICU adult patients.

Methods: A systematic review of randomized clinical trials was conducted. For the review of literature, we searched MEDLINE and EMBASE from January 1st 1980 through February 4th 2020 for parallel-group clinical trials testing pharmacological treatment for delirium. Inclusion criteria were randomized clinical trials of adult participants with delirium in the ICU. The exclusion criterion was trials including patients on antipsychotic treatment for pre-existing disorder. Title/abstract screening and full-text screening were independently conducted by two authors. In case of disagreement, a third reviewer was consulted. The primary outcome was the number of days with delirium. Secondary outcomes were delirium-free days, reduction in delirium scale scores, ICU and hospital length of stay, ICU and hospital mortality, mortality in longest period reported, mechanical ventilation-free days, incidence of coma, coma-free days and adverse outcomes. Quality assessment and data extraction were performed by two authors. Meta-analysis was not conducted due to between-study heterogeneity.

Results: From 1055 articles identified by the search strategy, seven fulfilled the inclusion criteria and were analyzed, comprising 1244 patients. The following drugs were analyzed: haloperidol, morphine sulfate, quetiapine, olanzapine, rivastigmine and dexmedetomidine. Significantly shorter duration of delirium in the intervention group was found in two studies (28.6%). Greater reduction in delirium severity among patients receiving intervention was found in one study (14,3%). More ventilator-free days in the intervention group was reported in one study (14,3%). Also, longer ICU length of stay in patients receiving intervention was found in one study (14,3%), and higher mortality in the intervention group was reported in one study (14,3%), although not significant (RR: 2.78 IC 95%, 0.958-8.051). Four studies (57,1%) reported the number of patients with adverse effects. See the attached figures for detailed data.

Adverse effects	44 (25.3%)	32 (17.2%)	Not reported	Not reported	Not reported	3 (7.9%)	2 (8.7%)	0 (0%)	0 (0%)	Not reported	Not reported	Not reported	Not reported	Not reported

Values are expressed as the mean (standard deviation), median (25th-75th percentile), or a number (percentage).

Conclusion: This systematic review concluded that pharmacological approach to delirium in the ICU may reduce duration of delirium. However, high heterogeneity between studies and their risk of bias compromise quality of evidence and analysis. Future assessment by more homogeneous trials with lower bias are required for solid conclusions.

Correspondence: L. Burry

Intensive Care Medicine Experimental 2020, **8(2)**: 000575

Introduction: Psychoactive drugs such as benzodiazepine/non-benzodiazepine sedatives and antipsychotics are routinely prescribed for sedation, agitation, and delirium in the intensive care unit (ICU). Although intended for short-term use, recent studies suggest these drugs may not be stopped on ICU discharge and continued at hospital discharge in some patients.

Objectives: Among ICU patients discharged alive, 1) determine if invasive mechanical ventilation (iMV) ≥48 hours is associated with new (i.e. initiated in the ICU) psychoactive drug use on hospital discharge; 2) to identify factors predicting the number of new psychoactive drugs, adjusting for potential confounders and clustering by site.

Methods: We conducted a multicentre retrospective cohort study of adult patients admitted to 3 academic ICUs during one year to characterize continuation of psychoactive drugs initiated in the ICU at hospital discharge. Data collected included demographics, severity of illness, clinical management, and drug exposures. Multivariable logistic and Poisson models were constructed to address primary and secondary objectives, respectively.

Results: Data collection has been completed for 1111 ICU patients that survived to hospital discharge. At discharge, 12.3% were discharged on one, 3.3% two, and <1% on three new psychoactive drugs; 83.5% were discharged without a new psychoactive drug. Psychoactive drug use prior to hospital admission and iMV ≥48 hours increased the odds of continuing a newly initiated psychoactive drug in the ICU on hospital discharge (adjusted odds ratio (aOR) 1.5, 95% confidence interval (CI) 1.0,2.1 and aOR 2.4, 95% CI 1.6,3.4 respectively) while female sex decreased the odds (aOR 0.7, 95% CI 0.5,0.9). We found females were discharged on fewer new psychoactive drugs (adjusted rate ratio (aRR) 0.7, 95% CI 0.5,0.9) whereas patients started on antipsychotics or non-benzodiazepine sedatives while in the ICU were discharged on a greater number of psychoactive drugs (aRR 2.5, 95% CI 1.9,3.3 and aRR 1.7, 95% CI 1.2,2.5 respectively).

Association between iMV and new psychoactive drug prescription on hospital discharge

Predictor	Adjusted OR (95% CI)	p-value
iMV ≥48 hours (ref = <48 hours)	2.37 (1.64, 3.42)	< 0.001
Age	1.0 (0.99, 1.01)	0.819
Female sex (ref = male)	0.66 (0.47, 0.94)	0.02
Any psychiatric history (ref = no)	1.33 (0.88, 2.01)	0.176

Association between iMV and new psychoactive drug prescription on hospital discharge

Predictor	Adjusted OR (95% CI)	p-value
Alcohol use disorder (ref = no)	1.04 (0.63, 1.74)	0.861
Illicit drug use disorder (ref = no)	1.32 (0.71, 2.43)	0.378
Smoker (ref = no)	1.04 (0.69, 1.55)	0.863
Psychoactive drug PTA (ref = no)	1.47 (1.0, 2.14)	0.047
Admission category (ref = medical)	0.97 (0.68, 1.4)	0.848
SOFA score	1.0 (0.95, 1.05)	0.995

Abbreviations: OR = odds ratio; CI = confidence interval, iMV = invasive mechanical ventilation; ref = reference; PTA = prior to admission; SOFA = sequential organ failure assessment.

Conclusion: Preliminary analyses suggest iMV ≥48 hours and psychoactive drug use prior to hospitalization are associated with continuation of an ICU-initiated psychoactive drug at hospital discharge. Furthermore, antipsychotics and non-benzodiazepine sedatives initiated in the ICU impact the number of prescribed psychoactive drugs on discharge. The final results will be used to inform the development of a quality improvement initiative to optimize medication reconciliation of psychoactive drugs initiated in critically ill patients.

Adjunctive acetaminophen for preventing postoperative delirium in surgical patients: a systematic review and meta-analysis

H. Yonekura¹; Y. Nakamori¹; S. Taito²

¹Department of Clinical Anesthesiology, Mie University Hospital, Tsu, Japan; ²Department of clinical practice and support, Hiroshima University Hospital, Hiroshima, Japan

Correspondence: H. Yonekura

Intensive Care Medicine Experimental 2020, **8(2)**: 000823

Introduction: Postoperative delirium is one of a common complication after major surgeries and associated with increased morbidity and mortality, prolonged mechanical ventilation, longer lengths of ICU or hospital stays, increased cost of care, and worse long-term cognitive function. Therefore, pharmacologic intervention to prevent postoperative delirium is of particular importance for surgical patients. Acetaminophen is commonly used to as adjuvant analgesics in surgeries and may reduce inflammatory response and decrease opioid consumption in surgical patients. Previous studies demonstrated that acetaminophen analgesia may decrease the incidence of postoperative delirium.

Objectives: The aim of this study was to determine the effects of adjunctive acetaminophen analgesia on postoperative delirium.

Methods: We searched randomized controlled trials (RCTs) in databases including MEDLINE, EMBASE, Cochrane Library, the National Institute of Health Clinical Trials Register, the World Health Organization International Clinical Trials Registry Platform, and the reference lists of retrieved articles from inception date to March 2020. The primary outcome was the incidence of postoperative delirium. The protocol has been registered with the International Prospective Register of Systematic Reviews (PROSPERO) registration number CRD42019145666.

Results: Out of 840 reports, 29 RCTs met the inclusion criteria and were appropriate for our meta-analysis. Of 29 RCTs, only 3 RCTs reported the primary outcome. The pooled results of included clinical trials indicated that acetaminophen significantly decreased the incidence of postoperative delirium: pooled risk ratio was 0.38 [95% confidence interval (CI) 0.18–0.80; I² = 0%; n = 263]. The certainty of the body of evidence was judged as moderate using the GRADE methodology.

Conclusion: The results of this systematic review and meta-analysis indicated that administration of acetaminophen was associated with decreased incidence of postoperative delirium.

Intensive Care Medicine Experimental 2020, **8(2)**: 000851

Introduction: Delirium has paramount morbidity and mortality burden; and requires early diagnosis and prompt treatment.

Objectives: We introduced a delirium tool including RASS scoring system first time in our trust in 2016 based on an audit at that time, best practice and NICE recommendations. To ensure the effective usage of these important tools we conducted a prospective audit to capture our compliance.

Methods:

- Location: ITU/HDU
- Time Frame: 4 months
- Data Collection: A questionnaire designed according to NICE recommendations that collected data regarding risk factors, indicators, preventive measures and diagnosis using RASS and CAM-ICU.

- Data Source: Information from patients, nursing staff, patients' notes, and nursing sheets.

Results: Results were analyzed according to NICE guidelines.

- Risk factor assessment: 91% of patients were at high risk for delirium on admission to ITU.
- Indicators of Delirium: Out of 4 major indicators of delirium defined by NICE, 77% of the patients had at least 1 of these indicators present.
- Interventions to prevent Delirium:
 - To prevent cognitive dysfunction, not a single patient had all the simple preventive measures that are recommended by NICE.
 - Mobilization was done only in 44% of the patients and out of this only 17% had walking mobilization (ventilated patients were excluded).
 - Pain scores were recorded only in 37% patients. 2 patients were currently in pain, but pain scores were not documented.
 - Sleep disturbance was found in 55% of the patients.
- RASS score hourly and CAM ICU once a shift is the key to diagnose delirium according to NICE. Results showed that hourly RASS was done only in 28% and CAM ICU only in 14%.

Conclusion: Delirium has paramount morbidity and mortality issues. Our audit highlighted several areas of potential improvement. As part of an action plan, formal and informal teaching sessions were arranged that showed positive feedback. Next step is to reaudit to assess quality improvement.

Introduction: To investigate the efficacy of enteral methadone (MET) to control difficult sedoanalgesia in critical ill patients ventilated due to ARDS in SARS-CoV-2 infection.

Methods: We analyze retrospectively case reports who received MET during the Pandemia. Descriptive analyses were used to describe demographic, clinical and evolutionary trends of the patients and sedative, analgesic and neuromuscular blockade doses five days before and after MET. Adverse effects were also described. Difficult sedoanalgesia was defined as difficulties to weaning from mechanical ventilation (MV) due to agitation and delirium while reducing sedatives and/or analgesics (group A); pain due to opiate withdrawal (group B) or nonoptimal patient ventilator interaction despite high dose of sedatives/analgesics (group C).

Results: 13 patients met the inclusion criteria and constituted the study population. Median age was 64 ± 9 years and 12 were male. With a median of VM of 49 ± 16 days from the first MET dose, 7 patients were included as group A, 3 group B and 3 group C, respectively.

Five days before starting MET, all the patients had a median cumulative IV morphine dose of 589 ± 332 mg. 11 patients were receiving propofol with a median dose 15.443 ± 11.189 mg. 5 patients were also receiving midazolam (median dose 589 ± 261 mg) and 5 patients needed cisatracurium (median 1.753 mg ± 1.706 mg) too. MET initial dose (enteral route) was 45 ± 23 mg.

Five days after MET treatment, 9 patients could reduce opiate treatment in a $68\% \pm 17\%$ of the initial dose. 4 patients could also decrease propofol in a $68\% \pm 27\%$. 3 of 5 patients that were taking midazolam reduced $51 \pm 31\%$ the initial dose. All patients that were receiving cis-tracurium decreased doses in $43 \pm 31\%$.

Regarding difficult sedoanalgesia, 3 patients of group A could progress in the weaning from MV, the other 4 patients could reduce sedatives and analgesics but couldn't progress from MV because of respiratory conditions. All group B patients could control the pain and all patients in group C reached optimal patient ventilator interaction while reducing analgesics and sedatives.

Hypotension was observed in 3 patients after the first MET dose and crystalloids and vasoactive were needed. No other adverse effects were reported.

Conclusion: We concluded that in patients with difficult sedoanalgesia, methadone is effective to reduce doses of sedatives and analgesics and help weaning from MV.

Intensive Care Medicine Experimental 2020, **8(2)**: 000938

Introduction: Critical illness is often related to the development of brain disfunction, which can present itself in several ways, either on the short or the long term.

Up to 80% of the critical illness survivors present with some form of brain disfunction either during the acute episode or when evaluated soon after hospital discharge, and in some patients even years after the acute episode.

Evidence points to the possible improvement in cognitive prognosis when α_2 adrenergic agonists are used in the critically ill. The sedation pattern of these agents is quite different from other sedatives, in which patients can easily be aroused and their cognitive performance in psychometric tests is usually preserved.

The main purpose of this work was to investigate the relationship between the use of dexmedetomidine in the critically ill and some dimensions of the post intensive care syndrome.

Methods: Data was collected retrospectively from the individual medical records of patients admitted to a Mixed Intensive Care Unit (ICU) during the year of 2017. Collected data focused on the results of the inquiries done during the follow-up outpatient clinic usually held between the third and sixth months after hospital discharge. The applied formularies were the Anxiety and Depression Scale, the ICU - Post Traumatic Stress Syndrome (PTSS) questionnaire and the ICU Memories questionnaire.

Results: A total of 318 patients were admitted to the ICU, 64% were male. Most of the patients (72%) were admitted for medical reasons and 64% received mechanical ventilation. The mortality rate was 26%. Dexmedetomidine was used in 26% of the patients, usually as part of a combined sedation strategy. Only 123 patients (39%) attended the follow-up outpatient clinic.

No significative difference was found in the group of patients under dexmedetomidine when considering the Anxiety and Depression Scale or the ICU - PTSS questionnaire. When the ICU Memories questionnaire was applied, we observed that patients seemed prone to recall more memories when under the use of dexmedetomidine, interestingly both pleasant and unpleasant ones.

Conclusion: Our study has some limitations, namely the fact that only a moderate percentage of patients attended the outpatient clinic, possibly explained by the fact that our ICU population assists many

foreigners as it is located in a touristic region. Still it allows us to conclude that patients who receive dexmedetomidine are more aware of their surrounding environment, more cooperative and less susceptible to some adverse effects from the sedative medications.

Level and duration of sedation and sedation agents before and after implementation of pain, agitation and delirium guideline – a before and after study

H. Birgisdóttir¹; R.J. Jónasdóttir¹

¹Faculty of nursing, University of Iceland; Landspítali - The National University Hospital of Iceland, Reykjavík, Iceland

Correspondence: H. Birgisdóttir

Intensive Care Medicine Experimental 2020, **8(2)**: 000943

Introduction: Deep sedation can have negative consequences for Intensive Care Unit (ICU) patients such as delirium, prolonged mechanical ventilation, and longer ICU and hospital stay.

Objectives: To compare the level and duration of sedation, sedative agents, and clinical outcomes of ICU patients before and after implementation of Pain, Agitation, and Delirium (PAD) guideline.

Methods: A before and after study design. Eligible patients were mechanically ventilated, 18 years and older, with 24 hours or longer ICU stay, of mixed ICU patient population in two, single-center ICUs. Data were collected over six weeks, from 1st December 2017 – 12th January 2018, before the PAD implementation and over six weeks, from 1st May – 15th June 2019, four months after completion of the PAD implementation. The sedation level was measured for the first three days of the patients' stay with the Richmond Agitation Sedation Scale (RASS). Sedation duration and types of sedation agents were collected through the patients' stay.

Results: There were 101 patients included, 52 in the before group and 49 in the after group. The two groups were comparable in age, gender, and reason for ICU admission. The after group had a lower APACHE II score compared to the before group ($p=0.01$). The level of sedation was -3 (median) on the RASS scale in both groups the first three days of the ICU stay ($p=0.18$). Patients in the before group were sedated 41 hours vs. 20 hours (median) in the after group, without difference between the groups after adjusting for background variables ($p=0.22$). Seven types of analgesia and morphine-based continuous sedation were used, in various combinations, from none to six in the before group and the after group. Propofol was the most common sedative in both groups (92% vs. 90%, $p=0.66$), and the duration of propofol sedation was shorter in after group (30 vs.16 hours, $p=0.04$). More patients in the after group were sedated with one drug compared to patients in the before group (37% vs. 17%, $p=0.03$) and fewer patients in the after group were sedated with a combination of two drugs than patients in the before group (12% vs. 29%, $p=0.04$). The difference between the groups in duration of mechanical ventilation (median, 36 vs. 16 hours, $p=0.44$), and length of ICU stay (median, 6.2 vs. 4.9 days, $p=0.44$), and hospital stay (median, 12.6 vs. 10.3 days, $p=0.46$) stay was not significant.

Conclusion: The level of sedation was moderate (RASS -3) before and after the PAD guideline implementation without a difference in sedation duration. The depth of sedation, the number of sedation agents administered, and the PAD guideline implementation needs further investigation.

000975**Epidemiological profile, clinical features and incidence of delirium during the first three days of ICU admission in Hospital Virgen de las Nieves (2019)**I. Guzmán Adum¹; L. Hidalgo Manchado¹; R. Diaz Contreras¹¹Intensive care unit, Hospital Universitario Virgen de las Nieves, Granada, Spain**Correspondence:** I. Guzman*Intensive Care Medicine Experimental* 2020, **8(2)**: 000975

Introduction: Delirium is a disturbance of consciousness with changes in cognition. It manifests as a constellation of symptoms with acute onset and a fluctuating course. Delirium is extremely common in the ICU especially amongst mechanically ventilated patients and it has prognostic implications (2.5 fold increase in short term mortality and 3.2 in 6months). Three subtypes have been recognized: hyperactive, hypoactive, and mixed. It is frequently undiagnosed unless specific diagnostic instruments are used. The CAM-ICU is the most studied and validated diagnostic tool.

Objectives: - To calculate the incidence of delirium during the first 72 hours of ICU admission.

- To use Confusion Assessment Method Scale (CAM- ICU) to diagnosed delirium in the ICU.

- To describe the main features and causes of admission in the ICU of the patients that developed delirium in the ICU, compared to the ones that didn't.

Methods: Observational, prospective and descriptive study that includes patients that entered the UCI between October 15th and November 15th, 2019. We performed the CAM-ICU scale at the admission and daily for the first 72 hours or until they were discharged to hospitalization ward, required orotracheal intubation or died. We excluded patients that required orotracheal intubation at admission and those who had mental disorders or central nervous system disorders that made impossible to evaluate delirium with CAM-ICU scale. The collected data was analyzed with SPSS and evaluated in terms of descriptive statistics. We used the mean and standard deviation for quantitative variables and absolute and relative frequencies for qualitative variables.

Results: 102 patients were included, the mean age was 68 (\pm 14 years), 39 (38.9%) patients were previously at the hospitalization ward. The incidence of delirium of those patients that were previously in the hospitalization ward was 64.10% (25 patients). The global incidence of delirium in the first 72 hours in the ICU was 28.4%, during the first day in the ICU the incidence was 15.69%, during the second day was 22.56%, and the third day was 11.76%. The disorders that were more strongly related with the development of delirium in the ICU were: Acute coronary syndrome (50%), decompensated cirrhosis (19%),

sepsis (16%), upper gastrointestinal bleeding (7%) and patients with transcatheter aortic-valve implantation (5%).

Conclusion: - Delirium is a frequent complication in the ICU, even in the first 72 hours, and without the presence of another factors related with delirium such as illness severity, mechanical ventilation and sedation.

- The incidence of delirium in this study is higher (28 cases per 100 patients) than the one described in other studies (11 cases per 100 patients).

- The disease that was most associated with the presence of delirium was acute coronary syndrome. This suggest the need of performing studies that include patients earlier and with less stay in the ICU.

- The use of a specific scale to diagnosed delirium in the ICU is a useful tool to diagnosed it in the ICU.

Introduction: Delirium is a condition characterized by an acute cognitive decline, a fluctuating mental status, disturbance of consciousness, inattention, or disorganized thinking. It is a well-recognized adverse prognostic index in Intensive Care Unit patients that is associated with increased morbidity, mortality, and the development of long-term neurocognitive deficits.

Objectives: To evaluate the presence of delirium, using a well validated scale the "Confusion Assessment Method for the ICU", in post-cardiac surgery patients and to identify possible risk factors which contribute in the development of delirium.

Methods: Our cohort consisted of 202 consecutive post-cardiac surgery patients admitted to ICU. All patients were evaluated for delirium using the CAM-ICU scale. According to this scale, patients developed an acute onset of cognitive decline or a fluctuating mental status, disturbance of consciousness, inattention, or disorganized thinking were diagnosed with delirium.

Results: Patients (mean age:66 \pm 13 years old) had a prevalence of delirium of 29.2%. Patients with delirium were 4 years older than non-delirium subjects ($p=0.002$), while there were no gender differences between the two groups.

Prevalence of chronic kidney disease in study cohort was significantly higher in delirium patients (12%) compare to non-delirium subjects (4%) ($p=0.040$).

The in-hospital mortality risk using Euroscore II score was 1,67% in the study cohort, while patients with delirium scored significantly higher Euroscore II compared with the non-delirium ones (2.32% versus 1.38%, respectively, $p<0.001$).

The median duration of anesthesia-sedation was 360 minutes, while patients presented with delirium had prolonged anesthesia-sedation duration compared to no delirium patients ($p<0.001$).

These patients had also prolonged mechanical ventilation (median duration in patients with delirium was 1230 minutes versus 717

minutes in non-delirium patients, $p < 0.001$) and a longer ICU stay (3210 versus 1440 minutes, $p < 0.001$).

According to ROC curve analysis, variables that predicted delirium were duration of anesthesia-sedation, age, Euroscore II, urea, lactic acid and intravenous vasoactive medications.

Moreover, in a multivariate logistic regression analysis it was shown that age, Euroscore II and duration of anesthesia-sedation were all independent predictors of delirium.

Conclusion: According to our study the prevalence of delirium in ICU after cardiac surgery was high. Age, prolonged duration of anesthesia and Euroscore II score represent independent risk factors of delirium. Delirium was associated with prolonged mechanical ventilation and ICU stay.

Relationship between ICU Acquired Weakness and Cognitive Deterioration: the muscle’s endocrine activity hypothesis

I. PREVIGLIANO¹; C. Foster¹; A. Cuenca²; MB. Leiva²; GM. Roldán²
¹Intensive care, Hospital Fernández, Buenos Aires, Argentina; ²Physical therapy, Universidad Maimónides, Buenos Aires, Argentina

Correspondence: I. PREVIGLIANO
Intensive Care Medicine Experimental 2020, **8**(2): 001019

Introduction: There is evidence of the muscle/brain interaction in several cognitive disorders due to the neurotrophic factors released by muscle endocrine, paracrine and autocrine activity. We didn’t found any research on this topic in Post Intensive Care Syndrome (PICS).

Objectives: Our hypothesis was to determinate if there is any relationship between cognitive impairment after critical illness (CIACI) and ICU Acquired Weakness (ICUAW).

Methods: Setting: teaching hospital, medical and surgical ICU. Maimonides University ethic committee aproved the protocol and waived informed consent. Inclusion criteria: >18yo, ARDS, sepsis or septic shock, APACHEII > 14, Clinical Frailty Scale, Delirium >48h, mechanical ventilation >4d, ICU stay >7 days, use of NMB or steroids, vasopressors. CAM-ICU and RASS (daily), Medical Research Council (MRC) scale and Spanish version of Montreal Cognitive Assessment (MoCA) were the evaluation tools. MRC <18 diagnoses ICUAW and MoCA>26 CIACI. Statistical analysis: IBM SPSS Macintosh 25.0. Descriptive statistics. Chi squared or Fischer exact test.

Results: From April 1st to September 30th, 92 patients were admitted. Of them 28 fulfilled IC. 13 (53.6%) were female, mean age (), in table 1 mean values are expressed. 75% presented delirium. At ICU discharge 64,3% presented ICUAW and 60.7 CIACI. There was a significant association between ICUAW and CIACI (Chi Squared test $p < 0.03$) as is shown in figure 1.

Conclusion: There was a significant association between ICUAW and CIACI in this PICS population. According to our pathophysiological hypothesis our data opens a window for myokines and neurotrophic factors measurements and for the evaluation of the efficacy of multimodal neurotrophic factors preparations.

Loss of mobility and independence in patients admitted for SARS COV-2

L. UGALDE JAUREGUI¹; R. PradaOsorio¹; MP. Eugenio Robaina¹; L. Santana-Cabrera²; JD. Martin Santana³; JC. Martin Gonzalez¹
¹ICU, Complejo Hospitalario Universitario Insular Materno Infantil, Las Palmas de Gran Canaria, Spain; ²Intensive care unit, Maternal and child Hospital, Las Palmas de Gran Canaria, Spain; ³Economics, Universidad de las Palmas de Gran Canaria, Las Palmas de Gran Canaria, Spain

Correspondence: L. UGALDE JAUREGUI
Intensive Care Medicine Experimental 2020, **8**(2): 001052

Introduction: Muscle weakness is a frequent entity in patients admitted to the ICU. Its most common presentations are polyneuropathy and critical patient myopathy, or a combination of the two. In addition, SARS COV-2 requires prolonged invasive ventilatory support and the use of neuromuscular blockers, favoring its appearance. Prevention has an important role in reducing the loss of functionality at ICU discharge.

Objectives: 1-Value the degree of functionality and independence of patients admitted for SARS COV-2 at ICU discharge.
2- Identify the risk factors associated with the loss of functionality and independence during admission.

Methods: Retrospective observational study conducted in a multipurpose ICU with 30 beds. All the patients admitted for hypoxemic respiratory failure secondary to SARS-COV-2 during the months of March - May 2020 were collected. Demographic data, days of stay in the ICU and risk factors associated with acquired ICU weakness were recorded, including the time of start of physical therapy after admission. The Barthel index was used to calculate the functionality and degree of independence of all patients, both at admission and at discharge from the ICU. In the statistical analysis, the Pearson correlation coefficient was used for the quantitative variables and the mean comparison test for qualitative variables.

Results: During the study period, 27 patients were admitted due to SARS COV-2 infection, of which 5 (18.51%) were exitus, for which a total of 22 patients were included in the study. All entered with a score on the Barthel index of 100 points, while the mean score on the Barthel index at discharge was 37.05 ± 16.67. In the association test carried out, we found a high correlation of the loss of functionality at discharge from the ICU with the variables: Days of admission to the ICU (p = 0.000), Days of mechanical ventilation: (p = 0.000), Days with sedoanalgesia and neuromuscular block: (p = 0.000), Days with delirium: (p = 0.000), Physiotherapy during the ICU stay: (p = 0.000), Days of initiation of physical therapy: (p = 0.000).

RISK FACTORS	BARTHEL		<i>r</i> (<i>p</i>)	<i>t</i> (<i>p</i>)
	Media	D.T.		
DAYS IN ICU	---	---	-0,811 (0,000)

DAYS WITH NEUROMUSCULAR BLOCKERS:	---	---	-0,796 (0,000)	
DAYS WITH DELIRIUM	---	---	-0,716 (0,000)	
PHYSIOTHERAPY:				
Yes	63,00	6,71	---	7,690
No	29,41	8,99	---	0,000
DAYS OF WAITING TO PHYSIOTHERAPY:			-0,812 (0,000)	

Conclusion: -Patients admitted to the ICU due to SARS COV-2 infection present a significant functional loss upon discharge from the ICU. -The delay in the start of physiotherapy adds to the risk factors already known for the appearance of weakness and loss of autonomy at discharge from the ICU. An early mobilization strategy for the critically ill patient could mitigate these consequences.

E-predeliric and predeliric as predictors of delirium in patients admitted for SARS COV-2 infection. Which scale is closer to reality?

L. Ugalde Jauregui¹; MP. Eugenio Robaina¹; R. Prada Osorio¹; JD. Martin Santana²; L. Santana-Cabrera³; JC. Martin Gonzalez¹

¹ICU, Complejo Hospitalario Universitario Insular Materno Infantil, Las Palmas de Gran Canaria, Spain; ²Economics, Universidad de las Palmas de Gran Canaria, Las Palmas de Gran Canaria, Spain; ³Intensive care unit, Maternal and child Hospital, Las Palmas de Gran Canaria, Spain

Correspondence: L. Ugalde Jauregui

Intensive Care Medicine Experimental 2020, **8(2)**: 001058

Introduction: The incidence of delirium in patients admitted to ICU due to SARS COV-2 infection is very high according to the different registers. The use of validated scores such as Predeliric and E-predeliric

that predict the likelihood of delirium development in different patients can help in setting priorities with regard to the use of delirium preventive measures, especially in situations of limited resources such as COVID infection.

Objectives: 1.Evaluate the correlation between the E-Predeliric and Predeliric values when they are recoded into four categories of risk of developing delirium (very low, low, moderate and high risk).

2.Evaluate the correlation between the predicted probability of delirium according to the E-Predeliric and Predeliric models with the actual rate of delirium developed in patients admitted to the ICU for SARS COV 2.

Methods: Retrospective observational study carried out in a multipurpose ICU with 30 beds. All patients admitted for SARS COV2 infection were collected during the months of March to May 2020. The E-PRE-DELIRIC was calculated in all patients at the time of ICU admission and the PRE-DELIRICa24 hours after admission, classifying patients into four risk groups according to the result (very low, low, moderate and high risk). We quantified the incidence of delirium after sedation was removed. The presence of agitation, maladjustment (in the absence of pain or ventilatory problems) and the need for administration of dexmedetomidine or an antipsychotic drug was considered delirium. And finally the results were compared with the actual rate of delirium observed in these patients.

Results: During the period from March to May 2020, a total of 27 patients were admitted to our service with the diagnosis of SARS-COV 2, with an average age of 65.81 ± 9.72 . There is a high correlation between the percentage values of E-Predeliric and Predeliric ($r = 0.608$, $p = 0.01$). This result is corroborated with the association test between both variables when they are recoded in four categories. There were no statistically significant differences in the percentage value of E-Predeliric and the patient's state of real delirium ($t = 1,481$, $p = 0.151$). Their mean values are very similar (38.95% and 33.50% for the patients who suffered delirium versus those who did not, respectively). The opposite occurs with Predeliric ($t = 5,460$, $p = 0.00$), with the mean values being 85.68% and 41.00%. These results are corroborated with the association test performed between the patient's actual state of delirium and these two scales coded in its four states.

Conclusion: 1.The E-Predeliric and Predeliricscores allow patients to be classified according to the risk of developing delirium in 4 groups, in a homogeneous manner, regardless of the score used.

2.The predicted risk at admission according to the E-Predeliric, in relation to the observed delirium rate, shows that the risk of delirium is underestimated, while the24h after admission calculatedPredeliric is better correlated with the actual incidence observed.

Intensive Care Medicine Experimental 2020, **8(2)**: 001148

Introduction: Identifying patients with delirium is essential for the prevention, treatment and management of the condition; this requires a structured assessment that can be done using the CAM-ICU methodology (Miranda et al 2018). We set a standard of recording twice daily CAM-ICU assessments in patients' electronic records (EPR). Access to these records has allowed us to audit compliance to our standards and to review outcomes of different types of delirium and review the frequency with which patients meet different stages of the assessment.

Objectives: To retrospectively assess 1-year mortality of patients with hyperactive and hypoactive delirium, to assess compliance with delirium assessments and to review the frequency with which patients met different components of theCAM-ICU.

Methods: The review was conducted in a 32 bedded general and neurosciences unit. EPR records (Sunrise Clinical Manager) of the CAM-ICU assessments from August 2018-August 2019 were exported to Excel files. Patients were categorised as who were delirium positive (with or without agitation), or negative but with or without cognitive

impairment. Cognitive impairment was defined as an acute change from a patient's normal mental state. These patients can then be divided into those with inattention errors using the Letters Attention Test, or with disorganized thinking using straightforward Yes/No questions and commands to follow.

Records were linked to the patients' Intensive Care National Audit and Research Centre (ICNARC) records to investigate reason for admission, co-morbidities, social history, length of stay and outcome. On six occasions we provided feedback to nurses about the number of assessments by individual nurses and with information about the assessments.

Results: There were a total of 2728 admissions (2408 total patients, 57% male, mean age 57 (SD 18 years)) in the ICNARC records. 1358 patients had 10,530 recorded CAM-ICU assessments, of these 1191 had full ICNARC records and were reviewed in more detail (6 patients with delirium had ICNARC details filled out from EPR). 214 (18%) had at least one positive assessment, of the remaining 977 patients, 82 had with cognitive impairment and 895 had no cognitive impairment, the remaining 167 remained in a coma. Of 10,530 assessments, 66 were excluded as incomplete, 7,243 were not deeply sedated. 989 had an acute change from their baseline mental state, out of which 775 had >2 inattention errors on assessment (CAM-ICU positive). The remaining 199 patients had 0-2 inattention errors (CAM-ICU negative). Of the 775, 246 were calm and alert; 199 had 2 or more points for disordered thinking. Patients with delirium had a longer length of hospital and ICU stay (LoS) compared to those without delirium (median (IQR) ICU LoS: CAM-ICU positive 9 (4-18) days, negative with cognitive impairment 4 (2-8) days, without 3 (2-6) days. Patients with delirium required more organ support, had a higher mortality (ICU: 14% vs 7% vs 9%) and were more likely to be male, their mortality rate increased from 13% at 30 days to 22% at one year. Those that died were older, had more co-morbidities and had worse functional status than those that survived. In all patients, 23% had an assessment completed once per shift and 62% once per day. In patients with a positive assessment, 65% had investigations to identify a cause, 42% required some form of restraint and 65% had cognitive impairment at unit discharge. Those suffering from hypoactive delirium were older (mean 60 years, SD 18 years) and more likely to die (1-year mortality of 26%).

Conclusion: Electronic records of delirium assessments can be used to audit compliance with standards for delirium management. Even with staff feedback, only 62% of patients had daily assessments. The study provides further evidence that patients with delirium are more likely to be male, have a higher mortality (particularly with hypoactive delirium), need more support, and continue to die in the 12 months after their ICU stay.

Intensive Care Medicine Experimental 2020, **8**(2): 000220

Introduction: Pupilometry is a simple and non invasive technique that allows to assess nociceptive responds to stimulus through pupillary dilation reflex (PDR) objective measurement.

Objectives: To evaluate diagnostic efficacy of PDR compared to BPS scale.

Methods: ICU patients over 18 years, under intravenous sedoanalgesic drugs, mechanically ventilated, basal BPS of 3, RASS between -1 and -4. Exclusion criteria: use of paralyzing drugs, neuromuscular diseases, polyneuropathy, pupillary damage, GCS <6, clonidine, dexmedetomidine, tramadol, ketamine, adrenalin, calcioantagonist, noradrenaline > 0.6 or dobutamine > 10 mg/kg/min. It will be assessed pain response with BPS and PDR in pain absence, pain stimulus of 10,20 30 and 40 mA and with tracheal aspiration. PDR measurements : Pupilometer AlgiScan®. Presence of pain was considered as BPS>3. It will be preformed a diagnostic PDR test vs BPS globally and separated for each painful stimulus or not. Significance as p < 0.05. Approved by Basque Ethics Committee (CEIm-E).

Results: We obtained an AUC of 0,885 (IC 0,830-0,940). PDR value of best diagnostic efficiency was 11,5%, with a sensitivity of 89,8% (CI 95% 78,2-95,6) and specificity of 78,4% (CI 95% 70,6-84,5) (Table 1).

Table 1. Diagnostic efficiency of different PDR cut points (global measurements).

	PDR 11,5%	PDR 7,5%	PDR 5,5%	PDR 3.5%
Sensitivity (%)	89,8 (78,2-95,6)	89,8 (78,2-95,6)	93,9 (83,5-97,9)	95,9 (86,3-98,9)
Specificity (%)	78,4 (70,6-84,5)	62,7 (54,3-70,4)	51,5 (43,1-59,8)	38,1 (30,3-46,5)
PPV(%)	60,3 (48,8-70,7)	46,8 (37,0-56,8)	41,4 (32,7-50,7)	36,2 (28,4-44,7)
NPV(%)	95,5 (89,8-98,0)	94,4 (87,5-97,6)	95,8 (88,5-98,6)	96,2 (87,2-99,0)
FP(%)	21,6 (15,5-29,4)	37,3 (29,6-45,7)	48,5 (40,2-56,9)	61,9 (53,5-69,7)
FN (%)	10,2 (4,4-21,8)	10,2 (4,4-21,8)	6,1 (2,1-16,5)	4,1 (1,1-13,7)
Accuracy (%)	81,4 (75,2-86,4)	69,9 (62,9-76,1)	62,8 (55,6-69,5)	53,6 (46,3-60,6)
Odds ratio	31,8 (11,5-87,6)	14,7 (5,5-39,7)	16,2 (4,8-54,9)	14,4 (3,3-62,0)
PPC	4,15 (2,9-5,8)	2,4 (1,9-3,06)	1,9 (1,6-2,3)	1,6 (1,4-1,8)
NPC	0,13 (0,06-0,3)	0,16 (0,07-0,4)	0,12 (0,04-0,3)	0,1 (0-0,4)

In 20 mA stimulus we found the best results on efficiency diagnostic parameters, with an AUC of 0,853 (0,7-1,0) and a sensitivity of 100% (34,2-100) and a specificity of 75,9% (57,9-87,8) for the cut point of PDR=11,5% (Table 2).

Conclusion: PDR values over 11,5% indicate pain with a 90% of sensitivity and 80% of specificity.

A pupillary response over 11,5% during 20mA stimulus could predict the need of analgesics during tracheal aspiration. Further studies will be needed to confirm.

Intensive Care Medicine Experimental 2020, **8(2)**: 000295

Introduction: Pain assessment in the non-communicative patient in critical care units remains under continuous evaluation. Clinical complexity of the critically ill patient could establish behavior responsiveness to pain.

Objectives: To determine the pain response in critically ill patients by comparing two tools: the behavior pain scale (BPS) and the pupillary dilation reflex (PDR), establishing the demographic (age) and clinical factors (severity level-APACHE II, and sedation level-Bispectral Index scale-BIS) which may interfere with their response.

Methods: ICU patients over 18 years, under intravenous sedoanalgesic drugs, mechanically ventilated, basal BPS of 3, RASS between -1 and -4. Exclusion criteria: use of paralyzing drugs, neuromuscular diseases, polyneuropathy, pupillary damage, GCS <6, clonidine, dexmedetomidine, tramadol, ketamine, adrenalin, calcioantagonist, noradrenaline > 0.6 or dobutamine > 10 mg/kg/min. It will be assessed pain response with BPS and PDR in pain absence, pain stimulus of 10,20 30 and 40 mA and with tracheal aspiration (TA) PDR measurements: Pupilometer AlgiScan®. Presence of pain was considered as BPS>3. Categorical variables as percentages % and compared using X2 o Fisher, continuous variables median IQR and compared using two samples T-test. Multivariate analysis was performed using a logistic regression model showed as odds ratios (OR) and 95% confidence intervals (CI). P<,05. Approved by Basque Ethics Committee (CEIm-E)

Results: 183 measurements on 31 patients. Demographic characteristics; mean±SD: age 62,4±17,1; APACHE II 21±8,3; BIS 63±19,5; RASS

-3,4±1,8. Percentage: Female 38,7; Admission: ARF 25,8; Post-surgery 32,2; Sepsis 29,1; Trauma 12,9.

Only in 49 measurements (26.7%) of them presented pain (BPS ≥4), with median of PDR of 28% (17-48), vs 134 where not experience pain (BPS<4) with a median of 5% (2-11) (p <0.001).

In the bivariate analysis, an age over 65, a higher level of severity (APACHE II >20) or a higher level of sedation (BIS ≤ 40) did not predict a lower likelihood of having pain measured for BPS (BPS ≥4) (Table 1). Similarly, age above 65 was not related to lower PDR. In contrast, BIS ≤ 40 and APACHE>20 were both significantly associated with lower PDR (Table 2).

Table 1. Behavior of BPS according to level of BIS, age and APACHE II.

	BPS<4		BPS≥4		p
	n	%	n	%	
BIS ≤40	20	14,9%	5	10,2%	0,41
BIS >40	114	85,1%	44	89,8%	
Edad≤65	70	52,2%	25	51%	0,884
Edad>65	64	47,8%	24	49%	
APACHE≤20	57	45,2%	26	57,8%	0,149
APACHE>20	69	54,8%	19	42,2%	

Table 2: Behavior of PDR according level of BIS, age and APACHE II.

	PDR			p
	n	P50 (P25-P75)		
BIS ≤40	25	3 (2-10,5)		0,020
BIS >40	158	9 (3,75-21)		
Edad≤65	95	9 (3-22)		0,242
Edad>65	88	7 (3-19)		
APACHE≤20	83	11 (4-29)		0,029
APACHE>20	88	6,5 (3-17)		

In the multivariate analysis adjusted by APACHE and BIS the OR in adjusted and non adjusted model was 1,095 (1,062-1,130) (p<0,001).

Conclusion: Higher PDR values are related to painful response according to BPS.

The response to pain is independent of the level of sedation, age and severity of the patients.

Scleroderma renal crisis – an unusual diagnosis in a district general hospitalC. Peers¹; M. Cooper¹; S. Sonia¹; F. Bond¹¹Intensive Care Unit, Princess OfWales Hospital, Bridgend, United Kingdom**Correspondence:** C. Peers*Intensive Care Medicine Experimental* 2020, **8(2)**: 000137

Introduction: We report a patient who presented with pulmonary oedema, hypertension and progressive renal failure. Recent investigations for systemic sclerosis had been performed but results were still awaited on admission. Systemic Sclerosis is a rare disease with an incidence of two to ten cases per million of the population. Scleroderma Renal Crisis, with an incidence of 5% in patients with diffuse disease, is a rare complication of a rare disease.

Methods: This 70-year-old lady presented with pulmonary oedema and acute kidney injury. A diagnosis of Systemic Scleroderma was considered due to presence of dermatological changes (fig.1), hypertension, presence of right heart strain on transthoracic echocardiography and rapidly progressive renal failure. Scleroderma renal crisis became the primary diagnosis following positive biochemical tests.

After immediate resuscitation and initiation of treatment with the angiotensin converting enzyme inhibitor, Captopril, the patient was transferred to the regional renal unit for continued management. The patient's renal failure worsened and she became dialysis dependent. She also developed left ventricular failure and worsening pulmonary hypertension. Despite prompt diagnosis of a rare condition and aggressive resuscitation, the patient did not survive her hospital admission.

Figure 1: Dermatological changes seen in this patient characteristic of scleroderma

Results: An immunological screen was sent with key positive findings including positive CENP B, PM-Scl100, anti-nuclear AB screen and P-ANCA screen pattern. Echocardiogram demonstrated left ventricular hypokinesia with an ejection fraction of 35% and moderate pulmonary hypertension. Urine dipstick showed protein ++++, blood ++++.

Conclusion: Acute renal failure is not always secondary to septic shock in a patient with sepsis. This case demonstrates the importance of considering rare causes of acute renal failure in the intensive care setting.

ARDS as debut of Pulmonary Sarcoidosis: Two case reportC. Saito¹; JR. Fernández Villanueva²¹Medicina Intensiva, Complejo Hospitalario Santiago de Compostela, Santiago de Compostela, Spain; ²Critical care unit, Hospital Clínico Universitario de Santiago de Compostela, Santiago de Compostela, Spain**Correspondence:** C. Saito*Intensive Care Medicine Experimental* 2020, **8(2)**: 000701

Introduction: Sarcoidosis is a multisystemic granulomatous disorder of unknown etiology that most commonly affects the lung and lymphatic system. It is characterized pathologically by the presence of noncaseating granulomas in involved organs. The estimated prevalence is 10 to 20 per 100,000 population. In approximately on-half the disease is detected incidentally by radiographic abnormalities prior to the development of symptoms, which includes fever, cough, dyspnea and chest pain.

Objectives: We present two cases of Sarcoidosis which had lately diagnosed because of their debut as acute respiratory distress syndrome (ARDS).

Methods: A 52 year old man and a 62 year old woman, both presented as fever and dyspnea of approximately two weeks of evolution, the chest radiography at presentation revealed extensive bilateral interstitial infiltrates. On physical examination: tachypnea with normal skin coloration and fever, no skin, eye or joint lesions. Severe hypoxemia and on auscultation “velcro-like” crackles in bibasilar areas.

Results: Complete blood count, electrolytes and rena and liver test were within normal limits. At day +6 and +4 of admission, respectively, they both presented poor respiratory income and required both orotracheal intubation and connection to mechanic ventilation. Both thoracic CT showed with bilateral extensive multifocal infiltrates with significant mediastinal and bilateral hilar lymphadenopathy. Empirical treatment with intravenous antibiotics and, in the first case, antituberculostatic treatment, was started, because of the appearance of positive Mantoux test. Fiberoptic bronchoscopy with bronchoalveolar lavage (BAL) were performed in both cases and revealed no evidence of PCP, acid fast bacilli, fungi, or malignancy. No other causes were found.

Conclusion: Due to this results, initiation of corticosteroids and pulmonary biopsy was performed in both cases. In the first case, endoscopic ultrasound guided needle aspiration was performed and in the second case transbronchial lung biopsy. Histopathologic detection of noncaseating granulomas, compatibility clinical and radiographic manifestations and exclusion of other diseases, concluded in the diagnosis of pulmonary sarcoidosis. By days +2 and +4 of initiation with corticosteroids, they both presented notably improvement in respiratory status and radiograph images.

Study of three clinical variables as a grading prognosis for acute severe pancreatitisA. Muñoz-Cantero¹; D. Pérez-Civantos¹; JD. Jiménez-Delgado²;M. Cidoncha-Gallego²; P. Nieto-Sánchez¹; J. Pérez-Bazaga¹¹Critical Care Unit, Complejo Hospitalario Universitario de Badajoz, Badajoz, Spain; ²Critical care unit, Don Benito-Villanueva Hospital, Don Benito, Spain**Correspondence:** A. Muñoz-Cantero*Intensive Care Medicine Experimental* 2020, **8(2)**: 000890

Introduction: The assessment of severity at the initial medical examination of serious acute pancreatitis plays an important role in introducing adequate early treatment and the transfer of patients to the ICU. Different early prognostic scores have been proposed but many are not sharply enough for many practitioners.

Objectives: To study the correlation of imaging using TC severity score against SOFA score plus serum lactate and the first 24 hours fluid balance as a predictor score for severe acute pancreatitis.

Methods: A lineal retrospective, two centers study was carried out. We enrolled all consecutive patients with acute pancreatitis admitted to the ICU of two Hospitals (a teaching tertiary center and a small county Hospital).

Univariate analysis was performed to identify the parameters which showed some correlation with the mortality. We used a square-Chi

model for qualitative parameters and T-Student for quantitative. We also performed a multivariate analysis using independent significant ($p < 0.05$) parameters in univariate analysis.

We evaluated the area under the ROC curve (AUC) for significant single parameters in a logistic regression model. Finally, we constructed a model using the analysis of three parameters altogether like an early predictor of the severity of acute pancreatitis. To assess the diagnostic performance of the model, we compared the AUC-ROC with each selected single parameter. The SPSS 22.0 program was used for statistical analysis.

Results: 64 patients were enrolled in the study. All data expressed as median and standard deviation. Age was 60,4 +/- 14. Sequential Organ Failure Assessment (SOFA) score at ICU admission was 3.3 +/- 3.1, Acute Physiology and Chronic Health Evaluation (APACHE-II) score were 11.6 +/- 5.8. We also analyze parameters like Fluid Balance during the first 34 hours, 3.2 +/- 2.5 litres, and serum lactate 2.0 +/- 1.4 mmol/l. The aetiology of acute pancreatitis was: gallstones (60.9%), alcoholism (14.0%), TGC (1.6%), and other causes (20.4%). ICU Mortality was 30.2%. Ten patients required surgical treatment and we found a significant correlation between mortality and the need for surgery ($p < 0.001$). In the same case SOFA score ($p < 0.0001$), serum lactate, initial fluid balance, ICTS and the sum of SOFA Score + Lactic + Fluid Balance were significantly associated with ICU mortality. For the early prediction of the severity, we used a three feet analysis model that was constructed using the SOFA score, Fluid Balance, and serum lactate on the first 24 hours of ICU admission. Our model showed a trend of a higher AUC (0.8892) than that of every single parameter (SOFA score, 0.766; Fluid Balance, 0.822; lactate, 0.852, ICTS, 0.447).

Conclusion: We can conclude saying that probably the sum of three clinical parameters like initial Fluid Balance plus Serum Lactate plus SOFA score is superior to TC severity score as an early prediction of mortality for severe pancreatitis. These preliminary results should need to be confirmed in further studies with a larger number of patients.

Regular immunosuppression does not lead to worse outcomes in critically ill patients infected with Covid-19

J.K. Rane¹; H.D. Aya²; A. Bhide²; J.M. Low¹; D. Padman¹; A. Rhodes³; M. Hamilton²; S. Leaver⁴

¹Intensive care unit, St George's Hospital, London, United Kingdom; ²General intensive care unit, St George's Hospital, London, United Kingdom; ³Anaesthesia and intensive care medicine, St George's University Hospitals NHS Foundation Trust, Londres, United Kingdom; ⁴Research lead critical care directorate, St George's Hospital, London, United Kingdom

Correspondence: J.K. Rane

Intensive Care Medicine Experimental 2020, **8(2)**: 001054

Introduction: Immunosuppressed Covid-19 patients were predicted to have poorer outcomes (1-3), however what contributes to these worse outcomes remains unknown.

Objectives: To assess whether immunosuppression on presentation is a predictor of poor outcomes in critically ill patients admitted with Covid-19 infection in an intensive care unit (ICU) and to identify principle determinants of the poorer outcomes.

Methods: Immunosuppressed patients were defined as patients on regular immunosuppressive treatments. PCR positive Covid-19 patients at St George's Hospital ICU from 01/03/20 to 15/05/20 were included in this observational study. Primary outcome was the odds ratio (OR) of mortality at 28-days after ICU admission. Disease severity was assessed as secondary end points, such as ICU length of stay (LOS), duration of mechanical ventilation (MV), duration of cardiovascular (CV) support, and the need for renal replacement therapy (RRT). A univariate analysis was performed with Chi square statistic, and a logistic and linear regression model was used for the multivariable analysis. Medians were compared with Mann-Whitney U test. P values greater than 0.05 were considered significant.

Results: A total of 132 adult Covid-19 patients were included in the study, out of which 15 (11.4%) were immunosuppressed. 6 (40%) of immunosuppressed patients died at 28 days (Figure 1), compared to 64 (54.7%) in the immunocompetent group (OR 1.8; 95% CI 0.6, 5.4; $p = 0.28$). Immunosuppression in Covid-19 patients did not affect LOS (12 days in immunosuppressed group (5, 22) vs 11 days (5, 17) $p = 0.8$), the requirement of RRT (26.7% vs 37.6%, OR 1.6, 95% CI 0.48, 5.5, $p = 0.4$) length of MV (6 days (0, 22) vs 9 days (3, 16), $p = 0.8$) or duration of CV support (1.5 days (0, 8.5) vs. 4 days (0, 9), $p = 0.3$).

Conclusion: Immunosuppression on presentation neither increases 28-day mortality nor pre-disposes patients to severe Covid-19 complications.

Correspondence: K. Shuji

Intensive Care Medicine Experimental 2020, **8(2)**: 000016

Introduction: Diabetes is a risk factor for various postoperative complications. One of the most serious of these complications is thromboembolism such as myocardial infarction and cerebral infarction, in which enhanced platelet α_2 -adrenoceptor function may play a key role (Ref. 1). Currently, many patients admitted to the postoperative intensive care unit (ICU) are sedated long-term by continuous intravenous infusion of the α_2 -adrenoceptor sedative dexmedetomidine. Therefore, it is extremely important to examine changes in platelet functions in patients with diabetes due to differences in anesthetics and sedatives, and to establish an optimal approach to perioperative management for prevention of postoperative bleeding and thromboembolism.

Objectives: The aim of this study is to analyze the effects of dexmedetomidine on expression of P-selectin, a platelet activation marker, by flow cytometry using peripheral blood samples collected before and after surgery from patients with and without diabetes who were admitted to the ICU after major surgery.

Methods: Informed consent was obtained from subjects and the protocol was approved by the ethics committee (R1109). The subjects were patients with (n=5) and without (n=4) diabetes who entered the ICU after subtotal esophagectomy or pancreatectomy. The exclusion criteria were age <20 years; abnormal platelet count, platelet function, or coagulation ability before surgery; treatment with antiplatelet drugs or anticoagulants up to 2 weeks before surgery; intraoperative blood transfusion, and intraoperative treatment with drugs that might affect platelet function. Blood samples were collected from arterial pressure lines before the start of surgery and immediately after admission to the ICU after surgery. Platelet-rich plasma was stimulated by ADP with dexmedetomidine (0-100 ng/ml) at room temperature for 30 min. Samples were coincubated with PerCP-labeled anti-CD61 antibody and PE-labeled anti-CD62P (P-selectin) antibody, and P-selectin expression levels were assessed by flow cytometry. Data from before to after surgery were compared by t-test. All other data were compared by one-way ANOVA, followed by a Dunnett *post hoc* test. $P < 0.05$ was considered to indicate significance in all analyses.

Results: In patients without diabetes, dexmedetomidine increased P-selectin expression in a dose-dependent manner, with no significant difference between pre- and postoperative data (Fig. 1). In patients with diabetes, P-selectin expression was higher than in patients without diabetes at all concentrations of dexmedetomidine before and after surgery (Fig. 2). P-selectin expression in patients with diabetes was enhanced in a dexmedetomidine dose-dependent manner, similarly to patients without diabetes, but was significantly higher after surgery than before surgery.

These results show that the P-selectin expression level in patients with diabetes is higher before and after surgery, compared to that in patients without diabetes, which indicates that platelets from patients with diabetes are activated and have a tendency for thrombosis. Our previous studies on healthy individuals showed that dexmedetomidine enhanced P-selectin expression in a concentration-dependent manner (Ref. 2). This is consistent with the results of this study and indicates that this tendency does not change after surgical invasion. In patients without diabetes, dexmedetomidine had similar levels of platelet activation before and after surgery, whereas patients with diabetes had significantly increased P-selectin expression after surgery. This suggests that the sensitivity of α_2 -adrenoceptors may be

enhanced or the number of α_2 -adrenoceptors may increase due to surgical invasion in platelets of patients with diabetes.

Conclusion: The function of platelet α_2 -adrenoceptor may be enhanced postoperatively and platelets may be activated more strongly by dexmedetomidine in patients with diabetes compared to patients without diabetes.

Intensive Care Medicine Experimental 2020, **8(2)**: 000417

Introduction: Coronavirus disease 2019 (COVID-19) is associated with coagulation abnormalities leading to numerous thromboembolic complications. Conventional coagulation tests show trends of coagulopathy, but reflect only limited parts of the coagulation cascade.

Rotational thromboelastometry (ROTEM®) is a digitized modification of thromboelastography reported to be useful in identifying hypercoagulable conditions.

Objectives: The aim of this study was to evaluate ROTEM® profiles of COVID-19 patients in identifying hypercoagulable states.

Methods: Patients admitted to the Intensive Care Unit with COVID-19 were included in this prospective observational study. Blood samples were collected for ROTEM® thromboelastometry. Coagulation patterns were analyzed using extrinsic and intrinsic rotational thromboelastometry activators (respectively EXTEM and INTEM). The following variables were recorded and analyzed: clotting time (CT), clotting formation time (CFT), clot firmness' amplitude after 5 minutes (A5) and after 10 minutes (A10), and maximum clot firmness (MCF). The ROTEM® results were compared with conventional coagulation parameters, which were collected as part of standard clinical care. Hypercoagulability was defined as a reduction in CFT and increase in MCF.

Results: Forty-seven COVID-19 patients were included, of which 81% were male. The median age was 63 years (range 29-79), and the median BMI was 28.8 kg/m² (range 24.4-48.4). The median length of stay at the ICU at the time of blood sampling for ROTEM® was 8 days (range 1-25). All patients required mechanical ventilation.

Mean ROTEM® clot formation time (CFT) was shortened in EXTEM (45.3 s; normal 46-149 s) and INTEM (45.6 s, normal 62-130 s). Mean maximum clot firmness (MCF) was increased with all three activators (EXTEM, 77.3 mm, normal 55-72 mm; INTEM 72.9 mm, normal 51-69 mm; FIBTEM 32.9 mm, 6-21 mm).

Conventional coagulation analyses showed the typical coagulopathy pattern with increased fibrinogen (mean 7.2 g/L, SD 1.5 g/L), prolonged PT (15.3 s, SD 2.0 s), and prolonged APTT (34.7 s, SD 8.7 s). Mean platelet count was slightly increased (404 109/L, SD 154 109/L).

Conclusion: ROTEM® confirmed an overall hypercoagulable state of COVID-19 patients admitted to the ICU.

Intensive Care Medicine Experimental 2020, **8(2)**: 000418

Introduction: Therapeutic plasma exchange (TPE), the use of which has been expanding in recent years, is a nonspecific extracorporeal treatment method and is used in many immunological and toxicological diseases.

Objectives: The aim of this study is to determine demographic and clinical characteristics of critically ill patients in the intensive care unit (ICU) with TPE

Methods: This study was performed prospectively in ICU. Patients in need of ICU, bigger than 18 years old and with TPE indication were included in the study.

Results: We enrolled 31 patients. A total of 207 sessions of TPE were performed. The mean age was 46 ± 18 years. The median APACHE II score was 20 (min:5- max:40). The most common reason for ICU admission were 56% microangiopathic hemolytic anemia (MAHA), 13%

Crimean-Congo Hemorrhagic Fever (CCHF) and 10% Guillain-Barre Syndrome, respectively. There were significant difference between survivors and non survivors APACHE II (survivors 17±7, non survivors 25±9, p=0.02) and GC score (survivors:12 (min:3-max:15), non survivors:8 (min:3-max:15), p=0.08). Length of ICU stay was 12 (min-max: 1-86) days. ICU mortality was 48%.

Conclusion: As a result of this study, the most common TPE indication was determined as MAHA in the ICU. The mean age of patients undergoing TPE was lower than the general ICU patient profile. Nearly half of the patients died. Scoring systems such as APACHE II score and GKS maybe effective in determining the mortality of these patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000741

Introduction: COVID-19 is a novel Coronavirus that is currently responsible for the Global Pandemic of 2019-2020. It has been reported that up to 25%(1) of hospitalized patients with COVID-19 develop VTE (Venous Thromboembolism) and this figure can be as high as 31% in ICU patients with COVID-19(2). We aimed to establish the incidence rate of VTE in COVID-19 patients admitted to ICU compared to patients admitted with Seasonal Influenza and mechanically ventilated without both influenza and COVID-19.

Methods: We included 38 patients that were admitted to the ICU at SJH with COVID between the 31/03/2020 – 13/04/2020. We also included the last 38 patients that had been admitted to ICU with Seasonal Influenza, as a comparison group. These patients were admitted between 06/02/2016 – 22/03/2020, as there were fewer cases per year. We used a control group consisting of the last 37 patients that had been admitted to the ICU and required Mechanical Ventilation for greater than 48 hrs for a non-respiratory reason.

Each patient's Electronic Patient Record was reviewed retrospectively. We recorded each patient's background and co-morbidities, whether they developed VTE or not and reviewed the radiological evidence. We also looked at each patient's Coagulation profile on admission and how they were anticoagulated in ICU. We used SPSS 26.0 to analyse the data.

Results: SAPSII scores and SOFA scores were significantly higher in patients without both influenza and COVID-19 compared to influenza and COVID-19 respectively (Table 1)The incidence rate of VTE in the COVID group was 13.2% (DVT 5.3%, PE 10.5%). The Rate of VTE in the Seasonal Influenza group was 15.8% (DVT 13.2%, PE 2.6%). The Rate of VTE in the Non-respiratory Group was 8.1% (DVT 8.1%, PE 2.7%). There was no significant difference between the groups (p 0.5).

All patients that went on to develop VTE had received prophylactic anticoagulation before diagnosis, and all received therapeutic anticoagulation thereafter.

Parameters	Normal Range	COVID-19 group (mean [Standard Deviation]) n=38	Seasonal Influenza group (mean [Standard Deviation]) n=38	Control Group (mean [Standard Deviation]) n=37	p-value
Sex (M:F)		28:10	20:18	26:11	0.1
SAPS II		49 (18.1)	56.8 (17.5)	61.5 (16.4)	0.009
SOFA		6 (4.1)	8.8(3.9)	9.2(3.3)	0.001
Age (years)		57.9 [14.8]	61.0 [17.4]	58.4 [18.2]	0.7
Diabetes (%)		9 (23.7)	6 (15.8)	4 (10.8)	0.3
Heart Disease (%)		6 (15.8)	18 (47.4)	12 (32.4)	0.01
COPD (%)		5 (13.2)	14(36.8)	8(21.6)	0.04
Active Smoker (%)		2 (5.3)	7(18.4)	9(24.3)	0.06
CKD (%)		3 (7.9)	1(2.6)	0	0.1
BMI (kg/m ²)		25.7 [5.4]	27.5 [9.2]	26.4 [6.4]	0.5
SAPSH		49.0 [18.2]	56.8 [17.5]	61.5 [16.4]	0.009
SOFA		6.0 [4.2]	8.8 [3.9]	9.2 [3.3]	0.001
PT (seconds)	9.9 -13.1	13.9 [2.7]	12.8 [4.1]	15.2 [4.1]	0.096
APTT (seconds)	24.0 – 36.0	30.9 [3.7]	16.8 [12.9]	15.2 [4.1]	<0.001
Fibrinogen (g/L)	1.9 – 3.5	6.2 [1.6]	34.6 [14.0]	30.8 [5.0]	<0.001
Platelets (x10 ⁹ /L)	140 - 450	235.9 [97.6]	186.7 [105.7]	233.5 [156.1]	0.5
CRP (mg/L)	<10	171.0 [107.5]	186.7 [105.7]	233.5 [156.0]	0.8
LDH (IU/L)	135 - 250	431.2 [237.8]	101.5 [84.6]	92.9 [108.6]	<0.001
VTE (%)		5(13.2)	6(15.8)	3(8.1)	0.5
PE (%)		4(10.5)	1(2.6)	1(2.7)	0.2
DVT (%)		2(5.3)	5(13.2)	3(8.1)	0.4

Conclusion: There was no significant difference in the rates of VTE between ICU patients with COVID-19 compared to Influenza, in our cohort. Yet, VTE still occurred despite prophylactic anticoagulation and remains a pertinent differential to keep in mind.

Intensive Care Medicine Experimental 2020, **8(2)**: 000857

Introduction: Since its emergence in December 2019, the coronavirus disease 2019 (COVID-19) epidemic rapidly progressed into a pandemic. A noticeable observation in critically ill patients affected by COVID-19 pneumonia is the high incidence of thrombotic complications, especially that of pulmonary embolism. Importantly, the majority of patients admitted to the ICU receive a central venous catheter of which a considerable proportion develops catheter-related thrombosis. When considering COVID-19 coagulopathy to cause an overall hypercoagulable state rather than mainly a local pro-thrombotic state in the pulmonary circulation, the prevalence of catheter-related thrombosis is presumably higher in COVID-19 patients than in non-COVID-19 patients with a central venous catheter.

Objectives: The aim of this study was to investigate whether COVID-19 is associated with catheter-related thrombosis.

Methods: This was a multicenter case-control study conducted at four intensive care units. Adult critically ill patients with an indwelling central venous catheter of the internal jugular, subclavian or femoral vein were included. Patients were excluded if catheter indwelling-time was less than 48 hours. All patients underwent a compression and duplex ultrasound examination of the cannulated vein. Cases and controls were patients with and without catheter-related thrombosis, respectively. Primary outcome was the association of COVID-19 with catheter-related thrombosis. Patients were considered to have COVID-19 pneumonia if they had a positive polymerase chain reaction assay for SARS-CoV-2 and had corresponding abnormalities on thoracic imaging.

Results: Ultrasound examination was performed in 87 intensive care unit patients. Catheter indwelling-time was less than two days or was unknown in five patients. A total of 82 patients were included in the analysis, of whom 18 were diagnosed with catheter-related thrombosis (22%). The majority was male (80.5%) and median age was 63.0 [IQR: 54.5, 70.0] years. The overall prevalence of COVID-19 was 76% (62/82) and 94% (17/18) among the cases. The crude odds ratio for catheter-related thrombosis in patients with COVID-19 versus controls was 7.2 (95% CI: 1.32, 130). The odds ratio for catheter-related thrombosis adjusted for anticoagulation dosage and catheter indwelling-time in critically ill COVID-19 patients was 18.3 (95% CI: 2.31, 410).

Conclusion: COVID-19 is highly associated with catheter-related thrombosis, suggesting a diffuse hypercoagulable state rather than mainly a local pro-thrombotic state in the pulmonary circulation leading to pulmonary immunothrombosis.

Correspondence: M. Törnudd
 Intensive Care Medicine Experimental 2020, **8(2)**: 000862

Introduction: The use of cardio-pulmonary bypass (CPB) during cardiac surgery is associated with bleeding complications. Alterations in platelet function has bearing on the risk of bleeding. The effect of CPB on the actual number and function of platelets is not fully understood.

Objectives: The aim of this study was to analyse the kinetics and function of platelets during and immediately after weaning from CPB.

Methods: Thirty-nine elective coronary artery bypass grafting (CABG) patients were studied with impedance aggregometry (Multiplate) and blood count. Samples were taken before anaesthetic induction (Baseline), 30 minutes after start of CPB (22 of the patients) (CPB30), after weaning from CPB before protamine administration (EndCPB) and five minutes after protamine (After Protamine). Adenosine diphosphate (ADP) was used as activator and aggregation was expressed as the area under the curve (AUC). The number of platelets was corrected for haemodilution by using haemoglobin as marker and expressed as number of platelets ($\times 10^9/L$) divided by haemoglobin concentration (g/L). Statistics used were paired t-test followed by Bonferroni correction for multiple comparisons. Data are expressed as mean \pm standard deviation.

Results: Mean CPB time was 85.1 ± 21.3 minutes (range 46-138 minutes). The number of platelets corrected for dilution was not reduced during CPB. Mean number of platelets divided by concentration of haemoglobin was at baseline $1.7 \pm 0.4 \times 10^9/g$. At 30 min of CPB it was almost identical at $1.7 \pm 0.3 \times 10^9/g$ and after weaning from CPB increased to $1.9 \pm 0.4 \times 10^9/g$ ($p < 0.05$). Five minutes after protamine it decreased to $1.7 \pm 0.5 \times 10^9/g$ compared to before protamine ($p < 0.001$). With impedance aggregometry, mean AUC for platelets activated with ADP was 77.1 ± 26.3 at baseline. After 30 minutes of CPB, AUC was reduced to 49.3 ± 24.7 ($p < 0.001$). After weaning from CPB, mean AUC had increased to 68.5 ± 28.4 . Five minutes after protamine, AUC decreased to 58.9 ± 29.3 ($p < 0.05$ compared to before protamine).

Conclusion: Platelet numbers corrected for dilution were not decreased and platelets were not consumed during CPB. Initially during CPB platelet aggregability was reduced but returned to baseline levels at the end of CPB. After administration of protamine platelets were consumed as expected. The reversal of heparin with protamine seems however to impair platelet function. These effects of CPB and protamine on platelet function can be of significance for the bleeding problems seen in cardiac surgery.

Targeted anticoagulation in Covid 19 patients based on d dimers: a retrospective study of Anti Xa versus APTTr monitoring in patients on systemic heparin infusions to establish superiority and patient outcomes

K. Bhalsod¹; J. Husselbee¹; R. Matthews¹; R. Carroll¹; R. Stumpf¹

¹Intensive care, Hammersmith Hospital, London, United Kingdom

Correspondence: K. Bhalsod
 Intensive Care Medicine Experimental 2020, **8(2)**: 000924

Introduction: COVID-19 patients with elevated d dimers have a higher mortality rate(1), which is reduced when treated with heparin(2), resulting in its recommendation for hospitalised patients.(3) However the type and dose of heparin and heparin infusion monitoring (Anti Xa versus APTTr (Activated Partial Thromboplastin Time Ratio)) remains under discussion (3,4,5).

Methods: We undertook a single centre, retrospective observational service evaluation examining COVID-19 positive critical care admissions receiving heparin infusions (based on d dimer > 3000ng/ml). Two groups of patients were identified: the first group had heparin monitoring via APTTr whilst the second by Anti Xa. We compared the two groups over 2 separate 10 day periods, assessing whether either method of heparin monitoring would affect the following endpoints:

1. The mean rate of heparin infusion
2. Number of monitoring blood tests sent (Anti Xa assay or APTTr)
3. Number of infusion changes made, as a surrogate marker for nursing interventions
4. The mean Anti Xa and APTTr values as a surrogate marker for adequate anticoagulation
5. Clotting and bleeding episodes.

Results:

Our sample groups comprised 18 patients monitored with APTTr and 21 patients monitored with Anti Xa. The table below describes results obtained.

Table 1: To compare Anti Xa vs APTTr monitoring in 2 separate defined 10 day periods

Variable	Anti Xa group	APTTTr group	P-Value *
Total number of patients	21	18	-
Mean heparin infusion rate (U/kg/hr)	18.46	16.31	0.09
Mean number of monitoring blood tests per patient per 24hrs (SD)	1.67 (±0.66)	1.88 (±0.78)	0.38
Mean number of heparin infusion adjustments per patient per 24hrs (SD)	0.68 (±0.39)	0.79 (±0.36)	0.37
Mean test** value (SD)	0.41 (Target 0.3-0.7) (±0.17)	2.00 (Target 1.5-2.5) (±0.42)	-
Total number of patients in each group on RRT (CVVHDF)	12	15	-
Mean number of RRT filter changes per 24hrs (SD)	0.15 (±0.24)	0.26 (±0.32)	0.34
Mean RRT filter lifespan (hrs) (SD)	72.2 (±37.1)	70.7 (±36.9)	0.91
Total number of VTE ***	1	2	0.47
Total number of bleeding complications ***	2	0	0.19

Conclusion: Overall, Anti Xa monitoring is at least comparable to APTTr monitoring in critically unwell COVID-19 patients. Our data suggests that Anti Xa monitoring may be more favourable (improved filter lifespan, less labour intensive and less blood test monitoring), however this needs further investigation.

Heparin remains the mainstay of treatment of covid-19 patients and given the ongoing pandemic, urgent studies are required to establish the optimum method of heparin monitoring in critical care patients.

Acute pulmonary embolism in critically ill COVID-19 patients

Introduction: COVID-19 patients typically have a prothrombotic status and acute pulmonary embolism (PE) may be a cause of persistent hypoxemia or sudden death. However, the incidence of PE has not been well reported.

Methods: Prospective institutional database of critically ill adult mechanically ventilated COVID-19 patients, conducted between March 10 and April 20, 2020. Patients were eligible if they underwent a computed tomography pulmonary scanner angiography (CTPA), as part of the routine management in case of persistent hypoxemia or respiratory deterioration. The primary endpoint of this study was the occurrence of PE; the impact of standard thromboprophylaxis (i.e. subcutaneous enoxaparin 4000 IU once daily) or high-regimen thromboprophylaxis (i.e. subcutaneous enoxaparin 4000 IU twice daily or therapeutic unfractionated heparin) on PE occurrence was also analyzed.

Results: Of 42 mechanically ventilated COVID-19, 36 underwent CTPA after a median of 7 [4-9] days since ICU admission and 13 [10-16] days since the onset of symptoms. Twelve (33%) patients were diagnosed of PE, which was bilateral in 5 patients and localized in the right lung in 7 patients. Ten of the patients with PE (83%) and 11 of the other 24 patients (46%) received standard thromboprophylaxis (OR 3.57 [1.09-13.47]; $p=0.04$). D-dimers on the day of CTPA had a predictive accuracy of 0.90 (95% CIs 0.78-1.00) for APE. Two patients with PE (17%) and 10 patients without PE (43%) died at ICU discharge (OR 0.28 [0.05-1.35]; $p=0.26$).

Conclusion: One third of COVID-19 mechanically ventilated patients have a pulmonary embolism visible on CTPA. Optimal diagnostic and prophylaxis strategies need to be further assessed.

Intensive Care Medicine Experimental 2020, **8(2)**: 000084

Introduction: As the cycling population grows, lack of public awareness of cycling while under the influence of alcohol has become an issue. The purpose of this study was to investigate the association between alcohol consumption and bicycle-related injuries such as traumatic brain injuries and EMR-ISS.

Methods: We conducted a retrospective analysis using data collected from the Korean Emergency Department-based Injury In-depth

Surveillance (EDIIS) database from 20 emergency departments during 2011–2016. Study subjects had sustained bicycle-related injuries at the age of over 18 years. Covariates included mechanism, place, and time of injury. Outcomes were traumatic brain injury (TBI) incidence and severe trauma EMR-ISS³25. Effects of alcohol consumption on these outcomes were analyzed, and differences in effects were determined using logistic regression.

Results: Of 24,297 individuals, 1,912 had alcohol-related bicycle injuries, which led to a higher proportion of single-vehicle injury incidents (alcohol 63.7% vs. non-alcohol 46.4%, $p < 0.001$). The alcohol group had a higher rate of TBI (alcohol 11.5% vs. non-alcohol 4.6%, $p < 0.001$) and severe EMR-ISS (alcohol 23.1% vs. non-alcohol 11.7%, $p < 0.001$). TBI (odds ratio [OR], 2.72; 95% confidence interval [CI], 2.33–3.16) and EMR-ISS (OR, 2.26; 95% CI, 2.01–2.53) showed a significant association with alcohol. Head and neck injuries were higher in the alcohol group (alcohol 73.7% vs. non-alcohol 40.0%, $p < 0.001$).

Conclusion: Our study showed an association of alcohol consumption with higher incidence of traumatic brain injuries and severe EMR-ISS. Education should focus more on the association between cycling under alcohol influence and injury severity.

Intensive Care Medicine Experimental 2020, **8(2)**: 000102

Introduction: Traumatic coagulopathy is often observed in patients with severe traumatic brain injury (sTBI). The association between TBI and coagulopathy is well established. Earlier transfusion with high blood product ratios is recommended for severely injured patients, and fibrinogen is known as one of the most important coagulation factor in the trauma field. Fibrinogen concentrate (FC) is widely used for severe trauma patient and its effectiveness is gradually recognized. However, FC for sTBI is less reported and usage criteria is not established. We started to use FC since 2019 after approval of clinical ethics committee and aggressively administer to multiple trauma patients. We aimed to identify predicting factors of fibrinogen declining in order to set the criteria of FC usage for sTBI.

Methods: We retrospectively reviewed successive adults sTBI in our hospital between January 2017 and December 2019. We compared factors between two groups (high fibrinogen group: fibrinogen value is less than 150mg/dL 3-6 hours after arrival, and low fibrinogen group: fibrinogen value is 150mg/dL or more 3-6 hours after arrival). We researched vital signs, laboratory data, findings of computed tomography(CT) and analyze predicting factor.

Results: 50 patients were enrolled. 35 patients achieved fibrinogen value 150 or more, and 15 patients did not. D-dimer on arrival above 50µg/mL, skull fracture and depressive skull fracture were strong predicting factors of low fibrinogen group.

Conclusion: Low fibrinogen group should be administered FC. Some laboratory data of Coagulation abnormality demonstrated low fibrinogen as reported. Likewise, skull fracture and especially depressive skull fracture reflect severe coagulopathy in this study and patients without skull fracture is enough treated by using only fresh frozen plasma. Skull fracture has possibility of provoking tissue factors and predicting severe coagulopathy.

Introduction: Pulmonary embolism (PE) is a major complication and crucial disease in patients with trauma. Previous studies have been scarce to investigate risk factors for PE in patients with trauma.

Objectives: Our aim was to investigate risk factors for PE among patients with trauma.

Methods: This is a nested case-control study using the Japan Trauma Data Bank (JTDB) from 2004 to 2017. The JTDB is a nationwide trauma registry in Japan. We included patients who had blunt or penetrate trauma; aged ≥ 16 years old; had Injury Severity Scores (ISSs) ≥ 9 ; and survived for more than 2 days after hospital admission. A nested case-control study (1:5) was conducted using propensity score (PS) matching. The variables included in the PS matching were age, gender, mechanism of injury, vital signs at emergency department, ISSs, and ward type. Then, we conducted a conditional logistic regression analysis to identify risk factors for PE in the matched cohort. The primary outcome was occurrence of PE during hospital stay. The explanatory variables were selected based on prior studies and univariate analysis, such as comorbidities, abbreviated injury scale (AIS), transfusion, central vein catheter placement, and surgical procedures.

Results: Of those who were registered in the JTDB database, 719 patients with PE and 3,595 patients without PE were selected by PS matching. The median age was 73 (interquartile range (IQR): 55–84), and 57% was female. The mean ISSs was 10 (IQR: 9–19). Patients with PE had upper and lower extremity open fracture more frequently than those without PE (7.9 vs. 4.6% [$p < 0.001$], 27.7 vs. 7.7% [$p < 0.001$], respectively). Patients with PE had central vein catheter placement

and surgical procedure more frequently than those without PE (7.0 vs. 2.9% [$p < 0.001$], 86.6 vs. 57.1% [$p < 0.001$], respectively). In-hospital mortality was higher in patients with PE than in those without PE (5.8 vs. 3.4% [$p = 0.003$]).

In the multivariate logistic regression model, lower extremity open fracture (odds ratio (OR) [95% confidence interval (CI)], 3.42 [2.65–4.41]), central vein catheter placement (OR [95% CI], 2.41 [1.55–3.73]), and surgical procedure (OR [95% CI], 5.34 [4.04–7.06]) were independently associated with PE.

Conclusion: Patients with trauma complicated with PE had high in-hospital mortality. Lower extremity open fracture, central vein catheter placement, and surgical procedures could be risk factors for PE among patients with trauma.

Introduction: In critically ill patients after trauma, the intestine can remain a vulnerable organ. Gastrointestinal system dysfunction is common in these patients. Intestinal damage occurs in about 50% of critical patients.

Objectives: In this study, it was aimed to investigate the intestinal barrier functions in adult critical patients who were followed up in the intensive care unit (ICU) due to trauma.

Methods: This study was performed prospectively. The study included 29 critical patients bigger than 18 age who were admitted to the ICU for 5 days or more due to trauma, and 18 healthy people of similar age and gender as the control group. Claudin, occludin, tricellulin and junctional adhesion molecule 1 (JAM-1) levels in the protein structure of the blood samples taken from patients to evaluate the intestinal barrier functions were measured using ELISA kits.

Results: The median age of patients was 35 (min:18- max:66) years. The GCS of the patients was 11 (min:3-max:15), and the APACHE II score was 11 ± 1 . The most common reason for ICU admission was traffic accidents (75%). A statistically significant difference was found between the baseline, 2nd day, 5th day, and 10th day plasma levels between patients with claudin, occludin and tricellulin levels ($p < 0.001$, $p < 0.001$, $p < 0.05$ respectively). An increase in claudin and occludin levels was found in patients' baseline plasma samples compared to controls ($p < 0.01$). This increase in plasma claudin levels of patients decreased gradually on the 2nd day, 5th day and 10th day ($p < 0.01$). However, plasma occludin levels of patients increased on the 2nd and 5th days ($p < 0.01$) then decreased on the 10th day ($p < 0.01$). The plasma tricellulin levels of the patients increased on the 2nd and 5th days compared to baseline ($p < 0.01$ and $p < 0.05$, respectively), then decreased on the 10th day ($p < 0.05$). Length of ICU stay was 15 (min:5-max:39) days. ICU mortality was 13%.

Conclusion: As a result, it was determined that gut barrier functions were impaired in adult critical patients who were followed up in the ICU due to trauma. We can suggest that claudin and occludin protein levels can be used as markers in these patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000350

Introduction: Systolic arterial blood pressure (SBP) increases with age. We aimed at testing the combination of SBP and age on mortality after trauma.

Methods: This retrospective Real World Evidence (RWE) monocentric study included all adult patients from a French level-1 trauma center. A Generalized Additive Model (GAM) was created to predict 30 day-mortality based on age and SBP. The gray zone technique served to determine SBP thresholds. Subgroup analysis focused on Injury Severity Score (ISS).

Results: Among 2655 patients, 717 (27%) were older than 50 yo. Median ISS was 13 [6 - 25], average mortality was 11.5% [10.3%; 12.7%]. Older patients had higher ISS, higher mortality (22% vs. 7%, $p < 0.001$); more so when $ISS \geq 26$. Threshold effects on mortality appeared as $SBP \leq 90$ mmHg, but none specific to ISS subsets. Risk appeared as $SBP \geq 130$ mmHg, increased when combined with $ISS \geq 26$, reduced with $ISS \leq 15$. Computation led to no SBP threshold depending on age; in particular not 110 mmHg for 50 yo.

Conclusion: We confirmed the threshold of SBP below 90 mmHg, and effects above 130 mmHg with severe ISS. Older age and lower SBP combined increased mortality. Computation did not prove 110 mmHg should be used as a threshold for patients older than 50 yo.

Intensive Care Medicine Experimental 2020, **8(2)**: 000363

Introduction: Frailty can be defined as a multidimensional syndrome characterized by organic and functional impairments associated with a decrease in physiological reserves. Current evidence suggests that frailty is associated with unfavourable outcome among the geriatric population exposed to a stressor event. No information is available

about the impact of frailty on long term outcomes in the subpopulation of TBI patients.

Objectives: The aim of our study is to create a reliable index to describe frailty among patients admitted to ICU with a diagnosis of TBI and to assess its association with the 6 months neurological outcome expressed in terms of Extended Glasgow Outcome Scale (GOSE<5) and mortality at 6 months.

Methods: The study was conducted using the data extracted from the CENTER-TBI database v2.1 with Neurobot v2.6. Patients' information were collected at ICU admission and used to build a frailty index (FI) as a compound of accumulated deficits. Thirty-five variables assessing health status at baseline were used to develop the FI. These features included chronic medical conditions, previous TBI, laboratory findings, number and type of drugs, alcohol or toxic agents abuse. For any subject, the FI was calculated as the sum of the reported deficits divided by the totality of evaluated items, expressed in percentage; FI (%) is related to an incremental factor of ≥ 2 points.

A Logistic regression model was performed to estimate the contribution of the FI to explain the 6-month outcomes and it was adjusted for the IMPACT core variables (i.e. age, pupillary reactivity and GCS motor). The model was also performed on the group of elderly subjects (≥ 65 years old).

Results: 1754 participants were included in this study ($n = 425$ subjects ≥ 65 years old). The median age was 49 [IQR: 29; 65.75] and sex prevalence of males (72.6%). The median baseline value of the FI overall was 8.82 (I-III quartiles 3.44-14.71; range 0.00 to 54.54) and 14.82 (I-III quartiles 9.09- 23.33; range 0.00 to 42.8) considering the subset of elderly subjects.

Frailty significantly increased the risk of unfavourable GOSE at 6 months, with an odds ratio (OR) of 1.03 (95% CI 1.01-1.04, p -value < 0.001) and also the risk of mortality, with an OR of 1.004 (95% CI 1.002-1.006, p -value $= 0.001$). Considering only elderly subjects, there was no evidence that frailty increased the risk of unfavourable outcome (OR = 1.03, 95% CI = 0.99 - 1.08, p -value = 0.204) and mortality (OR = 1.001, 95% CI = 0.997-1.006, p -value = 0.541).

Conclusion: In this study we developed a FI for the specific application on TBI patients. This index was built from data collected from a large cohort of TBI patients characterized by a wide age spectrum. Our results indicated a significant increased risk of unfavourable neurologic outcomes in patients with high FI score, regardless of age and other IMPACT variables.

Introduction: Tranexamic Acid (TXA) is used for a number of indications, including trauma, based on evidence that it decreases bleeding and improves survival. Its role in acute traumatic brain injury (TBI) is less certain, although a recent large randomized controlled trial (RCT) suggested it may improve head-injury related deaths. We conducted a systematic review and meta-analysis, including this latest RCT, to investigate the efficacy and safety of TXA in acute TBI.

Methods: We performed a comprehensive search of MEDLINE, PubMed, EMBASE, CINHAL, ACPJC, Google Scholar, and unpublished sources from inception until June 24th, 2020 for randomized controlled trials (RCTs) examining the role of TXA in adults with acute TBI. We pooled data using the inverse variance method and random effect model and report summary estimates using relative risk (RR) for dichotomous outcomes and mean difference (MD) for continuous outcomes, both with corresponding 95% confidence intervals (CIs). For outcomes reported at multiple end-points, we used the longest duration of follow-up for analysis. We assessed individual study risk of bias using a modified Cochrane risk of bias tool and certainty of evidence using GRADE methodology.

Results: We included nine RCTs (n= 14,846 patients). Pooled results demonstrate that TXA has no effect on mortality (RR 0.95; 95% CI 0.88 to 1.02; absolute risk reduction [ARR] 1.0%; 95% CI 2.4% reduction to 0.4% increase, moderate certainty), no difference in disability as assessed by the Glasgow Outcome Scale (GOS) (MD, -0.16 points; 95% CI -0.57 to 0.25; moderate certainty) or disability based on proportion of patients with a GOS score ≥ 4 (RR 0.87; 95% CI, 0.57 to 1.32; 0.4% ARR; 95% CI 1.3% reduction to 1.0% increase; very low certainty) compared to those that did not receive TXA. TXA may reduce hematoma expansion on subsequent imaging (RR 0.78; 95% CI 0.59 to 1.04, ARR 3.2%, 95% CI 6.0% reduction to 0.6% increase); however, this was based on low certainty evidence, limited by imprecision. Risks of adverse events including pulmonary embolism, deep vein thrombosis, stroke, and seizure (all moderate certainty) were similar between those receiving and those not receiving TXA.

Conclusion: In patients with acute TBI, TXA probably has no effect on mortality or disability. TXA may decrease hematoma expansion on subsequent imaging; however, this outcome is of unclear benefit to patients. Use of TXA is probably not associated with an increased risk of adverse events.

Intensive Care Medicine Experimental 2020, **8(2)**: 000934

Introduction: CPR related injuries were not properly observed since were established new guidelines for resuscitation (CPR) 2015 with stronger recommendation for bystander and topless CPR. Data were not objectivised by any scale in effort to establish seriousness of injury.

Objectives: To determine impact of trauma associated with resuscitation, describe their frequency and seriousness and their influence on morbidity and mortality of patients after OHCA (Out of Hospitals Cardiac Arrest).

Methods: Analyse of data from prospective registry of OHCA from regional Cardiac Arrest Center (CAC). Trauma patients were identified with clinical suspicion and subsequently with imagine methods (CT, X ray, sonography), trauma as cause of arrest was no included. To determine seriousness we used Abbreviated injury scale (AIS) and summary of all injuries with New injury severity score (NISS).

Results: In study were included 231 patients after OHCA admitted to ICU. 30 (13%) had relevant CPR related trauma established with clinical suspicion and confirmed with imagine methods. In baseline characteristics was no difference in gender (76,7% of men in TRAUMA group vs. 78,1% in nonTRAUMA group, p=0,82), no difference in age (65±13 years in TRAUMA group vs. 62±13 years in nonTRAUMA group, p=0,38), no difference in initial shockable rythm (57% in TRAUMA group vs. 73,1% in nonTRAUMA group, p=0,08) and no difference in witnessed arrest (83% in TRAUMA group vs. 87% in nonTRAUMA group, p=0,58). There was no differences in duration of bystander CPR (9,3±4,4 min in TRAUMA group vs. median 10 min, IQR 25-75:5-10 in nonTRAUMA group, p=0,77), but total duration of CPR until ROSC was significant longer in TRAUMA group (median 25, IQR 25-75:14,5-30 min in TRAUMA group vs. median 18, IQR 25-75:10-25 min in nonTRAUMA group, p=0,03). There was no differences in ventilation days (mean 6±5 days in TRAUMA group vs. median 4, IQR 25-75:1-7 days in nonTRAUMA group, p=0,35) and ICU stay (median 6, IQR 25-75:1-15 days in TRAUMA group vs. median 7, IQR 25-75:3-12 days in nonTRAUMA group, p=0,84). Cardiac cause of arrest was significant higher in nonTRAUMA group (37% in TRAUMA group vs. 71% in nonTRAUMA group, p=0,0003) and also coronarography was provided more frequent in nonTRAUMA group (37% in TRAUMA group vs. 64% in nonTRAUMA group, p=0,005), but without difference in frequency of revascularisation (28% in TRAUMA group vs. 43% in nonTRAUMA group, p=0,11). 30 days mortality was significant worse in TRAUMA group (66% in TRAUMA group vs. 38% in nonTRAUMA group, p=0,005, RR 2,76, 95%CI 1,4-5,6) and 30 days good neurological outcome (CPC 1,2) also worse in TRAUMA group (vs. 56% in nonTRAUMA group, p=0,0014, RR 3,5, 95%CI 1,6-7,7). In TRAUMA group was lung contusion present by 16,7%, pneumothorax by 36,7%, liver injury by 13,3% and spleen injury by 6,7% of patients. Ribs fractures were presented by 60% and sternum fractures by 20% of patients. Mean of fracutred ribs was 9± 5,2 ribs. Median of AIS was 3 (IQR 25-75) 2-4. Median of NISS was 11,5 (IQR 25-75) 7-19,25.

Conclusion: Trauma is present by 13% of OHCA patients with ROSC. There is no difference in age, gender, initial shockable rythm and bystander CPR between TRAUMA and nonTRAUMA group, but resuscitation is significant longer in TRAUMA group. In TRAUMA group we have observed worse 30-days mortality and good neurological outcome.

Quality assessment for in-hospital management of massive hemorrhage

R. Munoz-Calahorro¹; JA. Barea-Mendoza¹; C. Mudarra-Reche¹;

C. García-Fuentes¹; M. Chico-Fernández¹

¹Medicina intensiva, University Hospital 12 de Octubre, Madrid, Spain

Correspondence: R. Munoz-Calahorro
Intensive Care Medicine Experimental 2020, **8(2)**: 001168

Introduction: Massive hemorrhage in trauma is a diagnostic and therapeutic challenge. An early approach to hemorrhagic shock by transfusion of blood products and damage-control resuscitation is essential to avoid lethal pentad and death.

Objectives: To assess the quality of care in traumatic massive bleeding in a Level 1 Trauma Centre by analyzing two indicators: early activation of the massive transfusion protocol (MTP) and optimal transfusion of packed red blood cells (pRBC).

Methods: A retrospective single-center cohort study was obtained from two prospective databases of University Hospital 12 de Octubre (Madrid): the Severe Traumatic Disease registry and the MTP database in a 6-year period of time (2013-2019).

Study subjects: Traumatic patients who were admitted in the ICU and required transfusion of ten or more pRBC in the first 24 hours of admission (defining criteria of massive hemorrhage, MH).

Variables of interest:

- Early diagnostic sensitivity (S): Percentage of activation of MTP in patients with traumatic MH. The Trauma-Associated-Severe-Haemorrhage (TASH) Score, the Injury-Severity-Score (ISS) and the percentage of FAST were retrospectively calculated in the false-negative (FN) subgroup.

- Optimal transfusion of pRBC: According to scientific literature, three cohorts were described according to hemoglobin (Hb) at 24 hours of admission. The percentage of under-transfusion (UT) (Hb <8mg / dl) and over-transfusion (OT) (Hb > 11.9mg / dl) was studied.

Data analysis: SPSS Statistics 24.0.0. Variable expression: mean and standard deviation.

Results: Descriptive statistics

First, a descriptive analysis of the MH cohort (n = 145) was performed. The mean age was 40.7 ± 17 years, with male predominance (76.6%). The mean ISS was 42.8 ± 16, highlighting a 72.4% prevalence of hemorrhagic shock coagulopathy and an overall mortality of 43.4%.

Deaths were due to exsanguination (38%, n = 24), intracranial hypertension (36.5%, n = 23), multiple organ dysfunction syndrome (12.7%, n = 8) and limitation of therapeutic effort (6.3%, n = 4).

Regarding the mechanisms involved, the most relevant were precipitation (n = 45), sharp objects injury (n = 23), automobile accident (n = 21), motorcycle accident (n = 17) and pedestrian injury (n = 16).

FAST was performed in 71.7% of the cases. Therapeutic arteriography was performed in 28.8% of the cases. 81.3% underwent damage control surgery.

Diagnostic sensitivity

MTP was activated in 135 out of the 145 patients with MH criteria (S = 93.1%).

In FN (n = 10), the mean TASH score was 12.4 ± 3 and the mean ISS was 31.7 ± 12.

30% (n = 3) presented a TASH score ≤ 9 (MH pre-test probability <5%), all presenting with bleeding during damage control surgery requiring intraoperative transfusion > 6 pRBC.

In the remaining cases (n = 7) the TASH score was > 13 (MH pre-test probability range 28-35%), with FAST being performed in 57% of cases (n = 4).

Transfusion quality

68.7% of patients were in the optimal transfusion cohort, while 8.9% were in the UT cohort and 22.5% in the OT cohort. Mortality was respectively 25.6%, 50% and 24%, without statistically significant differences in subgroup analysis (p = 0.243).

Conclusion: The diagnostic sensitivity was similar to that achieved by the MH prediction scores, considered the gold-standard. Nonetheless, FN analysis shows the need to optimize early identification.

The transfusion target was suboptimal in one third of patients. Specific transfusion protocols need to be created for severe traumatic disease with intermediate pre-test probability of MH.

Intensive Care Medicine Experimental 2020, **8**(2): 000143

Introduction: Trauma remains the leading cause of death all over the world. To better exploit the trauma care system, precise diagnosis of the injury site and prompt control of bleeding are essential. Here, we created a nursing protocol for initial medical care for trauma.

Objectives: The aim of this study was to evaluate the impact of protocolized nursing care for trauma on measures of quality performance.

Methods: This was a retrospective historical control study, consisted of consecutive severe trauma patients (Injury Severity Score >16). People were divided into two groups: protocolized group (from April 2017 to March 2019) and control group (from April 2014 to March 2017). We set the primary endpoint as mortality for bleeding. The secondary endpoints included time allotted from arrival to start of CT scan and surgery, administration rate of several drugs (sedations, painkillers, preoperative antibiotics, and tranexamic acid). For the statistical analysis, continuous variables were expressed as median (interquartile range) and were compared by Wilcoxon rank sum tests given a non-normal distribution of the data.

Results: We included 152 patients in the study: 84 in the control group before the introduction of the protocol, 68 in the protocolized group. As a primary endpoint, the mortality for bleeding was similar between two groups (5% in the control group and 5% in the protocolized group). As a secondary endpoint, the time to CT initiation [Group A 11 (7-16) min vs Group B 7 (5-10) min; p <0.001], and emergency procedure [Group A 41 (33-56) min vs group B 29(25-43); p <0.001] were shortened by the protocol introduction. Furthermore, the administration rates of sedations, painkillers, preoperative antibiotics, and tranexamic acid were increased in the protocolized group compared with the control group.

Conclusion: Although the mortality as a patient-oriented outcome was not affected, improved quality of medical care by nursing protocol introduction may be suggested in this analysis.

000097**Limitation of life-sustaining treatment (LLST) in ICU: 16 years of experience**

M. Iturbe Rementería¹; N. Ruiz Cañas¹; JA. Urturi Matos¹; S. Castaño Avila²; I. Saralegui Reta¹

Intensive Care Medicine Experimental 2020, **8**(2): 000097

Introduction: care at the end of life of patients who die; includes the shared decision-making between health professionals and family members, the communication and registration of agreements.

Objectives: to analyze the LLST procedure from 1-1-2004 to 12-31-2019 (16 years), the evolution of recommendations and improvement actions.

Methods: retrospective descriptive study

Results: During the analyzed period, 12422 patients were admitted to the ICU, 1329 of whom died (10.69% mortality). LLST has been agreed in 10% of the admitted patients and in 81'46% of the deceased (range 73-94%). The opinion of the nursing staff evaluated through a survey detected training needs and interest in participating in decision-making and information for family members. The few conflicts registered have been resolved by postponing the decision and encouraging the participation of other specialists involved. The procedure has improved with: a) the use of a specific sheet of medical orders on LLST b) its subsequent computerization to be recorded in the electronic medical record c) Terminal Extubation procedure d) continuing training on Bioethics and LLST of health personnel. The opinion of the patients' relatives who died after LLST is collected through semi-structured interviews (in the study phase). The LLST experience facilitated the launch of the Controlled Asystole Donation procedure. More than 100 training and outreach sessions have been held, not only for

healthcare personnel but also for patient associations. Care and treatment planning (Advance Directives) have been promoted to try to improve decision-making through specific programs for the chronically ill, interviewing more than 500 patients and family members.

Conclusion: LLST is a common procedure, with established, published and improved recommendations. It allows palliative care to be integrated into the field of intensive medicine.

End of Life Sedation with Intravenous Morphine and Midazolam: A Guideline for the Medical High Dependency Unit in Aberdeen Royal Infirmary

K. Hudson¹; S. Roberts¹; C. Kaye¹

¹Intensive Care Unit, Aberdeen Royal Infirmary, Aberdeen, United Kingdom

Correspondence: K. Hudson

Intensive Care Medicine Experimental 2020, **8(2)**: 000935

Introduction: Sedation with morphine and midazolam (M&M) is often used at the end of life (EoL) to relieve symptoms during the terminal phase of a patient's illness. While the medications used can control these symptoms, excessive doses hasten death. Therefore, doses should be titrated carefully, based on the patient's condition. In Medical High Dependency Unit (MHDU), a prescription for Intravenous (IV) infusion of M&M would be written for a patient approaching EoL and nursing staff would titrate dosing independently based on their clinical judgment. Only 33% of nursing staff always felt comfortable titrating the infusion rate and 67% wanted more guidance on dose titration. It was also felt that a patient's infusion rate could vary dependent on the nurse looking after them.

Objectives: The aim was to implement clear guidance for IV M&M infusions into MHDU by February 2020 and for it to be used in 90% of IV M&M infusions. This would;

- provide guidance for nursing staff to tailor the infusion rate to the individual
- protect nursing staff from any legal uncertainty.

Methods: Existing practice was reviewed by surveying nursing staff and collecting data from the last 10 patients who received an IV M&M infusion from May to July 2019. A guideline was created for MHDU using the Respiratory Distress Observation Scale(1) and the Critical Care Pain Observation Tool(2) to provide a validated scoring system to guide dose titration. Small group teaching with both nursing and medical staff was organised for education. Data was then collected for 10 subsequent patients from October 2019 to February 2020 and analysed. Qualitative data via anonymous feedback forms was collected from staff after implementation.

Results: All patients received IV M&M infusions according to the guideline (n=10). The average maximum dose infused was reduced

(morphine: pre-intervention 4.75mls/hr, post-intervention 2.40mls/hr; midazolam: pre-intervention 4.75mls/hr, post-intervention 3.20mls/hr). The average rate of infusion was reduced (morphine: pre-intervention 3.87mls/hr, post-intervention 2.28mls/hr; midazolam: pre-intervention 3.87mls/hr, post-intervention 2.33mls/hr). The average time between starting IV M&M and death was not significant (pre-intervention 3.09hrs, post-intervention 2.99hrs). Documented reasons behind dose adjustments increased from 6% to 81%. All staff felt more comfortable titrating M&M when using the guideline (n=10). In one case, the scoring system within the guideline led to a patient not receiving any IV M&M and subsequently surviving to discharge.

Conclusion: The guideline was widely appreciated by the nursing staff and therefore used in all patients who required IV M&M. Using the guideline showed a reduction in the dose of M&M administered, without affecting the time to death. The guideline gave more confidence behind titrating dose to patient symptoms and the results also gave reassurance that the doctrine of double effect was not being taken advantage of via administration of these drugs.

Intensive Care Medicine Experimental 2020, **8(2)**: 000249

Introduction: Normothermic regional perfusion (NRP) in controlled donation after circulatory death is becoming a popular method due to the favorable results of the grafts procured under this technique.

Objectives: To study the differences between livers suitable vs. livers discarded for transplantation obtained from controlled circulatory death donors (cDCD) managed with NRP.

Methods: Retrospective study (February 2017/December 2019). We studied all cDCD managed by the mobile NRP team of the Autonomous Community of Madrid (Spain) in which the liver was evaluated for transplantation. The following data were recovered: 1) cDCD demographics: age, sex, ICU length of stay and reason for limitation of life sustain therapies (LLST); 2) warm ischemia times (WIT) defined as the interval between systolic arterial pressure < 60 mmHg to commencement of NRP; 3) NRP duration and 4) biochemical parameters (Figure 1) at the start and end of NRP together with the differences between final - initial NRP values.

Results: During the period studied the mobile NRP team assisted in the management of 55 cDCD. Liver evaluation was performed in 32 (58.2%) cases. The liver was deemed suitable for transplantation in 19 (59.4%) and discarded 13 (40.6%). We found no differences between suitable vs. discarded livers regarding: age [60(48-64) vs. 63(55-65) years], sex [9(47.4%) vs. 5(38.5%) males], ICU length of stay [8(4-14) vs. 6(4-13.5) days] or main reason for LLST [catastrophic brain injury: 19(100%) vs. 11(84.6%)]. Suitable livers had lower WIT [11(7-15) vs. 15.5(12-19) min;p<0.03] and longer NRP times [90(73-110) vs. 63(31-89) min;p<0.02]. We found no differences in the biochemical parameters analyzed (Figure 1). The main reason for organ rejection was the existence of an unfavourable visual assessment (n=12; 92.3%). One liver was rejected after a renal carcinoma was found during the

laparotomy. None of the livers were discarded due to a transaminase elevation during NRP.

Conclusion: In our series we found no differences between suitable vs. discarded livers in cDCD managed with NRP. An unfavourable visual assessment was the main reason for organ rejection. In order to improve the ratio of suitable livers coming from cDCD and managed with NRP, it might be necessary to search for more objective strategies that might include a microscopical evaluation of the organ and/or newer biochemical markers.

Intensive Care Medicine Experimental 2020, **8(2)**: 000492

Introduction: Controlled donation after circulatory death (cDCD) occurs after a decision to withdraw life-sustaining treatment (WLST) and subsequent family approach and approval for donation. We currently lack data on factors that impact the decision-making process on WLST and whether time from admission to family approach, influences family consent rates. Such insights could be important in improving the clinical practice of potential cDCD donors.

Objectives: The main aim of our study was to assess timing and patient characteristics that are associated with the decision-making process leading to the initiation of end-of-life care, in a large multicenter prospective study of potential cDCD donors. A second objective was to explore the influence of this timing in family approach on consent to organ donation.

Methods: In a prospective multicenter observational study, we evaluated the impact of timing and of the clinical factors during the end-of-life decision-making process in potential cDCD donors. Characteristics and medication use, of 409 potential cDCD donors admitted to the intensive care units (ICU), were assessed.

Results: End-of-life decision-making was made after a mean time of 97 h after ICU admission and mostly during the day. Intracranial hemorrhage or ischemic stroke and a high APACHE IV score were associated with a short decision-making process. Preserved brainstem reflexes, high Glasgow Coma Scale scores or cerebral infections were associated with longer time to decision-making. Our data also suggest that the organ donation request could be made shortly after the decision to stop active treatment and consent rates were not influenced by day- or nighttime or by the duration of the ICU stay.

Conclusion: In summary, our data provide valuable insights on the largely overlooked topic of end-of-life decision-making in potential organ donors and show that early prognostication occurs in certain patient categories more often. Although prognostication is more difficult in the acute setting, our data show that if the treating team believes decision-making about WLST is possible early after hospital

admission, this will not necessarily have a negative effect on the consent rates to organ donation.

Organ Donation within an Intensive Care Unit in Portugal

C. Roriz¹; D. Castro¹; F. Sequeira¹; H. Fernando¹; O. Gomes¹; L. Pereira¹
¹Serviço de medicina intensiva, Centro Hospitalar de Leiria, Leiria, Portugal

Correspondence: C. Roriz
Intensive Care Medicine Experimental 2020, **8(2)**: 000867

Introduction: Organ and tissue transplantation is often the only treatment for end stage organ failure. In 2017, Portugal ranked second among 82 member states which reported to the global observatory on donation and transplantation with 34.1 donors per million inhabitants. The development of organ support systems in recent decades led to the ability to artificially maintain organ viability, leading to the concept of brain death. Brain death is the irreversible cessation of cerebral and brain stem function; characterized by the absence of electrical activity in the brain, blood flow to the brain, and brain function as determined by clinical assessment of responses. The brain death diagnosis and organ donor treatment are primordial given the importance of achieving a better quality of organs available for transplant. Organ donor treatment represents a crucial part of the donation process being the ultimate goal to obtain as many viable organs as possible by donor.

Objectives: The purpose of this study is to characterize potential organ donors admitted to a 10-bed combined medical-surgical intensive care unit of a Portuguese hospital, identify reasons for non-donation, length of stay in the intensive care unit and to determine the number and type of donated organs.

Methods: A retrospective cohort study of all the potential organ donor admissions in a 10-bed combined medical-surgical intensive care unit of a Portuguese hospital between January 2018 and May 2020 and characterize demographic and clinical variables as well as the number of harvest organs.

Results: In the period of 2 years and 5 months 26 potential organ donors of whom 15 were effective donors, were identified and admitted to the intensive care unit, representing 3.7% of all intensive care unit admissions. Among potential donors the mean age was 60.6 and the majority were men (61.5%). With respect to the effective donors, the mean age was 59.5 and 73.3% were men. Hemorrhagic stroke accounted for 73% of brain deaths, anoxia and ischemic stroke were the cause of brain death in 26% of the patients (13.5% each type of lesion). Among the non-effective donors, the reasons for non-donation were refusal by the national coordination transplantation related with patient comorbidities in 4 patients, non-evolution to brain death in 2 patients and evidence of sepsis in 5 patients. The most common comorbidity of the potential donors was arterial hypertension (69.2%). The mean time from ICU admission to the diagnosis of brain was 56 hours, and the mean time from ICU admission to organ harvesting was 66 hours. The most frequently collected organs were the kidneys (93.3%) followed by the liver (66.7%) and the most common collected tissue was cornea in 53.3% of the patients.

Conclusion: At the time of the study, potential organ donors were mostly men, over fifty years old, had arterial hypertension as comorbidity and died of brain death follow hemorrhagic stroke. The kidneys and liver were harvested in most cases.

000253**A machine learning based model development for hypotension event predictor in ICU patients**B. Lee¹¹VHS medical center, Seoul, Republic of Korea**Correspondence:** B. Lee*Intensive Care Medicine Experimental* 2020, **8(2)**: 000253

Introduction: In the ICU, hypotension is one of the most critical event to reduce patient mortality. If we can predict the hypotension early, patient can take safer medical care. We developed the machine learning model for hypotension predictor (systolic blood pressure <60) (5 hours later) from the ICU data of 1968 patients between January and December 2018 in veterans' health service medical center at South Korea. In the ICU, hypotension is one of the most critical event to reduce patient mortality. If we can predict the hypotension early, patient can take safer medical care. We developed the machine learning model for hypotension predictor (systolic blood pressure <60) (5 hours later) from the ICU data of 1968 patients between January and December 2018 in veterans' health service medical center at South Korea.

Objectives: To develop the novel technique to predict short term hypotension event predictor in ICU with machine learning analysis

Methods: A total of 1968 patient stayed in ICU of veterans' health service medical center between January and December 2018 were enrolled and their electrical medical data including hourly recorded vital signs, clinical manifestations, demographic features were collected for analysis. Keras (version 1.2.0, backend engine: tensorflow 1.0) was used to generate multi perceptron neural networking model for modelling.

Results: Multi perceptron neuronal model with Keras was successfully generated from patient's data. The prediction rate of the model was 97.4% and no overfitting was observed during model generation. The AUC value from ROC curve was 0.996 for the generated model. To compile multi perceptron learning model, adam optimizer was used

Conclusion: Multi perceptron learning algorithm could be very useful to develop new hypotension prediction model. Further study is necessary to evaluate the validity of new short-term hypotension prediction model.

000291**Predicting fluid balance change in septic patients during deresuscitation**R. Ahlendorf¹; A. Rahman¹; Y. Chang¹; A. Peine²; E. Ghosh¹; L. Martin²¹Connected care and personal health, Philips Research North America, Cambridge, United States of America; ²Klinik für operative intensivmedizin und intermediate care, University Hospital RWTH Aachen, Aachen, Germany**Correspondence:** E. Ghosh*Intensive Care Medicine Experimental* 2020, **8(2)**: 000291

Introduction: Fluid overload resulting from suboptimal fluid management is common in critically ill patients and associated with adverse outcomes. Appropriate fluid management strategies to relieve fluid overload following the initial resuscitation period (the "deresuscitation phase") are largely variable in clinical practice - potentially as a result of the heterogeneity in disease progression and numerous other factors, such as age and pre-morbidities. There is a need to better understand patients' progression in the deresuscitation phase and to accurately predict strategies in fluid balance management with the goal of guiding fluid therapy to achieve optimal fluid balance.

Objectives: We extracted fluid balance and physiological factors in the deresuscitation phase from a large cohort of patients with sepsis in

a retrospective electronic health records database and built a machine learning model to predict fluid balance change periodically after patients had been stabilized.

Methods: We used MIMIC-III, a publicly available critical care dataset from Beth Israel Deaconess Medical Center, Boston, MA. Our cohort consisted of adult ICU patients with sepsis (based on the Sepsis-III criteria) who received vasopressors and/or inotropes during resuscitation. We excluded patients with Do Not Resuscitate status, cardiac surgery and burn patients. End of resuscitation phase was defined as the time of last vasopressor/ inotrope administration. Clinical data including, demographics, vitals, labs, fluid inputs and outputs, interventions and medications were extracted for the time period starting from end of resuscitation to ICU discharge. Data was segmented into 4-hour blocks. Fluid balance was calculated for each block and the change (increase, no change or decrease) within a block evaluated. We trained a 3-class logistic regression model to predict the change of fluid balance in the next block using the extracted clinical data in the current block. Model was evaluated using 6-fold cross validation and top predictors were calculated.

Results: A total of 2,565 ICU admissions were included in our cohort which was divided into 62,465 4-hour blocks. The mean area under receiver operator curve (AUROC) for predicting fluid balance increase was 0.78, mean AUROC for predicting no change in fluid balance was 0.71 and mean AUROC for predicting fluid balance decrease was 0.77.

Conclusion: We trained a model to predict fluid balance change during deresuscitation in our cohort. The model performs reasonably well in distinguish patients with no change in fluid balance, a decrease, and an increase in fluid balance. Additionally, we identified top predictors for fluid balance change, which agree with known physiology. The top positive correlates for fluid balance decrease are being on CRRT and cumulative output. Conversely, being on CRRT is a negatively correlated with fluid balance increase. Therefore our model uses clinically meaningful features to distinguish between the different classes.

Introduction: PaO₂ to FiO₂ ratio (P/F) is used to assess the degree of hypoxemia adjusted for oxygen requirements. The Berlin definition of Acute Respiratory Distress Syndrome (ARDS) includes P/F as a diagnostic criterion. P/F is invasive and cost-prohibitive for resource-limited settings. Pulse Oximetric Saturation (SpO₂) is noninvasive, continuous, and pervasive. Previous work suggests that SpO₂ to FiO₂ ratio (S/F) correlates with P/F and can be used as a surrogate in ARDS (1). It is unclear whether S/F can be used to identify intensive care (ICU) patients that are at high risk (2). We hypothesize that S/F is non-inferior to P/F as a predictive feature in the critically ill.

Objectives: To demonstrate the non-inferiority of S/F to P/F in the prediction of ICU mortality.

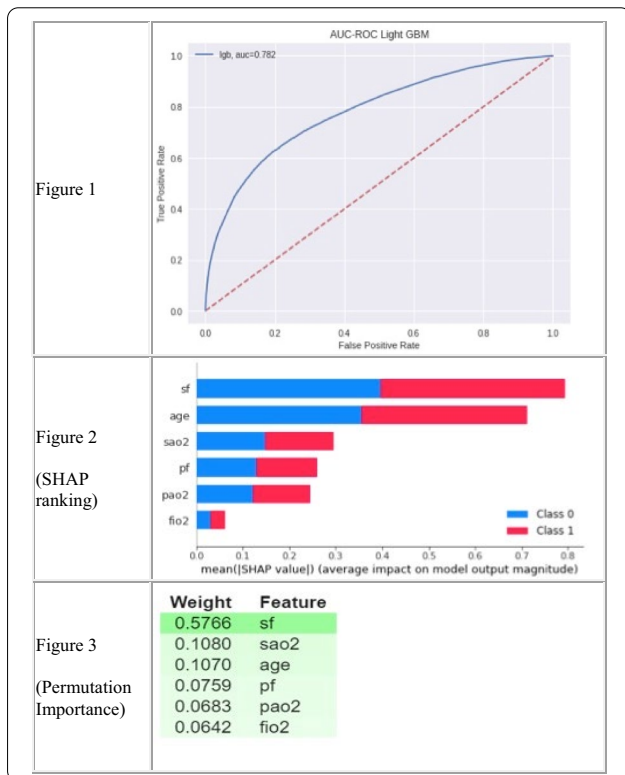

Methods: We extracted data from the eICU Collaborative Research Database. The dataset included seven variables (6 independent and 1 dependent) and 141,535 values (Table 1). Mortality was the dependent variable for our prediction models. Exploratory data analysis was performed in Python. Missing data was imputed with Sklearn Iterative Imputer. We split the six independent variables into a train and test set with an 80/20 distribution. We scaled the data using the Sklearn Min_Max Scaler. The mortality outcome (death) was rare (136,451 alive versus 8,184 died). We used a Gradient boosting decision tree algorithm variant called LightGBM as our model. We used AUC as our metric for model performance. Feature importance assessed using ELI5 and SHAP Python libraries. SHAP values reflect the contribution of the feature in the reduction of prediction error (3). ELI5 uses the permutation

of feature values and calculates the change in error. Feature value permutation leads to a large rise in prediction error.

Results: LightGBM demonstrates good classification performance with a AUC of 0.782 (Figure 1). S/F had the strongest average contribution to predicting mortality based upon the mean calculated SHAP value (Figure 2). S/F value permutation had the largest increase in prediction error, thus it ranks as the strongest feature (Figure 3).

Table 1

	count	mean	std	min	max
Age	141535.0	62.23	16.46	18.0	89.00
PaO2	141535.0	108.73	43.26	9.0	636.00
FIO2	141535.0	52.22	13.43	21.0	100.00
SaO2	141535.0	93.05	8.00	0.0	100.00
P/F	141535.0	225.69	61.15	17.0	1992.00
S/F	141535.0	183.68	43.78	0.0	476.19

	Weight	Feature
Figure 3 (Permutation Importance)	0.5766	sf
	0.1080	sao2
	0.1070	age
	0.0759	pf
	0.0683	pao2
	0.0642	fio2

Conclusion: S/F was a stronger predictor of mortality as compared to P/F based upon feature importance evaluation of our data. Our study is hypothesis-generating and a prospective evaluation is warranted.

Intensive Care Medicine Experimental 2020, **8(2)**: 000372

Introduction: SARS COV 2 pandemic infection has led to an increase in hospital admissions and in particular in Intensive Care Units (ICU) in last months.

Objectives: To report epidemiological characteristics and medical history of patients admitted in ICU with SARS COV 2 infection, and to describe clinical features and outcome of these patients.

Methods: Retrospective, single-center case series of consecutive critically ill patients admitted in ICU of a community hospital with severe pneumonia caused by SARS COV 2. Origin prior admission in ICU, APACHE II and SOFA at admission, medical history, age, gender, invasive mechanical ventilation requirement, time of mechanical ventilation, ICU length of stay, radiological pattern, procalcitonin and C-reactive protein levels, and mortality were collected. Statistical analysis: Data were analyzed by SPSS 18 and quantitative variables were expressed as a mean ± standard deviation.

Results: A total of twenty patients were admitted within a month in ICU with 17 beds; a capacity that had to be increased. At present three patients are currently still admitted to ICU. Mortality was 30%. 15% were admitted from the Emergency room, 15% from other hospital-sand 70% from a medical ward. 80% required mechanical ventilation and most of these patients were ventilated in prone position at admission, 93,75%. Haemofiltration was indicated in 20% and was related with higher mortality. Hypertension was the most common pre-existing medical condition, 50 % in deceased patients and 28,6% in survivors.

Table shows clinical characteristics based on mortality.

SARS COV 2 Respiratory Infection	Survival n:14	Exitus n:6
Age (years)	60±8,4	65,67±6,86
Gender (male/female)	64,3/35,7	66,6%/33,3%
Body mass index	28,14±4,71	31,64±5,53
Time from onset symptoms to ICU admission (days)	9,64±4,74	12±5,6
APACHE II at admission	10±4,85	11±2,36
SOFA at admission	3,21±2,11	4±1,09
ICU length of stay (days)	13,7±10,78	20,17±10,3
Creatinine/Urea at ICU admission (mg/dl)	0,84±0,28/44±44	1,25±0,24/86,3±50,02
PCR (mg/l)/PCT (ng/ml)	154,64±190,02/0,47±0,64	183,2±157/0,45±0,34
Fibrinogen mg/dl	641±280,9	685
D Dimer ng/ml	4397,36±8870	1068±596

CONCLUSION. Obesity and hypertension were risk factors associated with severe cases of SARS COV 2 infection.

Renal failure, and the need for haemofiltration and mechanical ventilation were associated with anincreased mortality.

Conclusion: Obesity and hypertension were risk factors associated with severe cases of SARS COV 2 infection. Renal failure, and the need for haemofiltration and mechanical ventilation were associated with anincreased mortality.

Intensive Care Medicine Experimental 2020, **8(2)**: 000574

Introduction: Several randomized clinical trials have suggested that different patient populations, such as medical or surgical critically ill patients, may benefit from different glucose targets [1,2]. While normoglycemia is often preferred in neuro-critically ill patients, the effects of hyper- and hypoglycemia on these patients is less clearly defined and optimal glycemic targets remain uncertain.

Objectives: We hypothesized that glycemic fluctuations may be associated with higher mortality amongst all neurocritically-ill patients, and set out to answer this question using an observational ICU dataset.

Methods: This analysis utilized the eICU Collaborative Research Database (eICU-CRD) [3]. For the 13448 adult patients diagnosed with primary central neurological disease, the following features were extracted: blood glucose measurements (finger-stick glucometer and serum values), age, diabetes status, and Acute Physiology And Chronic Health Evaluation (APACHE) IV score. Logistic regression (LR) was estimated to predict mortality during the first 24 hours of admission.

Results: When comparing characteristics for patients who survived versus those who expired (1,302,9.7%), survivors were younger (61.5y vs 65.8y; $p < 0.001$), were more likely to have a surgical admission (14.4% vs 9.2%; $p < 0.001$), and have lower APACHE IV scores (48.7 vs 80.0; $p < 0.001$). Additionally, survivors had lower mean glucose values (134.3 mg/dL vs 155.2 mg/dL; $p < 0.001$) and a lower glucose variability (-1.8 vs -4.0; $p = 0.001$).

Table 1. Logistic regression results

Covariate	Adjusted Odds Ratio (AOR)	95% Confidence Interval for AOR	p-values
APACHE score (per point increase)	9.14	8.62 - 9.70	< 0.001
Diabetes	0.64	0.61 - 0.67	< 0.001
Mean glucose (per mg/dL increase)	2.48	2.35 - 2.62	< 0.001
Mean Δ glucose (per mg/dL increase)	0.82	0.79 - 0.86	< 0.001

The LR model achieved AUROC of 0.84 in predicting mortality by day 1 of ICU admission (Table 1). Predictor variables include diabetes status, APACHE IV score, mean glucose levels and change in glucose levels within the first 24 hours of admission.

Conclusion: Older age, higher APACHE IV score, lack of diabetes, higher mean glucose levels and greater decrease in glucose levels were associated with higher mortality within 24 hours of ICU admission in neurocritically-ill patients.

Comparison of errors of death certificate related to poisoning between issued in emergency department and beyond emergency department

C. H. Park¹

¹University of Ulsan college of Medicine, Ulsan University Hospital, Ulsan, France

Correspondence: C.H. Park

Intensive Care Medicine Experimental 2020, **8(2)**: 000704

Introduction: We were to investigate the errors of death certificate (DC) issued after death associated with poisoning and compare the errors of DCs depending on the place of issue between the emergency department (ED) and beyond ED

Methods: We reviewed the DC related to poisoning issued in one training hospital for 9 years. The errors of DCs were categorized into major and minor errors depending on the influence for process of choosing the cause of death.

Results: Seventy-nine DCs related to poisoning were reviewed. Forty-three DCs were issued in emergency department (ED) and thirty-six in beyond ED. Total number of errors of the DCs were 3.7 with 0.4 for major errors and 3.3 for minor errors. The errors of DCs issued at the ED are less than beyond ED (3.3 vs 4.4). Incorrect manner of death, unacceptable cause of death and mode of dying as an underlying cause of death were common major errors. Incorrect time interval from date of onset to death, incorrect other significant conditions and no record for date of onset were common minor errors.

Conclusion: The total number of errors was less in DCs issued in ED than beyond ED. The most common major error and minor error of DCs related to poisoning were incorrect manner of death and incorrect time interval from date of onset to death.

Intensive Care Medicine Experimental 2020, **8(2)**: 000709

Introduction: One of the challenges of the COVID-19 pandemic is the lack of experience with the disease and its clinical courses in intensive care patients. Based on first data, specific models have been developed to predict lethal courses in COVID-19 intensive care patients (1). However, it is yet unclear whether lethal courses of COVID-19 patients actually differ from lethal courses in patients with other viral pneumonia.

Objectives: The objective of this project was to analyze whether a machine learning system trained on data of intensive care patients with non-COVID-19 viral pneumonia is also able to predict lethal courses in intensive care patients with COVID-19.

Methods: After approval by the local ethics committee, we trained a machine learning system to predict lethal courses in intensive care patients with non-COVID-19 viral pneumonia. To focus on predictions early enough to allow for adjusting treatment, we based the model on clinical data that was available at the time window of 96h-120h before the death of patients in contrast to patients without a lethal course at time windows matched in regard to duration since ICU admission. Therefore, we analyzed all data available in the electronic databases of Charité – Universitätsmedizin Berlin for 463 intensive care patients (including 193 lethal courses) with non-COVID-19 viral pneumonia. From these data, we extracted 163 clinical parameters of which we selected 10 parameters, based on clinical expertise supported by univariate analyses and bivariate covariance matrices. Using the data of the 10 selected parameters, we trained a gradient-boosted decision tree models by supervised learning using the open source software library XGBoost. Then we applied the resulting prediction model to predict lethal courses in 94 COVID-19 intensive care patients (including 34 lethal courses) and compared the predictive performance of our model with that of established clinical scores.

Results: The ROC-AUC to predict lethal courses in COVID-19 patients based on our model trained on non-COVID-19 patients was 0.86 [95%-CI: 0.78-0.94] and thus outperforms the established clinical scores SOFA (0.80 [95%-CI: 0.71-0.89]), SAPS2 (0.73 [95%-CI: 0.62-0.84]) and APACHE2 (0.61 [95%-CI: 0.49-0.73]).

Conclusion: Our machine learning system trained on data of intensive care patients with non-COVID-19 viral pneumonia shows a good performance for the prediction of lethal courses in COVID-19 intensive care patients. This suggests that despite all extraordinary features of COVID-19 intensive care patients the clinical parameters that indicate lethal courses widely match those of patients with other viral pneumonia.

Intensive Care Medicine Experimental 2020, **8(2)**: 001223

Introduction: Main feature of the COVID-19 outbreak is an acute respiratory failure linked with diffuse alveolar damages. There are reports of increased rates of acute kidney injury (AKI) ranging widely from 5% to 36% of hospitalized patients and rised up to 52.2% in ventilated ICU patients. Mechanism, risk factors and outcome of AKI related to COVID-19 are not fully understood.

Methods: We conducted a observational study to assess risk factors of AKI in patients admitted in ICU for COVID-19. All patients adults admitted in our ICU with COVID-19 confirmed by positive SARS-CoV2 RT-PCR or COVID-19 serology between 01/03/2020 and 30/04/2020 were included. We collected all clinical and biological data within the 14 first days following admission in ICU. Primary outcome was severe AKI was defined by stage ≥ 2 according the KDIGO definition. Statistical analysis was carried out by using a multivariate time-dependent Cox cause-specific proportional hazard model. Missing values of covariates in the multivariable model were handled by multiple imputations with chained equations. All tests were two-sided, with *P* values of 0.05 or less denoting statistical significance.

Results: Forty-nine patients were included in the study population and represented of 442 daily measurement points. Median age of patients was 70 [58-74] including 40 (81.6%) men and 9 (18.4%) women. Invasive mechanical ventilation were realized in 43 (87.8%) patients and vasopressors used in 37 (75.5%) patients. AKI occurred in 19 (38.8%) patients in a median time of 6 [3-8] days following ICU admission. Time-dependant Cox cause specific model showed that hemodynamic SOFA score (CSH = 1.52 [1.06-2.16], *p* = 0.02), arterial pCO₂ (1.27 [1.06-1.53] per increase of 5 cm d'H₂O) and arterial base excess (0.88 [0.78-0.97] per increase of 1 mmol/L) was associated with AKI. A statistical trend was observed with expiratory positive pressure (1.15 [0.99-1.34] per increase of 1 cm d'H₂O, *p* = 0.05).

Conclusion: Our findings show that severe AKI in a common complication observed in ICU patients admitted for COVID-19. Respiratory status with EPP levels, hypercapnia, metabolic acidemia and hemodynamic deficiency are associated with higher risk of AKI in COVID-19 patients. Impact of mechanical ventilation, with EPP levels, and severity of patient's respiratory state, highlighted by respiratory acidosis, are novel risk factors of AKI in ICU patients. Further studies are needed to confirm those findings and understand underlying mechanism of this pulmonary-kidney interaction.

001281

Acute kidney injury in critically ill COVID-19 patients: incidence and outcome

W. Zarrougui¹; N. Bejaoui¹; M. Alibenali¹; N. Elbeki¹; F. Lambiotte¹

¹Intensive care unit, Hospital Jean Bernard, Valenciennes, France

Correspondence: W. Zarrougui

Intensive Care Medicine Experimental 2020, **8(2)**: 001281

Introduction: In December 2019, coronavirus disease 2019 (COVID-19) emerged in Whuan, China and had rapidly spreading worldwide, to become the most global health issue nowadays. Kidneys are one of the extra pulmonary organs frequently affected by this infection. Acute kidney injury (AKI) is a well-recognized risk factor which increased the mortality rate in critically ill patients with sepsis.

Objectives: The aim of this study was to determine the frequency and risk factors of AKI in COVID-19 critically ill patients as well as to establish clinical and prognosis profile.

Methods: We retrospectively reviewed the charts of consecutive critically ill patients with confirmed COVID-19 infection between Mars 11 and Mai 15, 2020 in Valenciennes regional hospital. The study collected clinical features at admission, severity of illness, ICU course, the occurrence and management of AKI. The diagnosis of AKI was based on kidney disease improving global outcomes (KDIGO) classification. Univariate and multivariate regression analyses were performed to identify factors independently associated with AKI, and to determine the risk of mortality secondary to AKI

Results: A total of 77 confirmed COVID-19 patients were admitted to the ICU during the study period. Among them 37(48.05%) presented an acute renal failure. Their main characteristics were: mean age, 64.67±11.02; male, 29(78.4%); mean BMI, 31.97±6.7 kg/m²; mean Charlson index, 3.03±1.99; 4 (10.8%) patients with medical history of chronic kidney disease; mean SAPSII score, 39.78± 11.28; mean SOFA score, 5.56± 2.93; invasive mechanical ventilation, 32(86.5%); vaso-pressors, 33(89.2%); hydrocortisone, 14(37.8%). Renal replacement therapy (RRT) was required in 24(64.9%) patients and the most used modality was an intermittent hemodialysis in 10 patients (41.7%). Continuous veno-venous hemodialysis was used in 3(12.5%) patients and 9(37.5%) patients had received both modalities of hemodialysis. Mortality rate was 21(56.8%) and the mean length of ICU stay was 19.46±17.72 days. For ICU survivors, only 4 patients had their ad intergrum renal function restored and no patient need dialysis after hospital discharge.

Univariate then multivariate regression analysis identified the AKI as an independent risk factor for mortality in COVID-19 patients (OR, 17.74; 95%CI[4.22-74.52], p 0.000), and yielded the following variables as independently associated to AKI: age > 65 years (OR, 3.77; 95% CI[1.19-11.91], p 0.024), septic shock (OR, 5.54; 95% CI[1.49-20.5], p 0.01) and the use of muscles blocker agents (OR, 4.26; 95% CI[1.34-13.5], p 0.014).

Conclusion: The present study among COVID-19 critically ill patients identified acute kidney injury as independent factor associated with mortality and showed that the incidence of acute renal failure, increasing in patients aged more than 65 years, presented septic shock and had received muscle blocker agents during their ICU stay.

Correspondence: P. García Olivares

Intensive Care Medicine Experimental 2020, **8(2)**: 001342

Introduction: The cause of acute renal failure is often multifactorial with pre-existing co-morbidities further increasing the risk.

Objectives: To analyze the risk factors related to acute renal failure (ARF) in critically ill patient.

Methods: Prospective, observational study performed on patients admitted to ICU of HGU Gregorio Marañón between November-December 2019. Epidemiological data, ARF risk factors, patient clinical characteristics and renal function data, were collected. ARF was defined according to AKIN, RIFLE and KDIGO scores.

Descriptive data were reported as means with standard deviation (SD) for normally distributed continuous variables, medians with interquartile range (IQR) for non-normally distributed variables, and as percentages for categorical data. Univariate analysis was performed by means of Chi-square (RR) for the qualitative variables, and simple logistic regression (OR) for the quantitative variables. The risk factors related to acute renal failure were obtained by means of a multiple logistic regression analysis.

Results: Ninety-five patients included. 56% were male, mean age was 60±17 years and Charlson comorbidity index 2 points (1-4).

The main risk factors for ARF were hypertension 45%, dyslipidaemia 41%, peripheral vascular disease 34%, chronic heart failure 18%, diabetes mellitus 16% and arrhythmias 13%. **Reasons for admission:** neurological 30%, respiratory 26% and 20% infectious pathology. **Severity scores:** APACHE II 19±8, SOFA 7±4, the 52% of patients needed mechanical ventilation and 51% vasoactive therapy. 34% of patients developed ARF during admission, according to the following scales: 14% stage I/risk, 8% stage II/damage, 12% stage III/failure. 33% of patients with ARF required renal replacement therapy. The In-hospital mortality was 29%, with an average of 11 days of hospital stay (6-29).

In the **univariate analysis**, the variables related to ARF were: **age** (OR 1.05; 95% CI 1.01-1.08), **diabetes** (RR 5.27; 95% CI 1.62-17.17), **chronic heart failure** (RR 3.64; 95% CI 1.23-10.76), **arrhythmias** (RR 4.92; 95% CI 1.35-17.87), **infectious pathology** (RR 4.80; 95% CI 1.66-13.89), **APACHE II** (OR 1.21; 95% CI 1.12-1.32), **SOFA** (OR 1.58; 95% CI 1.29-1.94) and **vasoactive therapy** (RR 3.98; 95% CI 1.54-10.29).

In the **multivariate analysis**, on a maximum model including the previously described, **diabetes (OR 14.90; 95% CI 2.95-75.28)** and **SOFA (OR 1.45; 95% CI 1.13-1.86)** were the only variables independently associated with acute renal failure.

Conclusion: There is a high incidence of acute renal failure in critically ill patients. The only factors independently associated with the development of acute renal failure were diabetes and SOFA.

NephroCheck test to help assess the risk of acute kidney injury in trauma patients

S. De Rosa¹; M. Greco²; G. Golino¹; A. Rigobello¹; G. Pierbellini¹; P. Navalesi³; C. Ronco⁴; V. Danzi¹

¹Department of anesthesia and intensive care unit, San Bortolo Hospital Of Vicenza, Vicenza, Italy; ²Anesthesia and intensive care, Humanitas Research Hospital, Milano, Italy; ³Department of anesthesia and intensive care unit, University of Padua, Padova, Italy; ⁴Department of nephrology, dialysis, and transplantation, San Bortolo Hospital Of Vicenza, Vicenza, Italy

Correspondence: S. De Rosa

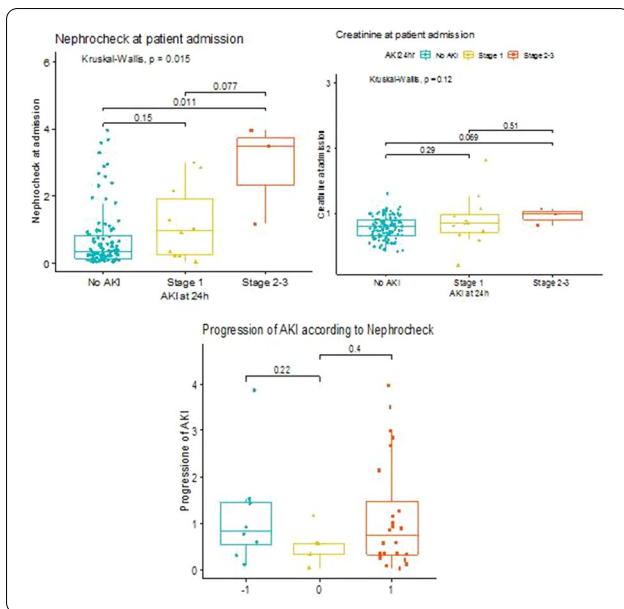

Intensive Care Medicine Experimental 2020, **8(2)**: 001373

Introduction: Acute kidney injury is frequently observed in trauma patients. A rise in serum creatinine and a fall in urine output are consequences of much earlier injury to the most sensitive part of tubular cells located at the proximal tubule. The G1 cell cycle inhibitors tissue inhibitor metalloproteinase-2 (TIMP-2) and insulin-like growth factor-binding protein 7 (IGFBP7) have been identified as novel biomarkers for the prediction of moderate to severe acute kidney injury (AKI) risk.

Objectives: The aim of the present study was to investigate the course of two cell-cycle arrest urinary biomarkers compared to serum creatinine in trauma patients.

Methods: A bedside test known as NephroCheck measures two urinary parameters: IGFBP7 and TIMP-2. The test is based on a sandwich immunoassay technique. The final test output, labeled AKIRisk, is shown as a numeric result. We conducted a cohort study, measuring [TIMP2]·[IGFBP7] levels in trauma patients admitted to the ICU and classified the patients as NephroCheck (NC) (+) or NC (-) according to [TIMP-2]·[IGFBP7] values and AKI (+) or AKI (-) according to Kidney Disease: Improving Global Outcomes (KDIGO) criteria

Results: 45 patients developed AKI (29.4%). 29 patients (19.9%) developed stage 1 AKI, 16 patients (10.5%) stage 2-3 AKI. RRT was used in 5 patients. In patients with no AKI at admission, AKI at 24h was associated with higher nephrocheck values at admission (median AKIRisk 3.49 (2.33-3.73) in stage 2-3 AKI vs 0.35 (0.14-0.82) in no AKI, p=0.011) but not with creatinine values at admission (0.99 mg/dl (0.9-1.03) in stage 2-3 AKI vs 0.79 mg/dl (0.66-0.99)). There was no difference in nephrocheck values at admission or creatinine values at admission in patients with AKI was present at ICU admission. In patients with AKI, there was no association between Nephrocheck and progression or regression of AKI (p 0.4 for progression and p=0.2 for regression of AKI). We defined 4 groups according to levels of biological and functional markers

Conclusion: Markers of acute tubular stress/damage such as TIMP-2 and IGFBP7 (cell cycle arrest biomarkers identified as NC are useful in the risk assessment for AKI with high ability to identify patients likely to develop stage 2/3 AKI within 24 hrs. NC may help to identify patients with tubular damage in trauma patients that may or may not evolve into a clinically manifest syndrome

Intensive Care Medicine Experimental 2020, **8(2)**: 001405

Introduction: Diffuse alveolar damage and acute respiratory failure are the main features of COVID-19 patients admitted to the ICU, although it may also cause damage to other organs such as the kidneys. Many of these patients with SARS-CoV2 infection develop acute renal failure, and their prognostic results are worse than in those who do not develop it. More attention should be paid to comorbidities in these patients, that can be related to the infection course.

Objectives: - To analyze renal support therapies and the need of other support devices used in patients admitted to the ICU with the diagnosis of SARS-CoV-2 infection who develop renal dysfunction.

- To study the association of this organic failure with morbidity and mortality.

Methods: This retrospective observational study was conducted in the medico-surgical Intensive Care Unit of Jerez de la Frontera Hospital. All the patients admitted to the ICU, with the diagnosis of SARS-CoV-2 infection, during the study period (March-June 2020) were included. Personal history, demographic, analytical and clinical variables, as well as severity and mortality scores were collected. *Statistical analyses were performed using SPSSv22 software.*

Results: Eleven patients, predominantly male (72.7%), with a mean age of 63.55 ± 7.53 SD, were included. With regard to the severity scales, mean SOFA value at admission was 4.27 points ± 2 SD and APACHE II 11.45 points ± 4.2 SD, with SOFA mean value on the day of the diagnosis of ARF of 9.1 points ± 3.2 DS. When analyzing CVRF, it should be noted that these patients had a high BMI with mean values of 31.93 ± 4.68 SD cm / m². These patients required IMV and prone position in 100% of the cases, requiring 81.8% to perform a tracheostomy and 90.9% hemodynamic support with norepinephrine. 63.7% (7) required CRRT, being CVH the predominant modality of choice (100%). With regard to the indications of renal support, the most frequent was oligoanuria 57.1% (4) followed by metabolic or ionic alterations in 28.6% (2) and refractory shock 14.3% (1). The most frequently venous access used was the right femoral one (42.9%) compared to the right jugular venous access used in 28.6% of cases (2). Heparin sodium was the anticoagulant of choice in 100% of the patients who required CRRT. When analyzing the scales of renal damage, we found that the day the ARF was diagnosed they presented: AKIN I 45.5%, II 18.2%, III 36.4%; RIFLE R 45.5%, I 9%, F 45.5%. Mortality was very high, reaching 63.7% (7) ($p < 0.05$) and in those who required CRRT was 100% ($p < 0.05$), despite of improving renal function according to creatinine criteria in 71.4% (5).

Conclusion: - In our series of cases, renal failure and the use of CRRT were independently associated with worst prognostic results.

- Those who developed ARF had a significantly higher BMI and required more organic support than those who did not develop it.

001415

Incidence of renal failure in patients with SARS_CoV 2 infection admitted to the ICU

JM. Martín Cano¹; M. Pérez Ruiz¹; B. Diez Del Corral¹; J. Villegas¹

¹University hospital of Jerez, Intensive care unit, Jerez, Spain

Correspondence: B. Diez Del Corral

Intensive Care Medicine Experimental 2020, **8(2)**: 001415

Introduction: COVID-19 disease is mainly characterized by acute respiratory failure and diffuse alveolar damage, but it may also cause damage to other organs such as the kidneys. Many of these patients develop acute renal failure, and may have a worse prognosis.

Objectives: - To look-over the incidence of kidney failure in COVID-19 patients admitted to the ICU of a second-level hospital.

- To analyze if there are differences between patients with kidney failure and those who do not develop this complication.

- To determine whether the development of renal failure is related to mortality.

Methods: This retrospective observational study was conducted in a medico-surgical Intensive Care Unit of a second-level hospital. All the patients, with positive PCR for SARS-CoV2, admitted to the ICU during the study period (March-June 2020) were included. Personal history, demographic, analytical and clinical variables, as well as severity and mortality scores were collected. *Statistical analyses were performed using SPSSv22 software.*

Results: Twenty patients, predominantly male, 63% (13), with a mean age of 61.8 ± 8.2 SD and BMI 28.9 cm / m² ± 4.9 SD, were included. With regard to the severity scales, we found a mean SOFA value at admission of 3.6 points ± 2.1 SD and APACHE II 10.25 ± 4.1 SD. The most prevalent comorbidities were HTN 45% (9); DLP 40% (8); DM 20% (4). The average ICU stay was 23.5 days. 55% (11) of the patients developed renal failure with a mean ICU stay of 7.8 days. 63.7% (7) required CRRT. The average SOFA on the day of the diagnosis of ARF was 9.1 points ± 3.2 DS, presenting AKIN I 45.5%, II 18.2%, III 36.4%; RIFLE R 45.5%, I 9%, F 45.5%. We found significant differences, between the total series and the patients who developed renal failure, in the following variables: BMI (31.9 cm / m² vs 25.2 cm / m²), Creatinine (1.2 mg / dl vs 0.8 mg / dl), pH (7.03 vs 7.31), bicarbonate (19.7 mmol / L vs 25.3 mmol / L) at admission or during the ICU stay ($p < 0.05$). With regard to the mortality, we found that patients who developed ARF had a much higher mortality, 63.7% (7), compared to those who did not have this

organic failure (35%) ($p < 0.05$). Those who required CRRT had a mortality of 100% (7) ($p < 0.05$).

Conclusion: - Patients admitted to our unit, infected with SARS-CoV 2, developed kidney failure in a high percentage.

- The presence of ARF is associated with a higher mortality compared to those who do not develop it.

- Renal failure in COVID-19 patients who require continuous renal replacement therapies reach 100% mortality in our series.

Intensive Care Medicine Experimental 2020, **8(2)**: 001426

Introduction: A novel coronavirus (SARS-CoV-2) caused a worldwide pandemic and human health emergency. Worldwide coronavirus disease 2019 (COVID-19) has led to a large number of hospital and ICU admissions. Critically ill patients with COVID-19 suffer from high morbidity and mortality. About 20% of critically ill COVID-19 patients need renal replacement therapy (RRT). Data on early prediction of acute kidney injury and RRT requirement are lacking. Mid-regional pro-adrenomedullin (MR-proADM), is an early marker of endothelial dysfunction predicting organ dysfunction in septic shock.

Objectives: The aim of this study was to investigate MR-proADM for prediction of RRT in critically ill patients with COVID-19.

Methods: We conducted a single-center observational study and consecutively included all adult patients with microbiologically confirmed COVID-19 treated at our department of intensive care medicine. Patient characteristics, severity of disease, course of the disease and ICU mortality were assessed. MR-proADM together with other biomarkers of inflammation was measured as part of clinical routine.

Results: Overall we could identify 64 critically ill patients with COVID-19. 49 patients (77%) were male, median age was 62.5 (54 – 73) years. 47 (73%) patients required mechanical ventilation. 25 (39%) patients had severe ARDS, and veno-venous extracorporeal membrane oxygenation was established in 10 patients. 50 (78%) patients needed vasopressor therapy. 29 (45%) patients required RRT during the ICU-stay. The median time from admission on ICU to start of RRT was 2 (1 – 9) days. MR-proADM on admission was significantly higher in patients requiring RRT (2.491 vs. 1.230 nmol/l; $p = 0.002$). ROC curve analysis showed that MR-proADM served as predictor of requirement for RRT with an AUC of 0.68 (95% CI: 0.54 – 0.81; $p = 0.02$). Multivariate logistic regression showed that MR-proADM was an independent predictor (OR: 4.02, 95% CI 1.13 to 14.27, $p < 0.05$) for the requirement of RRT.

Conclusion: MR-proADM was able to independently predict RRT-requirement in critically ill patients with COVID-19 upon admission to the ICU.

Correspondence: M. Jamme

Intensive Care Medicine Experimental 2020, **8(2)**: 001462

Introduction: Acute kidney injury (AKI) is one of the most common complication observed in ICU patients. Besides classical risk factors associated with AKI occurrence, several studies have found a protective renal effect favoring the use of balanced solution. This could have been explained by the deleterious effects of hyperchloremia acidosis induced by the administration of a highly concentrated solution in chlorine.

Objectives: We aimed to assess the association of chloremia [Cl] with AKI occurrence.

Methods: We included all adults patients admitted to a tertiary ICU between June 1st 2006 and June 13th 2019. AKI was defined by KDIGO stage ≥ 2 . Hypo and hyperchloremia were defined as [Cl] < 95 mmol/L and > 110 mmol/L, respectively. We assessed the relationship between chloremia and AKI occurrence within ICU stay as follows: Cox cause specific model using the first chloremia at ICU admission and time-dependent Cox cause specific model using all chloremia recorded within ICU stay before AKI occurrence.

Results: We included 4,908 patients. Median age was 65 [51-76] years with mostly males (58.1%). At ICU admission, sepsis was observed in 63.2%, acute respiratory failure in 47.2% and shock in 37.5%. AKI occurred in 896 (18.2%) patients in a median time of 4 [2-9] days. 388 (7.9%) patients died in ICU without AKI. Using first chloremia at ICU admission, hypochloremia and hyperchloremia were both associated with AKI with Cox cause specific hazard ratio (CSH) of respectively 1.40 (95%CI [1.07-1.09], $p = 0.01$) and 1.60 (95%CI [1.09-2.39], $p = 0.002$). Considering all chloremias before AKI as time dependent covariate, the statistical association was still observed but stronger with hyperchloremia (CSH = 2.39 [1.75-3.27], $p < 0.001$) than hypochloremia (CSH = 1.86 [1.49-2.33], $p = 0.02$).

Conclusion: Abnormal chlore levels was associated with AKI occurrence in a large cohort of ICU patients. While both hypochloremia and hyperchloremia were associated with AKI, hyperchloremia seemed to be strongly associated with renal outcome.

D-dimer as a Predictor of Acute Kidney Injury in the Covid-19 Patient Cohort

A. Sangam¹; HD. Aya²; S. Leaver³; A. Rhodes⁴; M. Hamilton²

¹Critical Care Medicine, St George's Hospital, London, United Kingdom; ²General intensive care unit, St George's Hospital, London, United Kingdom; ³Research lead critical care directorate, St George's Hospital, London, United Kingdom; ⁴Intensive care unit, St George's Hospital, London, United Kingdom

Correspondence: A. Sangam

Intensive Care Medicine Experimental 2020, **8(2)**: 001555

Introduction: From the Covid-19 pandemic of 2020 it is evident that this new condition, which largely presents to critical care as respiratory failure is, in fact, a multisystem entity (1,2). Although data interpretation thus far has identified clinical indices, such as elevated D-dimer, that are associated with increased likelihood of critical care admission or an increased mortality (3), less is currently understood about how such markers can prognosticate specific organ failures such as acute kidney injury, and the need for specific critical care interventions such as renal replacement therapy.

Objectives: Our aim was to assess whether a persistently elevated D-Dimer is predictor of acute kidney injury (AKI) in critically ill patients admitted with Covid-19 infection.

Methods: This is a retrospective, observational study examining the medical records of all adult patients admitted to critical care at St George's Hospital in South London between 1st March 2020 and 31st May 2020. The D-dimer level was recorded at critical care admission, at day 7 and day 14. AKI was defined as per the AKIN guidelines(4). Requirement of renal replacement therapy (RRT) and mortality after 28 days of admission were secondary outcomes. Proportions were compared using chi-squared statistic, and odds ratios are reported with 95% confidence interval (CI).

Results: From 132 patients, D-Dimer was measured in 95 (72%), with a median value of 1294 (503, 5520). 24.2% had a normal D-Dimer on admission, 49.5 % had a D-Dimer between 500 – 6000, 26.3% had a D-Dimer greater than 6000 (the maximum laboratory value). 16 (69.6%) patients with a normal D-Dimer on admission had AKI compared to 63 (87.5%) patient with elevated D-Dimer ($p=0.045$, OR 2.4, 95% CI 1.02, 5.8). 9 (39%) patients with a normal D-Dimer on admission required RRT compared to 25 (34.7%) patients with elevated D-Dimer ($p = 0.7$). 9 (39%) patients with normal D-Dimer on admission died, compared to 43 (60%) in the group of elevated D-Dimer ($p = 0.084$). At day 7, 71 patients remained in the ICU: 2 of 5 (40%) patients with normal D-Dimer had AKI, compared with 51 of 66 (77.3%) with elevated D-Dimer ($p = 0.065$). At day 14, 51 patients remained in the ICU: 1 of 4 (25%) patients with normal D-Dimer had AKI compared to 31 of 47 (66%) with elevated D-Dimer ($p = 0.10$)

Conclusion: An elevated D-dimer on admission, but not a persistent elevation, is a predictor of AKI in critically ill patients with Covid-19.

Early diagnosis of Acute Kidney Injury in Critically Ill patients

D. Paz¹

¹Intensive Care Unit, Coyoacan, Mexico City, CDMX, Mexico, Mexico

Correspondence: D. Paz

Intensive Care Medicine Experimental 2020, **8(2)**: 001615

Introduction: The incidence of acute kidney injury in critically ill patients is gradually increasing, it indicates a poor prognosis with higher morbidity and mortality. Failure on acute diagnosis may delay the onset of an adequate therapy which may cause an unfavorable outcome, such as the need for renal replacement therapy, generating high costs to the health system. The validation of new methods that identify the presence of acute kidney injury in its early stages is needed.

Objectives: To demonstrate which is the earliest marker for the diagnosis of acute kidney injury in critically ill patients, including creatinine, cystatin C, urinary sediment and N- GAL.

Methods: A prospective, longitudinal and descriptive study is presented, with data obtained from patients over 18 years of age admitted to Angeles Lomas Hospital Intensive Care Unit, between October 2019 and July 2020.

Table 1: Laboratory test at baseline.

Characteristics	Total (n=20)	AKI present (n=12)	AKI absent(n=8)	p Value
Serum Creatinine(mg/dL)	1.32±.5	1.58±.6	0.92±.2	<0.009
N-GAL (ng/dL)	191±207.4	274.1±232.3	63.3±48.3	<0.024
Cistatina C (ml/min)	65.8±24.8	56.7±21.3	79.5±24.7	<0.042
Cilinders in urine				<0.036
Absent	15 (75%)	7 (46.6%)	8 (53.3%)	
Present	5 (25%)	5 (100%)	0 (0%)	

AKI= Acute Kidney Injury, SD= Standard Deviation
Categorical variables are presented in frequency and percentages; Continuous variables are presented as mean ± SD. P value for the comparison between LRA present vs absent.

Results: Serum creatinine and cylinders in urine had similar capacity to detect cases of AKI (baseline sensitivity 57.1%, specificity 100% and sensitivity 41.7%, specificity 100%, 24 hours sensitivity 58.3%, specificity 100% and sensitivity 57.1%, specificity 100% respectively).

Table 2: Laboratory test at 24 hours.

Characteristics	Total (n=20)	AKI present (n=14)	AKI absent(n=6)	p Value
Serum Creatinine(mg/dL)	1.5±.9	1.9±1.	0.86±.181	<0.027
N-GAL (ng/dL)	295±298	393.2±307.6	65.8±41.9	<0.020
Cistatina C (ml/min)	60.7±28.3	50.7±25	84.1±22	<0.011
Cilinders in urine				<0.015
Absent	12 (60%)	6(50%)	6 (50%)	
Present	8 (40%)	8 (100%)	0(0%)	

AKI= Acute Kidney Injury, SD= Standard Deviation
Categorical variables are presented in frequency and percentages; Continuous variables are presented as mean ± SD. P value for the comparison between LRA present vs absent.

Cystatin C clearance showed better sensitivity (75% and 78.6%) but its specificity was reduced when detecting the mild and moderate cases of AKI (62.5% and 83.3%). N-GAL showed the best sensitivity (83.3% and 85.7%) and specificity (100% in both scenarios).

Conclusion: In this study we found that N-GAL is the most reliable biomarker for the diagnosis and prognosis of acute kidney injury in critically ill patients, compared to serum creatinine, cystatin C clearance and urinary sediment. Therefore, NGAL should be considered for the assesment on critically ill patients with or at risk of AKI. Future prospective and larger studies are required to validate its clinical utility as an early and accurate predictor of AKI.

Intensive Care Medicine Experimental 2020, **8(2)**: 001622

Introduction: Since February 2020, an outbreak of Novel Coronavirus disease (COVID-19) developed in Lombardy, Italy. COVID-19 primarily manifest as acute respiratory illness with bilateral interstitial pneumonia, however it can affect several organs, including the kidney. The exact mechanism of kidney involvement is unclear, and may be related with cytokine storm, direct cellular damage due to the virus, or prerenal AKI due to dehydration. The incidence and characteristics of AKI in acutely ill patients are not known.

Objectives: To assess the incidence and characteristics of AKI in acutely ill patients admitted to general wards in a large teaching hospital

Methods: We retrospectively collected data from all patients admitted to Humanitas Research Hospital for COVID19 infection, from February 2020,22 to April 2020. Study obtained IRB approval. Data were anonymized at extraction from EHR. AKI was defined according to KDIGO criteria, using both urinary output and creatinine values. When baseline creatinine values were not available, the lowest intra-hospital creatinine value was used as baseline. Data are described as median-IQR or frequency-percentage. Chi square test or Kruskal-Wallis test are used for comparison.

Results: A total of 544 patients were included in the analysis, with a median age of 66 (IQR 53-76, range 22-93). 353/544 (64.9%) patients were male. 219/544 patients (40.2%) developed AKI during hospital stay according to KDIGO criteria, with 78/544 patients (14.3% reaching stage 2-3 AKI)

Patients with AKI were older than patients without AKI. (71 (62-79 years) vs 61 (49-72) years, p<0.001) Patients with AKI had a two-fold increase in the risk of death (66 patients (30.1%) vs 47 patients (14.5%), p<0.001). Median LOS in the total population was 8 days (IQR 5-14). LOS increased according to AKI stage from 0 (3-10) days in patients with no AKI, to 12 (8-20) in patients with AKI stage 1, to 18 (11-26) days in stage 2-3 (p<0.001 in each comparison).

Stages of AKI according to hospital admission day are reported in

The cumulative percentage of AKI, according to hospital admission day, is reported in 3.

Conclusion: AKI is frequent in acutely ill patients with COVID-19 infection admitted to hospital, and leads to worse outcome, including increased mortality and prolonged hospital stay.

Right ventricular changes in critically ill COVID-19 patients are associated with the need for renal replacement therapy

C. Moxey¹; J. Powys-Lybbe¹; O. Blackford¹; L. Tong¹; O. Valencia¹; J. Aron¹

¹General intensive care unit, St George's Hospital, London, United Kingdom

Correspondence: P.L. James

Intensive Care Medicine Experimental 2020, **8(2)**: 001639

Introduction: Patients with COVID-19 who need renal replacement therapy (RRT) have higher mortality[1]. Acute kidney injury is multi-factorial[2], in the early stages inflammatory mediators reduce systemic and peripheral vascular resistance, in the later stages multi-system involvement due to micro-emboli and venous congestion are injurious. We hypothesize a hyperdynamic RV or a dilated RV could be seen, respectively, on echocardiography during these stages.

Objectives: To determine if there a hyperdynamic RV, of RV dilatation is associated with RRT in critically ill COVID-19 patients.

Methods: We performed an observational study of patients admitted to intensive care unit (ICU) in a tertiary hospital across a three-week period. Only patients with 2 swab PCR confirmed COVID-19 were included in the study. RV function was assessed using tricuspid annular plane systolic excursion (TAPSE) and right ventricular S prime (RV S') during their admission. RV was recorded as normal or dilated by qualitative method. We used fisher's exact test and odds ratio (OR) to determine the association between these variables and the need for RRT. ROC curve analysis was used to determine the best cut-off for continuous variables. P-Value of less than 0.05 is considered statistically significant.

Results: A total of 49 COVID-19 positive patients were included. Of these patients 36% (n=18) required RRT during their admission. TAPSE readings were available for 46 / 49 patients, including all 18 RRT patients. Using a cut-off of 26mm or more, 9 out of 20 patients (45%) needed RRT. 17 out of 26 patients (65.4%) with a TAPSE < 26mm did not need RRT. There was no significant association between TAPSE and RRT (p=0.47).

RVS' readings were available for 44/49 patients, including 16/18 RRT patients. Using a cut off of 16mm or more, 14 patients out of 30 patients (46.7%) needed RRT. 12 out of 14 patients (85.7%) with an RV S' < 16mm did not need RRT. P-value = 0.049. OR 5.25 (1.00 – 27.61).

Assessment on RV dilatation was recorded on all 49 patients. 38 of 49 patients (78%) had severe RV dilatation of whom 17 required RRT. 10 out 11 patients (90.9%) with a normal size RV did not need RRT. (p<0.038) OR 8.1 (0.94 – 69.69).

Conclusion: In ICU patients with Covi19 pneumonitis, a patient with a severely dilated RV or an RVS' greater than 16mm on echocardiography is more likely to need Renal Replacement therapy.

Correspondence: P. García Olivares

Intensive Care Medicine Experimental 2020, **8(2)**: 001301

Introduction: Difficulties associated with the evaluation and monitoring of glomerular filtration rate in critically ill patients are well known.

Objectives: To analyse the concordance between the estimated glomerular filtration rate (GFR) obtained by means of the application of formulas according to serum creatinine, compare to those according to serum cystatin.

Methods: Prospective, observational study carried out in ICU admitted patients, during the months of November-December 2019. General data and renal function analysis data were collected: creatinine (Cr) and glomerular filtration rate were estimated by MDRD 4-IMDS (GFRCr); Cystatin (Cs) and glomerular filtration rate were estimated by CKD-EPI (GFRCs).

Quantitative variables were expressed as mean (SD) or median (IQR) and qualitative variables as percentages. The concordance between the GFR values obtained by both methods was estimated by the interclass correlation coefficients (ICCs < 0.5 bad, ICCs 0.51-0.70 moderate, ICCs 0.71-0.90 good and ICCs > 0.90 excellent) and by Bland Altman plot (quantification of the mean difference between the two methods with 2DS with 95% CI). In view of the lower reliability of the MDRD method for high GFR, we performed a general analysis and another for low GFR (GFR < 60 ml/min).

Results: Eighty-five pairs of measurements were obtained in 95 ICU admitted patients. **General data:** male 56%, age 64±14 years, weight 73±18 Kg, height 166±9 cm, 90% white race. **Renal function values:** Cr 1.26±1.47 mg/dl; GFRCr 93.07±55.72 ml/min, Cs 1.32±0.76 mg/l; GFRCs 67.90±32.33 ml/min; 29% of patients had GFRCr < 60 ml/min and 39% GFRCs < 60 ml/min.

In the general analysis of data, a moderate agreement was obtained between the two methods of GFR (ICCs 0.54; 95% CI 0.19-0.73), with a significant difference between the means (24.32; 95% CI 11.86-36.78; p < 0,001) (Figure 1)

Performing the same analysis when GFR < 60 ml/min, a good concordance between the two methods was obtained (ICCs 0.78; 95% CI 0.38-0.92), with a non-significant mean difference (-5.91; 95% CI -14.57-2.74; p=0.13) (Figure 2).

Conclusion: Waiting to determine its clinical application, our study showed a good agreement between the values of glomerular filtration estimated by creatinine and cystatin when there is impairment renal function.

Intensive Care Medicine Experimental 2020, **8(2)**: 001455

Introduction: To assess in admitted patients to the ICU by coronavirus the influence on mortality and also at the development of multi-organ failure of renal function evaluated with the numbers of urea at the moment of admission to assess how coronavirus influence to the patients admitted by this ill at ICU on mortality and also on the development.

Methods: Prospective cohort study of patients with coronavirus admitted to the ICU at the Hospital Universitario de Jaén, Hospital San Agustín de Linares and the Hospital Infanta Margarita de Cabra. Continuous variables are expressed as median (25th percentile, 75th percentile) and qualitative variables with absolute and relative frequencies. U Mann Whitney was used for comparison of continuous variables and X² for qualitative variables. P < 0.05 was considered as statistically significant.

Results: We have studied 63 admitted patients AT ICU by coronavirus INFECTION, 43 of them AT Jaén hospital ICU, 11 at Cabra hospital and 8 at Linares hospital. The average age was 58 (37,62). The evaluated severity with APACHE II was 12 (9,17) points and the same evaluation but using SOFA was 6 (4,8) points at the first day. 63,5% (n=40) required tracheal intubation on their first day and 82,5% (n=52) during the entire ICU stay. Mortality in the ICU was a percent of 38 and (meanwhile) at the hospital was 39,7. Those patients who deceased were older than the survivors, 64 (60,72) vs 60 (52,70) years old, but the differences weren't statistically significant (e.s) (p=0.16.). These ones also showed most acutely according to Apache II, 18 (14,23) vs 14 (12,18) points (p < 0,005), and a higher SOFA at the admission 7 (4,8) vs 6 (3,8) points, but without being statistically significant (p=0.09).

The Who died show higher urea at the admission 63(34,59) vs 45(34,59) mg, (p=0.051) although the differences weren't s.s. Then, we classified the patients according to whether the urea was higher than 70 upon admission to the ICU and his relation to the mortality. The 46 patients (73%) whose urea were less than 70 showed a mortality of 30.43% and those that had a higher or equal urea than 70 (n=17, 26.98%) the mortality was 64.70%, (p=0.003)

On the third day, we evaluated the severity with SOFA and observed that the patients who died presented a higher SOFA 8 (7.9) vs 6 (3.8) points, (p = 0.021). When the relation between SOFA at the moment of the admission and SOFA on the third day was evaluated we could see that a correlation existed (r=0.588, p < 0.001). SOFA on the third day was higher in patients with Urea greater than 70 9 (8.12) vs 8 (7.11), (p = 0.007).

When SOFA on the third day of the admission was studied using multiple linear regression it was noticed that there was a relation with both SOFA at the day of admission (B=0.548±0.126, p < 0.001) and urea at the moment of the admission (B=0.019+0.003, p=0.033), R=0.629. Cuando se estudio con Regresión lineal múltiple el SOFA al tercer día se relacionó con el SOFA al ingreso (B=0.548+0.126, p < 0.001) y con la Urea al ingreso (B=0.019+0.003, p=0.033), R=0.629.

Conclusion: In ICU patients admitted for coronavirus infection, a higher urea at the admission is related to the mortality and is linked to a later worsening, as it was shown by an increase in the SOFA score on the third day compared to that which they had at admission in those patients with higher Urea numbers.

Intensive Care Medicine Experimental 2020, **8(2)**: 001525

Introduction: Critically ill patients with COVID-19 infection frequently have kidney involvement with clinical presentation ranging from mild renal failure to progressive acute kidney injury (AKI) necessitating renal replacement therapy (RRT). We describe our experience during the peak of the COVID-19 pandemic.

Methods: Retrospective cohort study of patients suffering from COVID-19 infection admitted to the ICU during the peak of COVID-19 pandemic from March to June 2020. We collected data from electronic medical records on demographics, Simplified Acute Physiology Score III (SAPS III), comorbidities, treatments received, need for RRT, use of low molecular weight heparin, length of ICU admission and mortality in ICU.

Results: 82 patients diagnosed with COVID-19 admitted to ICU. Mean age was 63.06 (+/- 10.036) and the majority (76.8%) were men. 68.3% patients (56) suffered AKI and 18 of those (32.1%) required RRT, the majority of them through continuous therapy (94.4%).

Comorbidities included hypertension (48.2%), diabetes (37.5%), chronic respiratory condition (asthma or COPD) 17.9%, obesity (defined by BMI > 30) 21.4%, ischaemic miocardiopathy 9.1% and 5.4% patients with some level of immunosuppression (all causes). No patients with autoimmune disorders within our population.

Patients with AKI received the following COVID-specific treatment according to our Hospital protocol: 98.2% of patients received Hydroxychloroquine, 91.1% Lopinavir/Ritonavir, 73.2% steroids (Methylprednisolone or Dexametasona), 58.9% Tocilizumab, 33.9% Beta-Interferon, 10.7% Baricitinib and 3.6% Anakinra.

Mean SAPS III score was 57.96 (+/- 8.6). Mean ICU length stay was 23.06 days (+/- 21.46) and mortality 71.4%, (OR 1.471; 1.022-2.117, p 0.018) against 41% mortality of patients without renal failure.

Conclusion: The proportion of critically ill patients with COVID-19 suffering from AKI was significantly higher in our population (68.3%) than figures published in the literature (20 to 40%). AKI has been considered a marker of disease severity and a negative prognostic factor for survival. In our cohort, mortality rate in patients with AKI was considerably higher than mortality in patients without AKI. RRT rate, however, was similar to the literature published (21,9%). Even though comorbidities were more frequently found in the AKI group of patients, multivariate logistic regression analysis failed to reveal an association. Furthermore, no association was found between AKI and COVID 19-specific treatment received.

A preliminary study on TIMP2 and IGFBP7 urinary biomarker in COVID-19 patients at ICU admission

M. Greco¹; S. De Rosa²; S. Spano¹; F. Baccanelli¹; R. Aceto³; M. Cecconi¹

¹Department of anesthesia and intensive care, Humanitas Clinical and Research Center-IRCCS, Humanitas University, Rozzano, Italy; ²Department of anesthesia and intensive care unit, San Bortolo Hospital Of Vicenza, Vicenza, Italy; ³Department of anesthesia and intensive care, Humanitas Clinical and Research Center-IRCCS, Rozzano, Italy

Correspondence: M. Greco

Intensive Care Medicine Experimental 2020, **8(2)**: 001634

Introduction: The novel severe acute respiratory coronavirus 2 (SARS-CoV-2) is the cause of COVID-19 disease. COVID-19 disease has a wide spectrum of manifestations, from asymptomatic individuals, to acute illness with respiratory failure requiring hospitalization, to critical illness requiring ICU admission and mechanical ventilation. While COVID-19 disease mostly affects the lung, Acute Kidney Injury (AKI) is frequent in patients with SARS-CoV-2 infection, specifically in patients admitted to critical care.

Immunoassay test based on the urinary concentration of two biomarkers, tissue inhibitor of metalloproteinases-2 (TIMP-2) and insulin-like growth factor-binding protein-7 (IGFBP7), have been proposed and validated for AKI in other settings. No data are available on TIMP-2 and IGFBP7 urinary concentration in COVID-19 patients with critical illness.

Objectives: To investigate whether TIMP-2 and IGFBP7 urinary biomarkers at ICU admission are related with the risk of AKI in patients admitted to ICU for COVID-19 disease

Methods: We conducted a preliminary prospective cohort study, enrolling subsequent patients admitted to COVID-ICU in Humanitas Research Hospital, due to COVID-19 disease. Study obtained IRB approval. Informed consent was obtained according to local regulations. Urinary levels of TIMP-2 and IGFBP7 biomarkers were measured at ICU admission (AKIrisk score by NephroCheck[®] Test), and after 12h, 24h and 48h from ICU admission. AKI was defined according to KDIGO criteria.

Data are described as median-IQR or frequency-percentage. Chi square test or Kruskal-Wallis test are used for comparison.

Results: A total of 13 patients were included in the study. Patients were mostly male (11/13, 83%), with a median age of 59 (IQR 45-67). 5 patients (38%) had no previous disease, while the most frequent comorbidity was diabetes (3 patients, 23). 11 patients underwent mechanical ventilation (84.6%).

A total of 9 patients developed AKI stage 2/3 (69%). 78% of patients needed diuretics during ICU stay, but none of these 13 patients underwent CRRT.

Urinary biomarkers (AKIrisk) values according to time of measurement are reported in Figure 1

AKIrisk values according to AKI stage and time of measurement are reported in figure 2. Only AKIrisk value at 12h were significantly associated with AKI stage 2-3 (p=0.03)

Conclusion: In this pilot study, TIMP-2 and IGFBP7 are generally elevated in patients admitted to ICU for COVID-19 disease, and present wide variability. This may be partly explained by the large variability in ICU admission time, according to the onset of symptoms and to the first day of hospitalization. Only TIMP2-IGFBP7 urinary values at 12h from ICU admission were correlated with AKI stage 2-3.

Unfractionated Heparin with Adequate Anti-Xa Activity Monitoring is Associated with Improved Filter Set Longevity Among Critically Ill COVID-19 Patients Undergoing Renal Replacement Therapy

R. Spencer¹; R. Appleton¹; E. Black¹¹Department of Critical Care, Queen Elizabeth University Hospital, Glasgow, United Kingdom**Correspondence:** R. Spencer*Intensive Care Medicine Experimental* 2020, **8(2)**: 001312

Introduction: Approximately 29% of all critically ill COVID-19 patients in Scotland required renal replacement therapy (RRT), and requirement for RRT is associated with greater mortality(1). Usual local protocol for anticoagulation to facilitate continuous RRT uses citrate, allowing anticoagulation of the filter circuit only without systemic anticoagulation of the patient. However, early in the pandemic it was noted that filtration circuits were clotting unusually quickly, perhaps related to the well documented procoagulant state of severe COVID-19. Therefore, a new protocol was devised using systemic unfractionated heparin. Ordinary monitoring of this would be activated partial thromboplastin time (APTT), however this was altered due to international evidence that it is unrepresentative of true coagulation state among COVID-19 patients(2,3). Therefore, anti-Xa activity monitoring was used, targeting a range of 0.3-0.7 initially, increased to 0.5-0.7 later.

Objectives:

1. To assess the impact of different forms of anticoagulation on continuous haemodiafiltration filter set longevity among COVID-19 patients, with particular attention paid to the effect of anti-Xa activity levels on longevity.
2. To assess the frequency of adverse events associated with systemic unfractionated heparin.

Methods: Patients admitted to our ICU whose primary diagnosis was 'COVID-19 confirmed/suspected' and who underwent at least one day of RRT were identified. Data were collected retrospectively regarding filter set longevity, the reason for stopping/changing filter set, method of anticoagulation, anti-Xa activity along with patient-level data on length of stay, mortality and adverse events. The data were analysed with regard to whether systemic heparinisation was associated with longevity, whether anti-Xa monitoring affected this and frequency of recorded adverse events related to heparin. Data were also analysed to identify any association between filter set longevity and patient outcome.

Results: In total, 144 filter sets were used in 21 COVID-19 patients. Citrate anticoagulation was used in 27 (19%) and heparin in the remaining 117. The reason for stopping/changing filter set was clotting of the set in 88 of these (61.1%). Median longevity in sets that clotted was 10 hours (range 0-87) and very positively skewed. No statistically significant difference in longevity was observed when comparing sets using citrate to all sets using heparin anticoagulation (median 9 vs 10 hours, $p=0.27$). We then compared three groups: citrate, heparin with no anti-Xa levels/first anti-Xa level less than 0.3, and heparin with the first anti-Xa level greater than 0.3. There was significantly greater longevity in sets with the first anti-Xa greater than 0.3 compared to the other two groups (median 30 hours vs 10 hours vs 9 hours, $p=0.012$). When analysing for an anti-Xa target range greater than 0.5, the median longevity was 35 hours, a further significant improvement ($p=0.022$, see chart).

A significant positive correlation was observed within filter sets between the percentage time spent with anti-Xa levels >0.3 and longevity ($p=0.007$). Two adverse events related to heparin (i.e. bleeding) were recorded, one fatal. Both occurred while anti-Xa levels were within the range 0.3-0.7. No significant association was seen between patients' average filter set longevity and their outcomes or severity scoring on admission to ICU.

Conclusion: This study provides evidence that the use of anti-Xa activity monitoring is useful in improving filter set lifespan among COVID-19 patients undergoing continuous RRT, while using unfractionated heparin without anti-Xa monitoring is no better than citrate anticoagulation. The effect is best seen with anti-Xa levels at a level greater than 0.5. However, the risk of adverse bleeding events related to heparin is a significant one and anti-Xa monitoring does not appear to be protective against this in our cohort.

Combined blood purification in patients with septic shock after neurosurgical interventions

A. Burov¹; T. Abramov¹; D. Korotkov¹; NS. Kostritca²; IA. Savin¹¹ICU, N. N. Burdenko National Medical Research Center of Neurosurgery, Moscow, Russia; ²Medical student, M. V. Lomonosov Moscow State University, Moscow, Russia**Correspondence:** A. Burov*Intensive Care Medicine Experimental* 2020, **8(2)**: 001529

Introduction: Sepsis and septic shock in patients with primary brain injury can lead to or aggravate the existing neurologic symptoms due to cytokine release impairing the hematoencephalic barrier. For such patients standard therapy may be insufficient for fast multiorgan failure (MOF) regress and hemodynamic instability correction. Blood purification is a potentially reasonable option for patients with septic shock not responding to standard therapy.

Objectives: The objective of the present study is to evaluate the effectiveness of the combined blood purification (CBP) in neurosurgical patients with septic shock.

Methods: We present 6 neurosurgical patients 29-82 y.o. with septic shock. All of them received standard therapy according to the Surviving Sepsis Campaign guidelines. CBP therapy was started within 10 hours after septic shock diagnosis in 4 patients and within 20 hours – in the other 2 patients. The procedure description: CVVHDF mode on Gambro Prismaflex. Increased adsorption capacity filters (AN69ST (5 patients) and Oxiris (1 patient)) action was amplified by CytoSorb adsorber for all patients. Systemic anticoagulation was performed with heparin in 2 patients, regional citrate anticoagulation – in 3 patients; 1 patient was not anticoagulated. The duration of the procedure was 24 hours.

We observed the procedure's influence on the vasopressor requirements, MOF (by SOFA score), PCT, CRP, IL-6 and lactate levels.

Results: In the course of CBP we observed clinical improvement in all patients. In 3 patients clinical improvement (MOF regress and lactate level decrease) was stable; in other 3 patients - transient.

Median NE demand for all patients reduced from 0,885 $\mu\text{g}/\text{kg}/\text{min}$ (0,18-2,13) before CBP to 0,19 $\mu\text{g}/\text{kg}/\text{min}$ (0-1,64) in 24 hours and to 0,16 $\mu\text{g}/\text{kg}/\text{min}$ (0-3,6) in 72 hours after CBP initiation (Figure 1). At the same time, we observed lactate level reduction from 3,25 mmol/l

(2–9,8) before CBP to 2,05 mmol/l (1,8–7,9) in 24 hours ($p < 0,05$) and to 1,8 mmol/l (0,7–5,8) in 72 hours after CBP initiation (Figure 2).

Mean SOFA score decreased from 14 (11–18) before CBP to 11 (4–17) in 24 hours ($p < 0,05$) and to 9 (4–18) in 72 hours after CBP initiation (Figure 3).

Mean PCT level decreased from 97.77 ng/ml (5.32 - >200) before CBP to 25.93 ng/ml (1.43–86.62) in 24 hours ($p < 0,05$) and to 22.8 ng/ml (3.1–101.45) in 72 hours after CBP initiation (Figure 4). Mean CRP level decreased from 138,5 mg/l (34,7–257,3) before CBP to 102,2 mg/l (35,4–254,4) in 48 hours and to 68 mg/l (28,2 –298,1) in 72 hours after CBP initiation (Figure 5). Mean IL-6 level decreased from 896 pg/ml (56–32280) before CBP to 249 pg/ml (19.46–9142) in 6 hours and to 80.5 pg/ml (20.98– 6352) in 24 hours after CBP initiation (both $p < 0,05$) (Figure 6).

3 patients with stable clinical improvement had shock reversal; in 2 of them we observed consciousness level increase. 2 Patients with transient clinical improvement died in 72 and 74 hours after CBP initiation due to cerebral herniation in the setting of malignant brain oedema, 1 patient died at 26 hours after the procedure start due to cardiac insufficiency progress after pulmonary embolism.

Conclusion: We observed that CBP in combination with standard intensive care contributed to overall clinical improvement in all patients (stable or transient). Among the key changes were the significant MOF regress, lactate, PCT and IL-6 level decrease and not statistically significant vasopressor demand reduction. The use of CBP in septic shock patients after neurosurgical interventions may be rational. Further studies on the method efficacy and safety in neurosurgical patients with septic shock are required.

Concentrations of fentanyl before and after initiation of continuous veno-venous hemodialysis in septic patients with acute kidney injury – a prospective observational study

K. Polok¹; I. Nowak-Kózcza¹; J. Fronczek¹; J. Górka¹; W. Szczeklik¹

¹Intensive care and perioperative medicine, Jagiellonian University Medical College, Kraków, Poland

Correspondence: K. Polok

Intensive Care Medicine Experimental 2020, **8(2)**: 001541

Introduction: Acute kidney injury (AKI) complicates sepsis in 40–50% of cases and often necessitates introduction of continuous renal replacement therapy (CRRT) which significantly affects pharmacokinetics of multiple medications commonly used in the intensive care unit. Association between use of CRRT and fentanyl concentration, particularly in the critical care setting, has not been well described yet.

Objectives: To compare concentrations of fentanyl before and during continuous veno-venous hemodialysis with regional citrate anticoagulation (RCA-CVVHD) in septic patients with AKI.

Methods: We enrolled patients at the of >35 and <85 years with severe sepsis or septic shock and clinical indications for CRRT due to AKI, according to KDIGO recommendations. RCA-CVVHD was initiated according to the local practice. It was performed using commercially available equipment and solution, with anticoagulation performed using 4% trisodium citrate and CaCl₂ solution. All CRRT settings were identical for every participant at the beginning of procedure and were subsequently adapted based on the patient's clinical status. Fentanyl

was administered via a continuous intravenous infusion with a dosage equal to 100 µg/h. The dosing of fentanyl was not changed after RCA-CVVHD was initiated. Fentanyl concentrations were measured in seven predefined timepoints both before and after the initiation of RCA-CVVHD with the use of high-pressure liquid chromatography – tandem mass spectrometry with an electrospray ionization source.

Results: Fourteen patients at the median age of 59.5 (IQR 45.0–64.0) years, among whom 9 were males (64.3%), were enrolled in the study. The concentration of fentanyl was similar before and after initiation of RCA-CVVHD in the entire cohort (0.535 vs 0.581 [ng/ml], $p = 0.14$) as well as in the subgroups of patients with residual diuresis (0.729 vs. 0.804 [ng/ml], $p = 0.50$) and in patients without residual diuresis (0.430 vs. 0.559 [ng/ml], $p = 0.21$).

Conclusion: There were no significant differences in fentanyl levels before and after initiation of RCA-CVVHD, irrespective of residual diuresis status. Results of presented study suggest a limited usefulness of fentanyl concentration monitoring in this population.

001543

Use of Continuous Renal Replacement Therapy with hemoadsorption (Oxiris®) in patients with severe acute respiratory failure due to COVID-19 and associated renal failure

M. Gonzalez-Fernandez¹; N. Quílez-Trasobares²; A. Lesmes¹; JA.

Barea-Mendoza³; JA. Sanchez-Izquierdo⁴; Z. Molina-Collado²

Intensive Care Medicine Experimental 2020, **8(2)**: 001543

Introduction: The use of continuous renal replacement therapy with hemoadsorption (Oxiris®) in patients with severe acute respiratory failure due to COVID-19 and associated renal failure, may modify the systemic inflammatory response associated with this disease based on cytokine clearance.

Objectives: Describe the characteristics of our serie, the therapy applied, and assess the impact of hemoadsorption on the outcomes of our patients.

Methods: Prospective, unicentric, observational study in patients admitted to the ICU from march to april 2020 due to SARS-CoV-2 infection with acute kidney injury (AKI) and need for Continuous Renal Replacement Therapy (CRRT) in which hemoadsorption with Oxiris® membrane is set up. We analyze epidemiology, severity scores, respiratory status and inflammatory markers before and after therapy, dose and complications of CRRT, ICU lenght of stay and mortality. Statistical analysis is performed with SPSS system.

Results: 128 patients were analyzed; 33% of them presented acute kidney injury, 18% required CRRT and in 11% (14 patients) was associated with hemoadsorption: median age of 62 years and male predominance (86%) were included, 57% of them were hypertensive, 43% obese and 21% chronic pneumopaths. The worst SOFA at 24 h of admission was 5 (IQR: 4-7), the worst PaFi was 105 (IQR: 66-120) and the worst compliance was 45 ml/cmH₂O (IQR: 40-52). Neuro-muscular blockade and prone position were used in 93% of them, and veno-venous ECMO was applied in one case. The main indication of CRRT was homeostasis (78%) and fluid balance (14%). The initial dose employed was 35 ml/kg (IQR: 35-40), final 30 ml/kg (IQR 30-45) and median duration of 72 h. The anticoagulation system used was: 86% citrate, 9% nothing and 5% heparin, without any case of citrate accumulation. We detected several complications, all of them in mild degree: persistence of metabolic acidosis 86%, hypothermia 50%, hyperkalemia 23%, metabolic alkalosis 14%, hypophosphoremia 9% hypomagnesemia and hypokalemia 5%. No statistically significant differences were found between inflammatory markers (PCR, PCT, ferritin, lymphocytes, fibrinogen), SOFA or PaFi pre and post-CRRT due to the small sample size, although they were found between pre and post-CRRT D-dimer ($p < 0.05$). ICU lenght of stay was 12 days (IQR 6-18) and ICU mortality rate was 50%.

Conclusion: In our serie, CRRT with associated hemoadsorption has been useful and safe technique in the management of acute renal failure in COVID-19 patients. This therapy could lower D-dimer levels.

Management of a Metformin-Associated Lactic Acidosis by Different Modalities of Renal Replacement Therapy

K. Van Laethem¹; B. Dewulf¹; M. Bourgeois¹

¹Intensive Care, AZ Sint-Jan, Brugge, Belgium

Correspondence: K. Van Laethem

Intensive Care Medicine Experimental 2020, **8(2)**: 001553

Introduction: The optimal treatment modality for a metformin lactate acidosis (MALA) remains controversial [1]. Though intermittent haemodialysis (IHD) is considered superior in correcting acidemia and clearing metformin, continuous renal replacement therapy (CRRT) is still used frequently due to a proposed better hemodynamic tolerability and less logistic implications [1-4].

Objectives: Does the fear of an increased risk of hemodynamic perturbation outweighs the proven benefit of a more effective clearance? In this paper we illustrate a significant difference in clearance between both modalities of RRT with a pharmacokinetic time course of metformin levels.

Methods: This trial is a retrospective, observational study. From July 2019 to December 2019, we identified all patients who were admitted to the ICU of the Sint-Jan Hospital in Bruges with the diagnosis of severe MALA requiring RRT. The metformin plasma levels were monitored with an interval of three hours. RRT was discontinued as soon as the clinical condition and renal function improved sustainably.

Figure 1: Metformin Serum and pH Levels (Case 1)

Results: Our trial population consists of 2 patients. The first patient underwent IHD (Qb 345 ml/min, Qd 500 ml/min) during 4 h after which CVVH (Qb 120 ml/min, Qe 40 mL/kg/h, 50% pre-dilution and 50% post-dilution with Hemosol BO replacement fluid) was started. Metformin concentrations were dramatically reduced in the first 4 h and metabolic acidosis was corrected. The mean rate of metformin elimination was 12%/h with IHD and 5%/h with CVVH (Fig. 1).

Figure 2: Metformin Serum and pH Levels (Case 2)

The other patient immediately received CVVHDF (Qb 120 ml/min, Qe 55 ml/kg/h, 66% pre-dilution and 33% post-dilution with Hemosol BO replacement fluid, Qd of 2000 ml/h) with a gradual normalisation of the metabolic acidosis and metformin concentrations in the first 24 h. The mean rate of metformin elimination was 2.4%/h (Fig. 2).

	Case 1	Case 2	Mean ± SD
Type	IHD / CVVH	CVVHDF	-
Metformin clearance			
Rate of elimination (%/h)	12 / 5	2,4	7,2±4,8
Outcomes			
ICU length of stay (days)	3	17	10±7
Survival to discharge	Yes	Yes	-
Discharge at home	Yes	Yes	-

Table 1: RRT and outcomes

The IHD was hemodynamically well tolerated, while the second patient was highly vasopressor dependent during the first 20 h of CVVHDF. Both our patients had a favourable outcome (Table 1).

Conclusion: CRRT and IHD are equivalent dialysis strategies regarding outcome for the ICU patient with AKI [5]. Arguments in favor of CRRT are a presumed better hemodynamic tolerability and its potential for gradual fluid removal. On the other hand, IHD is more flexible and cost-effective, offers the possibility to minimize anticoagulation and removes small solutes more efficiently [5]. Our study illustrates that IHD was more efficient to restore the metabolic homeostasis and eliminate metformin. It's our opinion that IHD is the preferred modality of RRT in MALA, despite the presence of hypotension. There is no need for net ultrafiltration and the hemodynamic instability is most likely induced by the extreme metabolic derangements related to metformin [5-6]. However, further studies are needed to determine the indication, timing and modalities of RRT and the potential role of hybrid therapies such as sustained low-efficiency daily dialysis in patients with MALA.

Introduction: On-line databases have grown as an alternative method for storing and analysing scientific data, respecting confidentiality, providing security and simplicity of use. Based on the use of an international database, initial evaluation of an on-line database for the follow-up of renal depuration techniques is presented.

Objectives: Analyze the initial results in a multicenter register which allows a continuous follow up of the patients with Continuous Renal Replacement Therapy (CRRT) with the objective of detect and solve the problems in their implementation.

Methods: Observational, prospective, multicenter and descriptive study, by the database DiallyReg, which one has the characteristic of a database with a little number of variables, making it easier to fill. REDCap is an on-line database which has the legal guarantees regarding security and confidentiality, feasibility and an easy access, with a possibility of data analyze in real time. Statistical analysis is performed with SPSS system and it has got the bioethical approve.

Results: In 2019, 159 patients has been included with the main admission diagnosis of medical illness(47%), postoperative (26%), sepsis (24%) and trauma (5%). The principal indication for the therapy was internal homeostasis (43%), oliguria (24%), hemodynamics (16%) and hydric disbalance (15%). The median of the number of catheter per patient was 1 (IQR1-1) with a median of duration by 6 days (IQR 3-9). The 82% of the catheters were coaxial dual lumen, and the preferential vascular acces was internal femoral vein (58%). The main complications derived by the therapy were hematoma (2%), infection (2%) and trombosis (1%). Median of the hemodialysis sets was 3 (IQR 2-6), with a median of therapy set by 22 hours (IQR 12-48 h). The initial therapy dosis was set in 30 ml per kilogram (IQR 20-40 ml) and dynamic adjustment was perform in the 68% of the sample. The main motive for discontinuation of the therapy was recovery (58%), exitus (29%) and intermittent renal replacement (8%). Discontinuation was: planned (37%),end of the treatment (18%) or a dialysis set coagulation (36%). The main complications derived by the therapy were hypophosphoraemia(15%), hypotermia(12%), metabolic acidosis, hypokalemia and hypocalcemia (6% respectively). 53% of the patients were discharged from the hospital while 40% died in the ICU and 6.5% during hospitalization.

Conclusion: The DiallyReg register is a feasible tool, affordable for a real time control of the results of dialysis therapy in our units. It could be usefull for the maintenance of security programs in these thecniques.

Intensive Care Medicine Experimental 2020, **8(2)**: 001582

Introduction: Citrate-based renal purification therapy is increasing its use over other conventional anticoagulation modalities, providing evidence of a safe and effective alternative. For this purpose we would like to analyse the impact of complications due to the use of citrate versus other anticoagulation modalities in Continuous Renal Replacement Therapy (CRRT).

Objectives: Comparison between citrate anticoagulation with other modalities in terms of efficacy and safety.

Methods: Prospective multicenter observational cohort study based on the DiallyReg registry, with the Clinical research ethics committee (CEIC) approval from both hospitals. We compare therapy doses, clot filter loss and common complications in patients undergoing Continuous Renal Replacement Therapy (CRRT) in 2019. Statistical analysis is performed with SPSS system.

Results: Data from 159 patients corresponding to 690 haemofilters are analysed. The distribution in anticoagulation systems was: heparin (35.8%), citrate (29%), and without anticoagulation (44.5%). The initial dose of therapy was similar in citrate group (30 ml/kg, IQR 25-35) with respect to the heparin and without anticoagulation groups. Dynamic adjustment was performed more frequently in the citrate group (84%) than in heparin (69%) and without anticoagulation groups (66%) ($p < 0.05$). The final therapy dose was lower with citrate (20 ml/kg, IQR 20-30) versus heparin (30 ml/kg, IQR 20-35) and without anticoagulation (25 ml/kg, IQR 15-35), ($p < 0.05$). Median duration of the set was higher in citrate group (55 h, IQR 24-72) versus 23 h in heparine group (IQR 12-48) and 12 h in no anticoagulation group (IQR 12-31) ($p < 0.05$). Coagulation of the system had a higher incidence with heparin (46.7%) than with citrate (29.5%) ($p < 0.05$). Complications associated with the technique were observed: hypothermia (19% citrate vs 9% rest), hypokalemia (18% citrate vs 3% rest) and hypomagnesemia (6.6% citrate vs 2% rest) ($p < 0.05$); although these findings observed in higher proportion in citrate group are attributable to the learning curve of one of the participating hospitals. Following proper use of the technique and the use of phosphate dialysis fluids, complications are similar to the other types of therapy. Citrate anticoagulation was also analyzed in the subgroup of hepatopathic patients (27 patients: 52% cirrhosis, 37% liver transplantation, 7% acute liver failure, and 4% acute-on-chronic failure). Heparin was used in 39%, citrate in 21%, and no anticoagulation was used in 38% of the sample. No statistically significant differences were found in terms of complications due to therapy, however there was a lower frequency of citrate use in hepatopathic patients than in non-hepatopathic ones (19% vs. 35%) ($p < 0.05$).

Conclusion: Citrate anticoagulation increases the duration of the haemofilters and allows better adjustment of the therapy dose in our series, possibly being more cost-effective. It is a safe anticoagulation system once the learning curve is covered.

Inflammatory response trajectory is associated with increased failure to wean neuromuscular blockade in ventilated COVID-19 patients

C. McCue¹; S. Norman¹; C. Macdonald¹; R. Cowan¹
¹Intensive care, Glasgow Royal Infirmary, Glasgow, United Kingdom
Correspondence: C. McCue
Intensive Care Medicine Experimental 2020, **8(2)**: 001189

Introduction: The global COVID-19 pandemic resulted in a significant proportion of hospitalised patients developing ARDS requiring mechanical ventilation(1). Prominent features of COVID-19 are a large inflammatory response with significant pyrexia and moderate-severe ARDS often requiring prolonged ventilation(2). Our unit uses an evidenced based protocol to manage patients with ARDS which includes lung protective ventilation, prone positioning and paralysis with neuromuscular blockade(3). Our clinical experience using this protocol to manage COVID-19 patients was that we encountered multiple episodes of failure to wean paralysis after an initial apparent improvement in oxygenation and respiratory mechanics. We hypothesised that this failure may be more likely if there was evidence of significant ongoing inflammatory response. We sought to analyse if ongoing significant inflammation as determined by pyrexia and rising CRP was associated with failure to wean paralysis.

Methods: Data was collected on ventilated patients admitted with COVID-19 pneumonia from March to May 2020. For each patient on each day ventilated we collected P/F ratio, mandatory vs spontaneous ventilation, whether paralysis was weaned successfully, peak temperature and CRP. Pyrexia was defined as temperature >38oC, CRP was compared to the previous 24 hour’s result to determine trajectory. We routinely use continuous atracurium infusions titrated to effect for paralysis. Statistical analysis was performed on Real Stats for Excel.

Results: Over the time period; 51 patients with COVID-19 pneumonia were ventilated in our ICU. We excluded patients whose medical records were unavailable (n = 1) or those who didn’t complete their entire ventilated stay in our ICU (n = 7). All were followed up until ICU discharge. As of June 17th 2020, 4 patients remained in hospital with 59% of patients (44) discharged home. Over the study period, there were 125 attempts at weaning paralysis of which 32 were successful. The median number of days receiving paralysis was 6. In pyrexial patients with rising CRP, 11% of attempts to wean were successful compared to 34% of attempts in apyrexial patients with falling CRP (p = 0.048).

Conclusion: To our knowledge there are no other reports of neuromuscular blockade management during the COVID-19 pandemic. We have seen high rates of failure weaning paralysis in our patient cohort, but improved success rates when there is evidence of improving inflammatory response.

Intensive Care Medicine Experimental 2020, **8(2)**: 001220

Introduction: Although there are few previous published observational studies examining the incidence and mortality of patients with acute respiratory failure and ARDS, there are no studies specifically assessing the epidemiological characteristics, patterns of ventilation and clinical outcomes in patients with acute hypoxemic respiratory failure (AHRF) in the current era of lung protective ventilation. Understanding the factors associated with AHRF outcomes could lead to development of effective interventions and improvement of patient care.

Demographic	Result
Male	70%
Median age (range)	57 (37-72)
ICU mortality	32%
Median ICU length of stay (range)	19 (2-72)

Table 1. Demographics and outcomes

Objectives: The aim of the study was to identify the intensive care unit (ICU) mortality for patients suffering from AHRF. Secondary aim was analysis of factors influencing patient mortality and investigation of the parameters of ventilatory management as well as the use of rescue therapies for hypoxemia.

Methods: This was a multi-centre prospective study carried out in nine hospitals in Wales, UK, over two 2-month periods. All patients admitted to ICU were screened for AHRF and followed-up until discharge from the ICU or hospital. Data was collected from patient charts on patient demographics, reason for ICU admission, methods of AHRF diagnosis, physiological and laboratory results, treating team management and complications during the ICU stay.

Results: We recruited 197 patients in our study. Fifty-nine (29.9%) were non-survivors, 101 (51.3%) were survivors and data was missing for 37 (18.8%). Inotropic support ($p=0.03$), re-intubation ($p=0.04$), pneumonia ($p=0.002$) and increased SOFA score ($p=0.04$) were associated with mortality. The majority of patients (87.8%) did not receive the optimal tidal volumes of ventilation (VT), recommended as 6-7 ml/kg predicted body weight (PBW), with only 13.35% of all VTmax and 27.98% of VTmin measurements within the optimal range. 77.90% VTmax and 23.69% VTmin measurements had values above 7 ml/kg PBW. Rescue therapies were not used in the vast majority of the patients. Muscle paralysis was used only for 21.3% and recruitment manoeuvres for 17.8% of patients, whereas prone positioning and more invasive technologies such as ECMO were used in less than 1% of patients.

Conclusion: AHRF is associated with high mortality despite increased awareness and recognition of this condition. Despite advances of care, mechanical ventilation and use of adjunctive measures is still not optimal for the vast majority of patients.

Prone Positioning as a Treatment for Hypoxaemia in Patients with Severe Respiratory Failure Secondary to SARS-CoV-2

K. Richmond¹; A. Laurie²; S. Stott²

¹Anaesthesia, Aberdeen Royal infirmary, Aberdeen, United Kingdom; ²Critical care, Aberdeen Royal Infirmary, Aberdeen, United Kingdom

Correspondence: K. Richmond

Intensive Care Medicine Experimental 2020, **8(2)**: 001231

Introduction: The global pandemic of SARS-CoV-2 resulted in a large cohort of patients requiring critical care support for severe respiratory failure (SRF) (1). Prone positioning (PP) is a well-established technique for improving oxygenation in patients with SRF (2).

Objectives: To describe our experience of PP as a management strategy for patients with hypoxaemia admitted to the intensive care unit (ICU) in Aberdeen Royal Infirmary (ARI) with SRF due to SARS-CoV-2 infection.

Methods: Patients admitted to the ARI ICU between March and May 2020 with respiratory failure and confirmed SARS-CoV-2 infection were identified. Retrospective clinical and demographic data were gathered from electronic notes, observation charts and the local incident reporting system. PaO₂/FiO₂ ratio (P/F) change was calculated using the last value prior to PP and the maximum value during PP.

Results: 46 patients with confirmed SARS-CoV-2 infection were identified. 16 patients underwent proning during their ICU admission. Demographic data is shown in table 1. There were 52 discrete proning episodes; the maximum number of times a single patient was proned was 12. In 33 episodes the P:F ratio prior to proning placed the patient in the category of severe ARDS. The mean time from admission to first PP was 4.1 days (0-11). Average prone episode duration was 14.6 hours (2-19.5). All prone episodes bar one involved invasive mechanical ventilation via an endotracheal tube or tracheostomy. Mode of ventilation when prone comprised 56% volume control and 44% pressure control. Average P/F ratio prior to PP was 13.4 kPa compared to 24.5 kPa during PP. In all proning episodes the P/F ratio improved with a mean percentage increase of 86% (8.7-197.5) (figure 1). The percentage increase for prone episodes involving volume control ventilation was 89% compared to 84% for those involving pressure control ventilation. Complications associated with PP included cardiac arrest on

proning (2 cases), brachial plexus injury (1 case) and facial pressure injury (3 cases). ICU mortality was 37.5% for those with prone episodes and 30% in those patients not proned.

Table 1 Demographic data for PP patients and those not proned. Values expressed as mean unless otherwise stated.

	Proned	Not proned	P value
Age, years	61.5	55	0.06
BMI	29.4	28.6	0.60
Comorbidity (%)	Hypertension	40.7	0.44
	Diabetes Mellitus	14.8	0.03
ICU LOS, days	20.6	6.7	0.0004
Mortality (%)	37.5	30	0.60

Conclusion: Based on our experience, for patients with moderate to SRF secondary to SARS-CoV-2, PP appears to improve oxygenation. The mode of ventilation does not seem to influence change in oxygenation. PP may be associated with increased risk of pressure damage, nerve injury and haemodynamic instability including cardiac arrest.

Intensive Care Medicine Experimental 2020, **8(2)**: 001238

Introduction: Acute respiratory distress syndrome (ARDS) is a form of acute, inflammatory lung injury with increased vascular permeability that results in respiratory failure (1). The outbreak of coronavirus disease 2019 (COVID-19) caused by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has triggered a rapid increase in the number of ARDS cases worldwide. The current best practice for management of ARDS includes low tidal volume ventilation (2) and prone positioning where appropriate. Iloprost is a prostacyclin which, in nebulised form, is licensed for treatment of primary pulmonary hypertension (3); its actions have been hypothesised to reduce V/Q mismatch in ARDS.

Objectives: This study aims to observe the current practice of using inhaled iloprost in patients with refractory ARDS at the Royal Free Hospital Intensive Care Unit, and evaluate its use in mechanically ventilated patients with COVID-19 related ARDS.

Methods: Ten COVID-19 positive patients with confirmed severe ARDS as per the Berlin criteria (1), and multi-organ failure were observed. Iloprost nebuliser solution was given every 4 hours at a dose of 5 micrograms initially, with stepwise increments of 5 micrograms to a maximum of 20 micrograms. Changes in oxygenation were monitored using the PaO₂/FiO₂ ratio (P/F ratio) from arterial blood gas (ABG) measurements. Measurements were recorded from 24 hours prior to the first dose to 24 hours after the last dose was administered. Data were analysed with linear regression and Pearson’s r correlation coefficient using SPSS. Mean arterial pressure was used to monitor for safety.

Results: Ten patients were followed (table 1). Iloprost treatment was given for 3 days on average. The average follow-up time was 106 hours per patient with 303 time points sampled. The correlation in the 24 hours prior to initiating iloprost was -0.225 (p = 0.67) (figure 1). The correlation between P/F ratio and time in the first 24 hours after iloprost was started was 0.146 (p = 0.2) (figure 2). No adverse drug reactions were reported. Two patients died during the study and four died in the days after iloprost was stopped.

Table 1: Patient demographics and outcomes

Cohort	n = 10
Age	53.9 (36-65)
Sex	
Female	5
Male	5
Ethnicity

Conclusion: The overall effect of nebulised iloprost was inconclusive. There were possible short-term improvements in oxygenation during treatment but there was no evidence that inhaled iloprost conferred a survival benefit. Inhaled iloprost was well tolerated with no safety concerns. The findings reported are in keeping with current literature however the study lacked statistical power to draw conclusions that may influence practice (4,5). Inhaled iloprost may offer a potentially useful treatment intervention in the management of COVID-19 related ARDS and appears to be safe even in patients with multiple co-morbidities. Further, more powerful studies are needed to determine the precise clinical value of iloprost in ARDS and COVID-19 related ARDS.

Intensive Care Medicine Experimental 2020, **8(2)**: 001290

Introduction: Laboratory parameters in COVID-19 regarding disease severity have been extensively evaluated [1, 2]. However, duration of their normalization is unknown.

Objectives: To determine the normalization time and sequence of laboratory parameters in critically-ill COVID-19 survivors.

Methods: Medical records of COVID-19 patients, admitted to ICU between March 29th and June 1st 2020 and discharged till July 18th 2020 were examined. For each laboratory parameter, normalization date was accepted as the first day of the normal laboratory result series following two or more abnormal consecutive results. PaO₂/FiO₂ (P/F) of ≥ 200 mmHg was accepted as improved value for oxygenation.

Results: A total of 21 patients were enrolled in the study. Patient characteristics, normalization and treatment details are demonstrated in table. P/F improved first, and D-dimer normalized last. The sequence of normalization is demonstrated in figure.

Conclusion: In critically-ill COVID-19 survivors, oxygenation improves before inflammatory parameters, and D-Dimer normalizes last, suggesting prolonged coagulopathy.

Intensive Care Medicine Experimental 2020, **8(2)**: 001297

Introduction: Patients with COVID-19 pneumonia are at major risk for acute respiratory distress syndrome (ARDS). Prone positioning (PP) has many beneficial effects on pulmonary physiology and improves oxygenation in patients with ARDS.

Objectives: We aimed to investigate the effects of PP in non-intubated patients with COVID-19 related pneumonia.

Methods: In this retrospective, single-center, before-after study we enrolled spontaneously breathing patients with confirmed diagnosis of COVID-19 pneumonia who received PP between March 21th and July 5th, 2020. We collected baseline data of demographic variables, SOFA score, APACHE II Score, oxygen therapy methods (as nasal cannula, simple face mask, non-rebreather mask) and non-invasive ventilation. We compared PaO₂, SpO₂, FiO₂, PaO₂/FiO₂, SpO₂/FiO₂, respiratory rate (RR) before PP, during PP and 1 hour after return to supine position. The main outcome is improvement in oxygenation. For statistical analysis of related repeated measures the Friedman test was used. Results are expressed as median (IQR).

Results: Fifteen patients (13 males) were enrolled in the study. Age was 67 (59-75), APACHE II and SOFA Scores were 15 (12-19) and 3 (3-5). As seen in Table PaO₂, SpO₂, FiO₂, SpO₂/FiO₂ and RR improved during PP compared to baseline. Overall 3 patients were intubated in whom PaO₂/FiO₂ improved less than 15% during PP. Six of 12 patients had > 15% improvement in PaO₂/FiO₂ during PP. There was not any improvement in PaO₂/FiO₂ after PP except 1 patient. Two intubated patients died.

Table: Patient characteristics, normalization and treatment (n=21)

Clinical characteristics	Normalization time according to ICU admission, days	Patients with normal values	Medications	Treatment duration, days	Medication start date according to ICU admission
Age, years	59 [49–75]	P/F 4 [1–25]	P/F* 18 (85.7)	HQ* 17 (81.0)	HQ 7 [4.5–10]

Intensive Care Medicine Experimental 2020, **8(2)**: 001305

Introduction: Previous studies have described the respiratory mechanics of COVID-19 related acute respiratory distress syndrome (ARDS) and different phenotypes. However, their characteristics regarding transpulmonary thermodilution variables, such as extravascular lung water (EVLW) and pulmonary vascular permeability, have been rarely described. Considering these parameters are important to fluid management strategy, our study aimed to describe EVLW and pulmonary vascular permeability in COVID-19-related ARDS and compared them with a historical control group of patients with non-COVID-19 ARDS.

Objectives: To describe the characteristics of extravascular lung water index (EVLWi) and pulmonary vascular permeability index (PVPI) in COVID-19 ARDS patients. To investigate the relationship of EVLWi and PVPI with mortality and to compare these patients to a historical cohort of patients with non-COVID-19 ARDS.

Methods: In this observational multicentre study performed in three ICUs, we included patients with mild to severe COVID-19 ARDS and monitored by transpulmonary thermodilution. Demographic and relevant clinical data were collected. Transpulmonary thermodilution variables were collected at least once a day for a maximum of 14 days. We selected values corresponding to the maximum value of EVLWi (EVLW_{max}) and of PVPI (PVPI_{max}) per day. Other hemodynamic values, the ratio of arterial partial pressure of oxygen (PaO₂) over FiO₂ (PaO₂/FiO₂) and other respiratory parameters were recorded at the time when the transpulmonary thermodilution values of interest were assessed.

Results: From March 13th to May 10th, 45 ARDS patients with confirmed COVID-19, monitored by transpulmonary thermodilution were included. On day 1, EVLWi was 17 (13–19) mL/kg and PVPI was 3.4 (2.6–4.2). EVLW_{max} and PVPI_{max} was reached on 3 (1–4) and 2 (1–3) days, respectively. EVLW_{max} was higher in non-survivors than in survivors

(24 (19–28) vs. 18 (16–25) mL/kg, respectively, $p=0.03$). PVPI_{max} was also elevated in non-survivors than in survivors (4.9 (3.9–6.0) vs. 3.8 (3.4–4.7), respectively, $p=0.03$). Nevertheless, 4 of 27 patients with PaO₂/FiO₂ \leq 100 mmHg exhibited moderately increased EVLWi (\leq 15 mL/kg) and PVPI ($<$ 4). Compared to non-COVID-19 ARDS patients, COVID-19 patients had similar values of EVLW_{max} (22 (17–27) vs. 20 (14–26), respectively) and PVPI_{max} (4.5 (3.6–5.4) vs. 3.9 (3.0–5.5), respectively). At multivariate analysis of the merged cohorts of ARDS patients with and without COVID-19, EVLW_{max} (odds ratio (OR) = 1.06, 95% confidence interval (CI) [1.01–1.10]), PVPI_{max} (OR = 1.23, 95% CI [1.01–1.49]), and the COVID-19 status (OR = 2.73, 95% CI [1.17–6.37]), were independent factors of 28-day mortality.

Conclusion: COVID-19 ARDS is characterized by elevated EVLWi and PVPI, which do not differ from non-COVID-19 ARDS. The maximal values of these variables are associated with the outcome. COVID-19 ARDS seems to be an independent risk factor for mortality.

Prone Positioning in a COVID-19 ARDS Cohort - A Retrospective Analysis on Oxygenation and Ventilation

C. McGarrigle¹; M. Ahmed¹; B. Doyle¹; I. Medan¹

¹Anaesthesia and intensive care medicine, Tallaght University Hospital, Dublin, Ireland

Correspondence: C. McGarrigle

Intensive Care Medicine Experimental 2020, **8(2)**: 001310

Introduction: An acute respiratory disease, caused by a novel coronavirus (SARS-CoV-2), the coronavirus disease 2019 (COVID-19) has spread throughout the world. COVID-19 induces a severe inflammatory response causing acute respiratory distress syndrome (ARDS) and respiratory failure. The management of ARDS is primarily supportive which includes ventilatory and non-ventilatory management. Due to acute lung parenchymal injury, ventilation often proves difficult and rescue measures are required, which include prone position ventilation. In previous studies, prone position ventilation has shown dramatic improvement in oxygenation and ventilation but no statistically significant difference in mortality and ICU length of stay.

Objectives: To Assess the effects of prone positioning on ventilation and oxygenation of patients with COVID-19 ARDS.

Methods: Following ethical approval, data was collected from both written and electronic records (IntelliSpace Critical Care and Anaesthesia information system). All patients admitted to Tallaght University Hospital's Intensive Care Unit (ICU) over a four month period between February 2020 to June 2020 with a COVID-19 positive viral PCR and who were subsequently intubated, ventilated and prone were included in this study. Self-proning, non-intubated patients were excluded. Clinical data was extracted at four periods around each proning session; immediately prior to prone positioning (R1), two hours post prone positioning (R2), one hour pre-supination (R3) and one hour post supination (R4).

Data was collected and analysed using Microsoft Excel.

Results: In total, 16 patients (4F,12M) were intubated and prone. Five patients were of Asian origin, three of African Origin and eight were Caucasian. The mean age was 51 and the median body mass index (BMI) was 31.5 kg/m². 14 patients (87.5%) survived and were discharged from ICU. Significant cardiovascular comorbidities were present in the two non-surviving patients. 77 proning sessions took place in total. The mean day of proning post intubation was day 2, with an average of 4.8 sessions per patient, lasting a mean of 17.1 hours. The mean PaO₂/FiO₂ ratio (PFR) prior to the first proning session was 17 (11–29) versus the mean PFR after the patient's final proning session of 26 (15–46).

A PFR increase of $>$ 30% was present in 44% (34/77) of sessions immediately post proning (R1 vs R2) vs 64% (49/77) found after a full proning session (R1 vs R3), suggesting an improvement in oxygenation with time. Comparing the PFR in the supine position pre and post proning sessions, an improvement was present in 68% of cases (R1 vs R4).

Where end tidal CO₂ levels were accurately recorded, a reduction in the End tidal-Arterial CO₂ gradient was present in 68% (45/66) of

sessions after proning (R1 vs R3) with a median change of -0.3 kPa, suggesting a reduction alveolar dead space.

Conclusion: Prone positioning of patients with ARDS caused by COVID-19 appears to improve the oxygenation and ventilation in a similar manner compared to ARDS attributed to other causes.

Covid-19 Critical ill patients in Santiago de Compostela. Case series

B. Lence¹; C. Rivero¹

¹Intensive Care Unit, Santiago Clinic Hospital, Santiago de Compostela, Spain

Correspondence: B. Lence

Intensive Care Medicine Experimental 2020, **8(2)**: 001338

Introduction: Our experience with Covid-19 critical ill patients in Santiago de Compostela during spring 2020.

Objectives: To learn about what we did and how we did it, getting new perspectives and ideas as next steps to improve.

Methods: We identified 23 patients with severe acute respiratory syndrome that needed ICU admission. Clinical data were reviewed of medical records. The data reported here are those through March 12 to June 26. Each patient had the whole hospital stay of follow-up.

Results: We admitted 23 patients with SARS-CoV19 in ICU. The average age was 65 years old, being the youngest 42 years old and the oldest 80 years old. 19 of those patients were men and only 4 were female.

All patients reported were admitted for respiratory failure, 35% needed mechanical ventilation in the admission moment, finally requiring the 80% of the patients mechanical ventilation (during the ICU stay). The initial approach for 52% (12) of the patients were high flow nasal cannulas, failing to meet the oxygen needs and requiring in 10 of them to initiate mechanical ventilation. In 14 patients (78%) pronal therapy brought benefits. The maximum time on mechanical ventilation was 43 days, with an average amount of 14 days, being the longest 53 days. Most of the initial chest x-ray during the hospital admission showed consolidation in 4/4 lung fields, whilst those x-rays that initially showed diffuse infiltration and only consolidation in 1/4 or 2/4 lung fields deteriorated quickly on the following hours. The initial chest x-ray affectation at the ICU admission was not related to the oxygen support needed.

Concerning the treatment:

- All of the patients in this ICU were treated with hydroxychloroquine and lopinavir/ritonavir, with disparities on how long were administered (between 5 and 15 days).
- Only 1 patient had hypotension and needed vasopressors during the ICU admission.
- 87% (20) of the patients received corticosteroid therapy. 9 with dexamethasone, 10 with methylprednisolone and 1 with hydrocortisone.
- Regarding anticoagulant therapy, all the 23 patients received Low-Molecular-Weight-Heparin in different doses (0.5 mg/kg/day; 1 mg/kg/day; -1,5 mg/kg/day; 1 mg/kg/12 h). More information must be addressed to determine an accurate dosing.
- 56% of the patients received tocilizumab when IL-6 levels exceeded 40 UI/L.
- Only 21% of them required continuous renal replacement therapy.

Furthermore, the highest ICU occupancy rates were on the first week of April, yet maintaining capacity to admit more patients.

Conclusion: During the SARS-CoV19 pandemic, 23 patients were admitted to ICU with the common admission criteria of hypoxemic respiratory failure leading to mechanical ventilation. Most of these patients received corticosteroid therapy and this could play a significant role regarding to mortality: 83% of our patients survived.

COVID-19 in a critical care unit: several characteristics and mortality analysis of patients with severe pneumonia due to SARS-COV-2

M. Aseguinolaza Lizarazu¹; I. Eguibar Villimar¹; M. Diez Bengoechea¹; L. Vidaur Tello¹; T. Ormazabal Zabala¹; R. Sebastian Alda¹

¹Critical care, Hospital Universitario Donostia, San Sebastián-Donostia, Spain

Correspondence: M. Aseguinolaza Lizarazu

Intensive Care Medicine Experimental 2020, **8(2)**: 001347

Introduction: In the face of the SARS-COV-2 pandemic, the intensive care units (ICU) have been involved in a dynamic of hard work by a little known disease, but which has caused serious illness and has involved the use of many health resources. The aim of this study is to show our experience with this kind of patients.

Objectives: The objective of this study is to analyse demographics, clinical and analytical characteristics, complications and health care resources consumption in a cohort of patients with a diagnosis of severe COVID-19 infection admitted to an ICU of a University Hospital. Secondary objective is to analyse factors related with mortality in his group of patients.

Methods: This is a retrospective observational study including all the critically ill patients admitted to ICU with COVID-19 severe infection. Patients were included during the COVID-19 pandemic, starting in March 2020. The analyzed demographic variables included age, sex, comorbidities and severity at admission measured by APACHE II and SOFA scores. Analytic variables studied were those related to prognosis in other studies such as lactate dehydrogenase (LDH), creatine kinase (CK), Ferritin, D-Dimer, C-reactive protein (CRP) or

procalcitonin (PCT). Health care resource consumption was measured by the days of mechanical ventilation and ICU stay. Quantitative variables are expressed as mean \pm standard deviation and the qualitative ones as absolute and relative frequencies. The comparison between quantitative variables was made by student-t test and qualitative variables by chi squared test for a 95% confidence interval.

Results: A total of 60 patients were admitted to our department for severe pneumonia due to SARS-COV-2 and 43 of them (72%) were male. The average age has been 66.5 years, indeed, age has been mortality related factor. Each patient has been admitted to the ICU for 23 days on average. Among all the patients, 82% were intubated and connected to mechanical ventilation (MV) at admission, and this MV has gone on for 19 \pm 11 days, increasing morbidity and mortality, and resource consumption. Overall mortality has been 23.3%, especially up to the age of 60 (under the age of 60, only one patient died amongst 16). High blood pressure ($p = 0.03$), obesity ($p < 0.01$), APACHE at admission ($p = 0.04$) and SOFA at admission ($p = 0.02$) have been related to higher mortality as well. Although they have not been statistically significant, it seems that the elevation of LDH, CRP, PCT, ferritin and D-dimer are associated with greater death rate.

Demographic variables			
Patients (n=60)	Results		
Mean age [p25 -p75]	66,5 [58 - 71,75]		
Sex: Male, Female (%)	43(72%) /17 (28%)		
ICU stay in days [p25-p75]	23 [14,5 30,75]		
Mortality (%)	14 (23,3%)		
<50 (n=7)	0		
51-60 (n= 9)	1 (11%)		
61-70 (n=26)	6 (23%)		
71-80 (n=18)	7 (39%)		
MV at admission n (%)	49 (82%)		
APACHE score / SOFA score	12 \pm 4,6 / 5,1 \pm 2,5		
MV days	19 \pm 11		
Univariate analysis of mortality			
	Dead (%)	Survivors (%)	p
APACHE score	14,2	11,3	0,04
SOFA score	6,4	4,7	0,02
CRP at admission	209,9	190,6	0,56
PCT at admission	0,6	0,37	0,08
LDH / D dimer / ferritine	625 / 2786 / 3061	478 / 5837 / 1750	0,053 / 0,058 / 0,06

Conclusion: Patients admitted to ICU with severe COVID-19 infection have a great mortality with an important health care resource consumption. In this group of patients age, high blood pressure and obesity have been associated with mortality. LDH, ferritine,..... are higher at admission in patients who died.

Intensive Care Medicine Experimental 2020, **8(2)**: 001371

Introduction: COVID-19 has emerged as a rapidly spreading communicable disease affecting people worldwide. A particular concern exists regarding the vulnerability of patients who have been

immunosuppressed prior or during this pandemic. Data on COVID 19 in solid organ transplantation (SOT) that required intensive care are scarce.

Objectives: Describe our mortality in SOT recipients that have been infected with COVID-19 and have required intensive care.

Methods: Case series of adults (age > 18 years) SOT recipients from the Intensive Care Unit (ICU) of a third level hospital in southern Spain with a positive test for COVID-19 between March 24, 2020 and May 29, 2020. The data were extracted from a database of 42 patients that have required admission in our ICU with a positive reversed-transcriptase PCR of COVID-19.

Results: 3 patients were admitted with a median age of 53 years. Our patients were a kidney-pancreas recipient, a kidney recipient, and a lung recipient. They had a median APACHE score of 14, SOFA score of 9, and a Brescia scale of 8. The most frequently found comorbidity was chronic kidney failure. Two patients were in treatment with domiciliary corticoids, two patients with mycophenolate, and three patients with tacrolimus. At the admission time they had a leukocyte median of 2640 mm³, a lymphocyte median of 430 mm³, a CD4 median of 440 mm³, a IgG median of 438 mg/dL, a IL-6 median 46.2 pg/mL, and a C-Reactive Protein median of 100.7 mg/dL. In all of these patients airway isolation were required, with a median of invasive mechanical ventilation (IMV) of 8 days. One patient received High Flow Nasal Cannula (HFNC) support that failed. Two patients suffered renal graft dysfunction, one of them required renal replacement therapies. Three patients received Hydroxychloroquine, two patients received Lopinavir/Ritonavir, one patient received Interferon and one patient received Immunoglobulin. In all of these patients, mycophenolate and tacrolimus were discontinued, maintaining methylprednisolone at 1 mg/kg. One patient was co-infected with CMV and received empirical antibiotic therapy. One patient had secondary bacterial infections during the ICU stay, one Ventilator-Associated Pneumonia and one Catheter-Associated Bacteremia. The three patients were alive at the ICU discharge, and at the hospital discharge. The mean of ICU stay was 10 days, and hospital stay of 26 days.

Conclusion: In our setting, all patients with COVID-19 and TOS survived. These data suggest that the prognosis associated with critical illness due to COVID-19 in SOT recipients may not be as poor as previously reported, and that being a SOT recipient does not indicate worse mortality.

Intensive Care Medicine Experimental 2020, **8(2)**: 001374

Introduction: The COVID-19 pandemic has led to rapidly saturation of resources and the availability of ICU bed. Prone positioning is strongly recommended in intubated patients with severe acute respiratory distress syndrome. Recently, small case series showed feasibility and improvement in oxygenation in awake COVID-19 patients placed in the prone position with noninvasive ventilation (NIV). It is unknown if the proning with NIV can reduce the rate of intubation.

Objectives: To evaluate the feasibility, the safety and efficacy of prone positioning with continuous positive airway pressure (CPAP) in COVID-19 patients with acute hypoxemic respiratory failure.

Methods: This prospective observational cohort study was conducted, from Mars 25, 2020, to September 24, 2020, in King Fahad armed forces hospital, Kingdom of Saudi Arabia. All adult patients with confirmed COVID-19 pneumonia and developed acute hypoxemic

respiratory failure defined by PaO₂/FiO₂ less than 200 mmHg, and required CPAP, were included in this trial, if they fulfill the inclusions criteria. Demographic, clinical, laboratory, radiological, ventilation setting, and treatment data were collected and analyzed. The patient will be included in one of the two groups, CPAP with proning (prone group) or CPAP without proning (supine group). The supine group included either patient refused proning or who used CPAP in the ward. The primary outcome was the rate of tracheal intubation. The secondary outcomes were, the rate of ICU mortality, the length of stay, and the rate of health care workers (HCWs) infected by SARS-CoV2.

Results: In this preliminary analysis, a total of 79 COVID-19 patients were included, 31 patients in the prone group and 48 patients in the supine group. The two groups were similar on term of baseline characteristics, general management and ventilatory support. In the prone group there was significant increase of PaO₂/FiO₂ during proning compared to supine setting. The general acceptance of proning was from moderate to well and no complications or events were observed during proning periods. The rate of intubation was 6.5% (2 patients) in the prone group and 25% (12 patients) in the supine group ($P=0.035$). Five patients died in the supine group versus one patient in the prone group ($P = 0.395$). One nurse caring for a patient in the supine group was infected with SARS-CoV2.

Conclusion: In COVID-19 patients with acute hypoxemic respiratory failure, the use of prone position combined with CPAP, is feasible, safe and decrease the rate of tracheal intubation.

Intensive Care Medicine Experimental 2020, **8(2)**: 001382

Introduction: Although respiratory virus infections are generally self-limiting, they are one of the leading causes of community-acquired pneumonia, acute respiratory failure (ARF), sepsis and death as we have experienced from miserable pandemics in the last two decades.

Objectives: To compare the clinical characteristics and prognosis of COVID-19 and influenza patients with ARF admitted to intensive care unit (ICU).

Methods: Patients with laboratory confirmed COVID-19 who were admitted due to ARF to our ICU between 20th March and 23th June 2020 and patients with laboratory confirmed influenza who were admitted due to ARF between 1st January 2015 and 1st March 2020 were retrospectively evaluated. Clinical characteristics and outcomes of patients were compared.

Results: 36 COVID-19 patients and 59 influenza patients were evaluated and 34 COVID-19 and 55 influenza patients who presented with ARF due to viral pneumonia were included in this study. Age, gender, SOFA scores, duration of symptom onset to hospital and ICU admission were similar between two groups. Diabetes, chronic lung disease and cardiac diseases were more frequent in influenza patients. ECOG, Clinical Frailty Scale© (CFS), APACHE II score of influenza patients were worse than COVID-19 patients. Invasive mechanical ventilation requirement was higher in influenza group, while admission PaO₂/FiO₂ ratio was similar. Frequency of ARDS on admission was higher in COVID-19 patients, but mild ARDS was seen more in COVID-19 patients. Prone positioning was utilized more in COVID-19 patients. Bacterial co- and superinfection, sepsis and acute kidney injury (AKI) were encountered more in influenza group. ICU and hospital mortality in COVID-19 patients were significantly lower than patients with influenza (24% vs 47%, $p=0.025$) (Table).

Table: Clinical Characteristics and Outcomes of Critically-III COVID-19 and Influenza Patients

	All (n=89)	COVID (n=34)	Influenza (n=55)	p value
Age* (years)	63 (55-77)	63 (55-76)	62 (51-77)	0.970
Male gender, n (%)	51 (57)	22 (65)	29 (53)	0.267
Comorbidities, n (%)

Correspondence: M. Wilson

Intensive Care Medicine Experimental 2020, **8(2)**: 001402

Introduction: Northwick Park Hospital supplies a diverse population of at least 40% black, Asian and minority ethnic groups (BAME). During the COVID19 pandemic, the Intensive Care Unit (ICU) experienced an unprecedented demand for beds, leading to the declaration of a critical incident on 19th March demanding a rapid expansion and restructure.

Recent analyses of COVID19 transmission and susceptibility have shown that the BAME population is disproportionately affected by both a high infection rate and increased mortality from COVID19. These inferences have been attributed to both socioeconomic disparity and occupational hazard. Similarly, an association has been found between the male sex and the severity of COVID19 infection.

This study investigates these associations. The large sample size provided within a single clinical setting provides valuable insights into BAME disparity in order to optimise future treatment of COVID19.

Methods: We performed a retrospective cohort study of all the patients admitted to ICU at NWP with COVID19 between 01/03/2020 and 31/05/2020. Data were collected from patient notes, local histopathology databases and the ICNARC database. These included baseline characteristics (ethnicity, date of birth, sex and comorbidities), baseline P/F ratio (PaO₂/FiO₂), organ support requirements and mortality. Statistical analyses were performed in R. We used logistic regression to determine predictors of mortality and differences between BAME and white patients.

Results: 264 patients were admitted to the ICU with COVID19, of which 83.3% of these identified as BAME. 80.3% of patients were male. Stepwise regression showed that increasing age, and male sex, were the significant predictors of low P/F at admission. Logistic regression analyses showed that pre-morbid state (OR 1.67, 95% CI 1.22-2.32), BAME (OR 4.92, 95% CI 1.77-17.70) and age (OR 1.04, 95% CI 1.01-1.06) were significantly associated with requiring haemodialysis, but as expected, only P/F on admission was significantly associated with likelihood of intubation (OR 0.96, 95% CI 0.94-0.99). Regression analyses on admission parameters demonstrated that age (OR 1.05, 95% CI 1.02-1.08), pre-morbid state (OR 1.47, 95% CI 1.07-2.05), and low PF (OR 0.97, 95% CI 0.94-0.99) were significantly associated with death. Adjusting regression for intra-ICU parameters showed that age (OR 1.05, 95% CI 1.02-1.08) and haemodialysis (OR 3.00, 95% CI 1.67-5.44) were the statistically significant predictors of death. Ethnicity was not associated with mortality in the ICU.

Conclusion: While BAME patients are over-represented in ICU admissions for COVID19, the BAME population had parity in severity of ARDS on admission and mortality. Pulmonary capacity at admission was negatively affected by being male and by increasing age, in keeping with national and international data.

Being of BAME ethnicity was significantly associated with haemodialysis requirement on ICU, which is something to be considered during a second wave of the pandemic.

Intensive Care Medicine Experimental 2020, **8(2)**: 001411

Introduction: Coronavirus disease 2019 (COVID19) is caused by severe acute respiratory syndrome coronavirus 2 (SARS-COV2) and represents the causative agent of potentially fatal disease that is of great global public health concern. About 5% are critical infections characterized by acute respiratory distress syndrome (ARDS). There is scarce information about clinical characteristics and prognosis in these patients.

Objectives: The aims of this study are: (I) compare demographic and clinical characteristics of COVID19 versus others respiratory virus. (II) Analyze outcome.

Methods: Retrospective cohort study of all adults admitted to Tertiary Hospital in Spain from October 2018 to 15th June 2020. We evaluated all adults admitted to Intensive Care Unit (ICU) with confirmed SARS-COV-2 virus infection and other respiratory virus with acute respiratory failure. Main variable was COVID19 aetiology. We evaluate overall mortality in ICU and at 60 day of admission. Exposure variables were: demographics, previous conditions, clinical characteristics, severity of illness, pharmacologic, support therapy and outcome. For categorical variables we applied chi square test (fisher when needed) and for continuous t test or U Mann-Whitney test when needed. We allied Kaplan Meier Survival analysis and log rank test for overall 60 day mortality and aetiology.

Results: During the study period there were included a total of 82 patients: 42 patients with confirmed COVID19 versus 40 patients with

other respiratory virus infection and acute respiratory failure. Clinical characteristics of COVID19 cohort were: median age was 60.6, majority were males 64%. The most frequent comorbidity was hypertension (54%), followed by obesity (33%). 3 Patients with solid organ transplantation were included. 64% of patients with COVID19 needed mechanical ventilation and 21% renal replacement therapy. In comparison with those with other respiratory virus infection, COVID19 patients had less severity of illness, SOFA at admission (5 vs 7, p=0.04), APACHE II (12.7 vs 20, p=0.001). Mortality at 60 days was 26.1% (11) in COVID19 and 22.5 in other respiratory virus infection. Survival Kaplan Meier analysis of overall mortality at 60 days and unfavorable did not showed differences between COVID19 and no COVID19 cohort (p=0.74); at this time there were still admitted in ICU 7% of COVID19 patients.

Conclusion: COVID19 patients had more age and less APACHEII and SOFA at admission in ICU than those with other respiratory virus infection. Overall mortality at 60 day was not statistically higher in COVID19 (log rank p=0.74). Taking into account that 7% of COVID19 were still admitted, prognosis variables at longer time (ej: overall mortality at 6 months) may be more precise to evaluate prognosis in COVID-19 patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 001414

Introduction: It has been suggested that COVID-19-associated severe respiratory failure (CARDS) might differ from usual acute respiratory distress syndrome (ARDS) due to failing auto-regulation of pulmonary vessels and higher shunt.

Objectives: To investigate pulmonary hemodynamics in patients with CARDS compared to patients with ARDS due to other causes.

Methods: Retrospective analysis of ten CARDS patients treated on our ICU in 04/2020 and comparison of the data to matched controls with ARDS (n = 10) that were treated on our ICU from 01/2014 to 08/2019 and for whom pulmonary artery catheter data were available.

Results: COVID-19 patients had similar ventilation characteristics and showed similar PO₂/FiO₂ ratio at a higher degree of hypercapnia as compared to ARDS patients as the estimated CO₂ production was significantly higher (p < 0.05). Cardiac output was higher in CARDS vs ARDS patients (mean 8.1 ± 1.7 L/min vs. 5.4 ± 1.5 L/min; p < 0.05). COVID-19 patients had similar pulmonary artery pressure but significantly lower pulmonary vascular resistance. Shunt fraction was similar in CARDS compared to ARDS (mean 26% ± 13% vs. 23% ± 15%, p > 0.05) and was in both groups correlated with hypoxemia, as was VD/VT (CARDS 46% ± 20% vs. ARDS 43% ± 18%; p > 0.05). The arterio-venous pCO₂ difference (DpCO₂) was elevated (CARDS 5.5 ± 2.8 mmHg vs. 4.7 ± 1.1 mmHg; p > 0.05) as was venous-arterial CO₂ gap to arterial-venous oxygen content difference (P(v-a)CO₂/C(a-v)O₂) ratio (CARDS mean 2.2 ± 1.5 vs. ARDS 1.7 ± 0.8; p > 0.05), indicating

global microcirculatory dysfunction in CARDS. AaDO₂ was similar in both groups ($p > 0.05$).

Conclusion: Respiratory failure in COVID-19 patients differs only slightly from ARDS in ventilation characteristics and pulmonary hemodynamics mainly due to increased CO₂ production. Our data indicate microcirculatory dysfunction. More data needs to be collected to assure these findings and gain more pathophysiological insights in COVID-19 and respiratory failure.

Intensive Care Medicine Experimental 2020, **8(2)**: 001427

Introduction: Pathogenesis of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is poorly understood. Neutrophil extracellular traps (NETs) have been involved in infection-related acute respiratory distress syndrome. The role of NETs in SARS-CoV-2 related pneumonia is unknown.

Objectives: Investigate the association between the quantification of blood NETs at ICU admission and the respiratory failure evolution towards refractory hypoxemia in ICU patients with SARS-CoV2 related pneumonia.

Methods: Prospective bicentric study including consecutive patients with SARS-CoV2 related pneumonia admitted in intensive care unit. NETs blood levels were quantified in blood samples at day-1 and day-3 by flow cytometry (using myeloperoxidase [MPO] and citrullinated histones [Cit-H3] markers). The primary outcome was the association between the day-1 blood level of NETs and the number of days with refractory hypoxemia defined by a PaO₂/FiO₂ ratio < 100 mmHg.

Results: 58 patients (median age 62 [54, 69], mostly male (75.9%)) were included in the analysis. The median number of days with severe hypoxemia (PaO₂/FiO₂ < 100 mmHg) was 4 [2, 6] days and day-28 mortality was 27.6% (n=16). In multivariable negative binomial

regression, MPO+ NETs were negatively associated with the number of days with severe hypoxemia within 7 days (0.84 [0.73, 0.97]), while neither single positive Cit-H3+ NETs nor double-positive NETs were significantly associated with the primary outcome. The blood level of NETs was lower at day-1 than at day-3 in patients who died (32.6 [22.3, 70.3] vs. 56.7 [23.3, 105.6] $p < 0.001$, 0.37 [0.0, 1.45] vs. 2.2 [0.0, 4.3] $p < 0.001$ and 4 [1.2, 7.6] vs. 6.8 [1.8, 15.0] $p < 0.001$ for MPO+, Cit-H3+ and double-positive NETs, respectively).

Conclusion: The blood level of NETs at day-1 was negatively associated with the number of days with severe hypoxemia in patients admitted to the intensive care unit for SARS-CoV2 related pneumonia. This could suggest a functional deficit of neutrophils in these patients that require further investigation.

²Acute medicine, Addenbrooke's Hospital, Cambridge, United Kingdom

Correspondence: A.M. Karimi

Intensive Care Medicine Experimental 2020, **8(2)**: 001444

Introduction: Understanding the behaviour of Severe Acute Respiratory Syndrome CoronaVirus 2 (SARS-CoV-2) in precipitating the spectrum of Coronavirus disease (COVID-19) has been the scientific challenge of 2020. Genomewide association analysis has suggested an association with the ABO blood-group system; with blood group A being more susceptible, while blood group O seemingly conferring a protective effect in the development COVID-19.

Objectives:

1. To compare the ABO blood-group of patients admitted with COVID-19 to that of the general population in the UK.
2. To investigate whether any ABO blood groups correlated with more severe illness.

Methods: Contemporaneously recorded data from our electronic medical record system (Epic[®], WI, USA) was used to retrospectively analyse ABO and clinical data of patients admitted to our hospital with PCR positive SARS-CoV-2 for a 6 week period starting April 2020. Data included APACHE II calculations, whether patients received mechanical ventilation, renal replacement therapy or developed thrombotic complications. The peak sustained FiO₂ in ICU patients was deemed if stable for 2 or more hours.

Results: Blood group data was available in 92 hospital patients, 52 of whom went to ICU. The distribution of blood groups was similar to that seen in the background population (Table 1). Overall mortality was non-significantly lower in patients with blood group O compared to patients with blood group A; 16% (95% CI 6-35%) vs 39% (95% CI 20-61%) $p = 0.09$ by chi-squared. Comparison of illness severity markers between the two largest groups (A & O) in ICU did not reveal any obvious indication that blood group A patients had greater severity of illness to explain their apparent worse outcomes (Table 2).

Table 1: Distribution of blood groups amongst COVID-19 patients admitted to ICU and wards

ABO Blood Group	ICU Cohort (n=52)	Ward Cohort (n=40)	Combined Ward and ICU patients (n=92)	Background population rate
A	18 (35%)	13 (33%)	31 (34%)	38%
B	7 (13%)	4 (10%)	11 (12%)	10%
O	25 (48%)	23 (58%)	48 (52%)	48%
AB	2 (4%)	0 (0%)	2 (2%)	3%

Table 2: Severity of illness markers amongst blood group A and O ICU patients

Parameter	A (n=18)	O (n=25)
Median APACHE II score (range)	14 (3-21)	15 (6-30)
Median age (range)	63 (34-77)	64 (17-83)
Median peak sustained FiO2 (range)	0.72 (36-100%)	0.70 (35-100%)
% Mechanically ventilated (95% CI)	78% (55-91%)	84% (65-94%)
% Received renal replacement	44% (25-66%)	40% (23-59%)
% Developed DVT/PE	6% (1-26%)	16% (6-35%)

Conclusion: ABO blood groups in our population were similar to the background population in the UK and did not appear to predict ICU admission. There was a trend towards increased mortality in patients with blood group A amongst those admitted to ICU but this was not associated with the severity of illness markers examined. The finding of increased mortality in patients with blood group A is consistent with a recent large genome-wide association study; the mechanism of this increase in mortality, and implications are currently unclear.

Intensive Care Medicine Experimental 2020, **8(2)**: 001501

Introduction: Severe ARDS due to SARS-CoV-2 infection has been a huge challenge to the health systems. Many adjuvant therapies have been proposed to manage the disease, such as antivirals to reduce viral load, interleukin inhibitors, and early steroids to decrease the inflammatory response, or the use of convalescent plasma to enhance the immune system. Since the evidence of the use of these treatments was scarce, and the pharmacology availability was limited, we decided to apply our standard ARDS protocol, based on the limitation of tidal volume, best PEEP titration, sequential application of neuromuscular blockade and prone positioning, and fluid restriction, leaving extracorporeal oxygenation as rescue therapy for refractory hypoxemia and to administer selected therapies according to different patient profiles: thrombotic or inflammatory profile, based on clinical and laboratory results.

Objectives: To present the results of a protocol on severe respiratory failure due to COVID-19 in the management of patients with severe and critical pneumonia, with selective use of novel therapies.

Methods: Observational clinical study. We analyzed prospectively from March 21st to July 21st, 2020 all patients admitted with severe and critical COVID-19. We describe demographic, clinical, and laboratory characteristics. The main outcomes were hospital stay and hospital mortality. Data were analyzed by descriptive statistics, distribution was evaluated according to the Shapiro-Wilk test, and were expressed according to mean \pm SD and/or median and p25-75, as appropriate.

Results: Hundred thirty-eight patients were included (age 55 years \pm 13.8, 60 women (43.5%), PaO₂/FiO₂ at admission was 148 \pm 34.8. The number of symptomatic days before hospitalization was 7.8 \pm 3.9. SARS-CoV-2 virus was identified in all patients. Mechanical ventilation

in 128 patients. Of them, 66,4% received NMB, prone positioning in 67 (52%). Use of high-dose steroids for a high inflammatory profile in 6 patients. 21 patients were fully anticoagulated due to a high thrombotic profile. No other pharmacological therapies were used, and no patients were connected to ECMO. Tracheostomy use in 13%. The median time in MV and ICU were 12 [9 - 17] and 15 [10 - 20] days, respectively. In hospital and 28-days mortality was 9,4%.

Conclusion: A protocolized management of acute respiratory failure using validated and easy to implement therapies allows satisfactory outcomes. The use of standardized protocols on severe patients and health policies to control infection spreading may act synergistically in the care of communities during pandemics.

Intensive Care Medicine Experimental 2020, **8(2)**: 001530

Introduction: Previous studies have proven that prone positioning optimizes lung recruitment and ventilation-perfusion matching, resulting in an improvement of gas exchange. However, reliable predictors of prone positioning response and the effect on ARDS morbidity and mortality remains to be determined.

Objectives: Evaluate the outcome of patients with ARDS with prone positioning.

Methods: Observational retrospective study on Acute Respiratory Distress Syndrome patients, according to Berlin criteria, mechanically ventilated from January 2017 to December 2019. Patients were divided into those who underwent prone positioning (n = 54) and those who did not (n = 35). Data were extracted from medical records.

Results: 89 ARDS patients were included (mean age of 60,1 \pm 13,7 years, 62 male/27 female). Severity scores were calculated at admission and mean results were 20,3 \pm 7,06 for *Acute Physiology, Age, Chronic Health Evaluation* (APACHE) II, 47,2 \pm 12,7 for *Simplified Acute Physiology Score* (SAPS) II, and 9,46 \pm 3,26 for initial *Sequential Organ Failure Assessment* (SOFA). No statistically significant differences in background characteristics were observed. The main cause of ARDS was pneumonia (n = 57 cases, 64,0%). Moderate ARDS in 47,1% of the cases and severe ARDS in 32,6%.

We found a mean improvement in partial pressure of oxygen to inspired fraction of oxygen in the prone group of 14% vs supine group ($p < 0,001$). After adjustment for other covariates: the severity of ARDS, primary or secondary ARDS, the length of stay in the ICU and the length of hospital stay we did not find a significantly difference in mortality between the two groups. The mortality of patients with severe ARDS at the time of discharge from the intensive care unit, was 34,9% in the prone and 28,6% in the supine group (RR, 0,75; 95% CI, 0,121-4,701; $P = 0,571$), while their 60-days mortality was 46,8% and 28,6%, respectively (RR, 1,06; 95% CI 0,31-13,1; $P = 0,670$).

Conclusion: Although limited by its retrospective nature, small sample size and heterogeneous ARDS etiologies: our study shows that prone positioning contributed to improve the blood oxygenation in patients with moderate and severe hypoxemia, however, does not improve survival in patients with ARDS.

Intensive Care Medicine Experimental 2020, **8(2)**: 001550

Introduction: Coronavirus disease 2019 (COVID-19) is an emerging disease that frequently has a self-limited course, but 15% patients develop pneumonia that requires supplemental oxygen and 5% progress to critical illness with respiratory and organ dysfunctions (1).

Objectives: To describe the characteristics and outcomes of COVID-19 patients admitted to an Infectious Diseases Intensive Care Unit (ICU) in Porto, Portugal.

Methods: Adults with confirmed SARS-CoV-2 infection admitted to the Infectious Diseases ICU of Hospital São João, between March 13 and July 28/2020 and treated with oxygen supplementation or invasive mechanical ventilation (IMV) were included. Demographic and clinical data were collected.

Results: Fifty-seven patients were included (median age 72 years [IQR, 55-78], 63.2% male). One patient still remains in the ICU, 7 were transferred to other ICUs after intubation for IMV and 39 were discharged. Comorbidities were identified in 53 (93%) cases, most frequently hypertension (63.2%) and diabetes mellitus (35.1%). Median time from symptoms onset to admission was 8 days (IQR, 4-12) and the most common were fever (78.9%), dyspnea (57.9%) and dry cough (56.1%). Thirty-one (54.4%) patients received IMV while 18 (69.2%) of the remaining were treated with high flow nasal cannula. Between IMV and non-IMV patients no significant differences were seen in age, sex, comorbidities or respiratory symptoms. Differences between IMV and non-IMV patients lymphocytes, AST, ferritin and D-dimers mean values were $-397 \times 10^6/l$ (95% CI -619 ; 208), 59 U/l (95% CI 28;84), 1095.3 ng/ml (95% CI 383.9;2029) and 3.1 ug/ml (CI 95% 1.86;5.33), respectively. The mean lowest PaO₂/FiO₂ ratio was 94.09 (95% CI 80.33;107.85) in IMV and 180.84 (95% CI 136.77;224.91) in non-IMV patients. IMV parameters, mean (\pm SD), included compliance 39.87 ± 15.09 ml/cmH₂O, PEEP 12.48 ± 2.27 cmH₂O, plateau pressure 25.3 ± 4.1 cmH₂O and driving pressure 13.61 ± 3.87 cmH₂O. IMV duration was 17 ± 9.03 days, eighteen (78.2%) patients needed prone positioning, two CVVHF and two other ECMO-VV. Besides respiratory failure, cardiovascular (40%) and renal (26%) were the most common dysfunctions, and nineteen (38%) patients had bacterial superinfection. Cardiovascular dysfunction and bacterial superinfection were significantly different between the two groups ($p < 0.001$). Hydroxychloroquine (HCQ) was given in 23 cases (46%) and HCQ plus azithromycin in 15 cases (30%), with no side effects. Eleven patients (22%) were given corticoids, one tocilizumab and two remdesivir. Overall mortality was 20% (10 patients), including five IMV patients (20.8%) and five with no indication to escalate intensive care due to subjacent condition. No readmissions were registered.

Conclusion: Although COVID-19 is a new disease that remains largely unknown, critically ill patients may potentially recover if early and

appropriate intensive care is provided. Our cohort allowed us to offer medical and human support to all patients admitted.

Intensive Care Medicine Experimental 2020, **8(2)**: 001564

Introduction: The factors that lead to critical illness in individuals infected with SARS-CoV-2 are not completely understood and the development of severe disease does not seem to be solely related to viral load and could involve an excessive inflammatory response. One aspect of the immune response that has, to date, been greatly understudied in COVID-19 patients is whether lipid mediator production is dysregulated with increasing disease severity. These molecules, which are produced from essential fatty acids, constitute a central part of the immune regulatory mechanisms activated during infections and are responsible for initiating and amplifying inflammation as well as for its termination.

Objectives: We objected to characterise the profile of lipid mediators in patients with COVID-19 in order to identify whether lipid mediator production is dysregulated with increasing disease severity and identifying the pathways that may become disrupted in COVID-19 infections.

Methods: We collected plasma from 41 patients with polymerase chain reaction confirmed SARS-CoV 2 infection that were admitted to Beaumont Hospital, Ireland between the 16th of March and the 1st of May 2020. We categorized the patients into two main groups, severe and non-severe disease. Patients were categorized as severe if they required invasive mechanical ventilation in the intensive care unit. We defined non-severe as those who were managed at ward level with supplemental oxygen or non-invasive ventilation. Employing a liquid chromatography tandem-mass spectrometry-based approach we then quantified lipid mediators from the four main bioactive metabolomes that include the classic eicosanoids and the omega-3 fatty acid-derived pro-resolving mediators. These molecules were identified and quantified in accordance with established criteria.

Results: Eight samples were excluded as they did not meet quality control criteria. Using partial least square discriminant analysis we found that overall plasma lipid mediator concentrations were distinct between the severe group when compared with the non-severe group. Further analysis demonstrated that mediators from the leukotriene (LT) metabolome, including the potent chemoattractants LTD₄ and LTB₄, as well as the pro-resolving mediator Resolvin D1 (RvD1) were upregulated with patients with non-severe disease when compared with those with severe disease. Statistical assessment of lipid mediator concentrations demonstrated a significant downregulation of mediators from the LT metabolome in plasma from patients in the non-severe group when compared with those in the severe group. We also found that the concentrations of the 22-hydroxy-Maresin 1 (22-OH-MaR1), the further metabolite of the pro-resolving mediator Maresin 1, were significantly upregulated in plasma from patients in the severe group. Notably, we did not observe significant differences in plasma prostaglandin concentrations, including PGE₂ and PGD₂, between the two groups. This observation can be attributed to the fact that all patients received paracetamol. We observed an increase, albeit not reaching statistical significance of the Thromboxane B₂ in patients in the severe group which is in line with the increased incidence of thrombosis in these patients. In order to designate the best

subset of lipid mediators as predictors of disease severity, least absolute shrinkage and selection operator regression analysis was used. This analysis identified 4 lipid mediators, LTD4, 20-OH-LTB4, RvD1 and 22-OH-MaR1 that gave the strongest predictive value.

Conclusion: These results indicate that increased disease severity in patients with COVID-19 was linked with a failure to engage lipid mediator biosynthesis. They also suggest that the use of therapeutics that interfere with lipid mediator production and /or actions should be considered with caution given that it may exacerbate disease severity. The present study was limited to one hospital and evaluated lipid mediator concentrations in 33 patients. Despite these limitations the present findings suggest that plasma lipid mediator concentrations may also be useful markers for evaluating the efficacy of therapeutics in rectifying host immune responses during COVID-19 infections.

Intensive Care Medicine Experimental 2020, **8(2)**: 001600

Introduction: COVID-19 outbreak has led to an unprecedented need for mechanical ventilation (MV). Tracheostomy might help ease airway management and early weaning of the patients. However, it has not been widely used since it exposes physicians at high risk of contracting COVID-19 infection.

Objectives: We aim to describe the cohort of the 46 patients who underwent percutaneous tracheostomy during ICU-stay at our unit.

Methods: We retrieved from the electronic medical records data from all COVID-19 patients undergoing tracheostomy during ICU admission at the Rimini Hospital in the period 2/3/2020-29/4/2020.

Results: Among the 68 patients that received MV and admitted to the ICU, tracheostomy was performed in 46 patients (66%). 76% (n = 35) were males and the median age was 68 (range 32-80). Median SOFA score at admission was 7 (3-18). All tracheostomy were percutaneous (Griggs or percutwist). Median ICU length of stay at the day of tracheostomy was 11 days (1-22) and the median P/F ratio before procedure was 172 (67-298). Five complications were recorded, none during the procedure, two bleeding from the stoma, two stoma infections, and one patient experienced accidental decannulation with subsequent cardiac arrest. All complications were treated successfully including the patient with accidental decannulation that survived and was discharged from ICU. ICU-mortality rate was 32.6% (n = 15) with a median ICU length of stay of 23 (7-108). Decannulation was performed before ICU discharge in all of ICU survivors and the median length of open tracheostomy was 17 (3-78). Only one patient was still admitted to the ICU at the 30/07/2020 after 132 days of ICU admission. By following the ICU safety protocol, no healthcare worker involved in the procedures has been infected.

Conclusion: Our results showed that percutaneous tracheostomy may be safely performed in severe COVID-19 patients allowing a better airways management in patients that require long ICU stay.

Improved ROX Index Following Awake Prone Positioning in COVID-19

R. Khorasane¹; A. Isted¹; R. Sykes²; C. Cox²; A. Bhalla²; B. Rose¹

¹Critical Care, University Hospital Lewisham, Lewisham High Street, London, UK, London, United Kingdom; ²Department of critical care, University Hospital Lewisham, London, United Kingdom

Correspondence: R. Khorasane

Intensive Care Medicine Experimental 2020, **8(2)**: 001626

Introduction: Awake Prone Positioning is an increasingly widespread treatment modality for hypoxaemic respiratory failure in patients with COVID-19. We sought to evaluate whether this technique could improve ROX index – a non-invasive composite measure of oxygenation and work of breathing shown to predict need for intubation in patients with acute respiratory distress syndrome (ARDS).

Methods: In this prospective cohort study, adult patients with COVID-19 pneumonia requiring supplemental oxygen were recruited at a district general hospital in London. Baseline characteristics were collected and ROX index calculated as the peripheral oxygen saturation (SpO₂) divided by the product of the fractional concentration of inspired oxygen (FiO₂) and the respiratory rate (RR). Patients were instructed or assisted into prone position and ROX index recalculated at 15 to 60 minutes and again at 120 to 240 minutes where tolerated.

Results: In a cohort of 12 patients, ROX index improved significantly from a median of 3.61 (IQR 3.00 – 5.16) to 4.58 (IQR 3.83 – 5.77) after 15 to 60 minutes (p = 0.012) and in the seven patients that maintained prone position, they experienced a further increase in ROX index to 8.00 (IQR 4.86 – 11.73) at 120 to 240 minutes (p = 0.028).

Conclusion: Awake prone positioning was feasible and significantly improved ROX index, which has previously been shown to predict need for intubation in ARDS. Safe avoidance of intubation of COVID-19 patients would be beneficial to avoid harms from invasive ventilation and to optimize usage of scarce hospital resources in both high and low income countries. ROX Index is a simple composite measure of respiratory parameters that may be valuable in assessing patients when access to blood gas analysis is limited by availability or by patient numbers. Further work is needed to delineate potential risks and outcome benefits of this technique and to clarify its optimal mode of delivery, and to establish whether changes in ROX Index in COVID-19 are associated with patient relevant outcomes.

001628**Viral respiratory infections and ARDS in the pre-Covid19 age, a small case series**R. Amaral¹; C. Carvalho¹; B. Costa¹; H. Santos¹; A. Pais¹; J. Carvalho¹¹Intensive Medicine, Centro Hospitalar De Trás-Os-Montes E Alto Douro, E.P.E., Vila Real, Portugal**Correspondence:** R. Amaral*Intensive Care Medicine Experimental* 2020, **8(2)**: 001628

Introduction: Acute Respiratory Disease Syndrome has one of the core topics of intensive medicine due to its relative high incidence, and important morbidity and mortality. Since Covid19 disease emerged all literature is focusing on this new entity. Through discussions about this respiratory disease some have questioned although Berlin criteria for ARDS are met and because the lung compliance is not the most common in usual ARDS if this not truly ARDS.

Objectives: To report on our experience with viral respiratory infections causing ARDS in 2019, pre-covid19.

Methods: Retrospective analysis of the clinical information of patients admitted in intensive care with diagnosis of ARDS according to Berlin criteria, and laboratory specimens of viral colonization of airway.

Results: We obtained 7 patients with diagnosis of ARDS due to viral pneumonia. Most of the patients were male (n=4), median age 62 (first quartile (1Q) 52 and third quartile (3Q) 74). Severe ARDS was diagnosed in 2 patients median partial arterial oxygen pressure inspired oxygen fraction quotient (PaO₂/FiO₂) of 80,5 (1Q 77,75 and 3Q 83,25); moderate ARDS in 3 patients median PaO₂/FiO₂ 142 (1Q 136,5 and 3Q 149); mild ARDS in 2 patients median PaO₂/FiO₂ 226 (1Q 214 and 3Q 238). Invasive mechanical ventilation was necessary in 42,9% of patients (n=3), the other 4 patients were managed exclusively with non-invasive ventilation. Median days of mechanical ventilation were 11 (1Q 6 and 3Q 15,5) in invasive and 3 (1Q 1 and 3Q 8,75) in non-invasive ventilation. Median positive end expiratory pressure was 8 (1Q 8 and 3Q 10). The 2 patients with severe ARDS were managed with invasive mechanical ventilation and prone positioning. Identified respiratory virus were: rinovirus, adenovirus, influenzae A and B, parainfluenzae, coronavirus 229 and metapneumovirus. Co-bacterial-infection was observed in 1 patient, identified agents were *Moraxella* and *Haemophilus*. Antibiotics were administered to all patients (n=7) and 58,7% (n=6) were treated with anti-virals. Corticosteroids were administered to 5 patients (71,4%). Severity scores were: APACHE II 21 (1Q 16 and 3Q 22,5); SAPS II 40 (1Q 36,5 and 3Q 40,4); SAPS 3 59 (1Q 59 and 3Q 70); SOFA at admission 7 (1Q 6,5 and 3Q 8). Mean length of stay in intensive care was 11 (1Q 5,5 and 3Q 13) days and in hospital was 21 (1Q 13 and 3Q 21,5) days. Hospital mortality was the same of net mortality: 2 patients (28,6%) - with severe ARDS.

Conclusion: Although with limitations due to its retrospective nature, this study presents our reality and exposure to ARDS due to viral pneumoniae. All our patients were medicated with antibiotics, although only 1 patient had confirmed bacterial infection. The majority of patients received corticosteroids. Outcome was linked to disease severity and comorbidities. Applied PEEP levels were lower than does presented by ARDSnet suggesting normal compliance.

001638**Lung Ultrasound abnormalities as a diagnostic adjunct for COVID-19 pneumonitis: a pilot study**J. Powys-Lybbe¹; L. Tong¹; C. Moxey¹; O. Valencia¹; H. Aya¹; J. Aron¹¹General intensive care unit, St George's Hospital, London, United Kingdom**Correspondence:** P.L. James*Intensive Care Medicine Experimental* 2020, **8(2)**: 001638

Introduction: Covid-19 pneumonitis has caused a pandemic surge in Europacross the globe, with almost 700,000 dead at the time of writing [1]. Current diagnosis of Covid-19 is based on PCR detection of surface antigens [2], however radiological features of Covid-19 infection have been reported and use as adjuvant diagnostic tool [3]. We hypothesise that lung uss ultrasound (LUS) can also identify a characteristic pattern associated with Covid-19 infection.

Objectives: We aimed to assess and describe a lung ultrasound pattern associated with COVID-19 pneumonitis.

Methods: We performed a prospective observational study on patients admitted to the ICU in a tertiary hospital during a three-week period. A 6-point Lung ultrasound assessment on all new admissions, scoring each region 0 to 3 (as per FUSIC guidance [4]). The primary outcome was the likelihood ratio (LR) of cumulative lung scores at admission to ICU with COVID-19 diagnosis, confirmed by at least two COVID-19 antigen-positive swabs, using fishers exact test. ROC curve analysis will be used to establish best threshold for continuous variables. P-Value of less than 0.05 is considered statistically significant.

Results: From 69 patients admitted during the study period, 61 were included with a complete US assessment. 43/61 (62%) had a positive antigen COVID-19. Cumulative scores ranged from 0 to 14 to both groups. A cut off of > 6 was used to discriminate the two populations. 34/43 patients (79%) who had a score > 6 were diagnosis of COVID-19. 17/18 patients (94.4%) who scored 6 of under were negative for COVID-19. Positive Predictive Value 0.97 (0.85 – 0.99). Negative Predictive Value 0.65 (0.46 – 0.81). Accuracy 0.84. Area under the Curve 0.87. OR 64.2 (7.51 – 549.4). Sensitivity 79% (0.65 – 0.89) specificity 94% (0.74 – 0.99).

Conclusion: A cumulative score greater than 6 on 6-point Lung Ultrasound is a useful screening tool for COVID-19 pneumonitis.

001611**The role of Brixia score to assess severity of lung damage and management of ventilatory support in severe COVID-19 patients**M. Emily¹; P. Giaccaglia¹; C. Serraiocco²; R. Mitri²; R. Lupi²; T. Digiacom²; S. Cicconi²; R. D'angelo²; E. Cavagna³; G. Nardi²; A. Potalivo²; J. Montomoli²; F. Facondini²¹Anesthesia and intensive care unit, Marche Polytechnic University Faculty of Medicine, Ancona, Italy; ²Anaesthesia and intensive care, Infermi Hospital, AUSL della Romagna, Rimini, Italy; ³Dept of radiology, Ospedale "Infermi" di Rimini, Rimini, Italy**Correspondence:** J. Montomoli*Intensive Care Medicine Experimental* 2020, **8(2)**: 001611

Introduction: Adequate ventilation strategy is crucial in patients affected by COVID-19. The Brixia score could help categorizing patients.

Objectives: Our purpose was to observe Brixia score values and the outcome of different ventilation strategies.

Methods: Hospitalized COVID-19 patients at Rimini Hospital requiring noninvasive ventilation (NIV) or invasive mechanical ventilation (IMV) between February 26 and April 18, 2020 were enrolled in this observational cohort study and followed up to 60 days after hospital admission. The Brixia-score assesses the extent of lung damage in COVID patients dividing each lung into 3 sectors on the transverse plane; to each of the obtained six sectors a score is assigned, ranging from 0 (no alteration) to 3 (interstitial-alveolar infiltrates). The overall score may

range from 0 to 18 and it was reported by the radiologist at the time of the chest x-ray.

Results: 112 patients were treated with NIV and/or IMV. Among those, 46 (41.1%) were treated only with NIV, 25 (22.3%) underwent IMV after a NIV trial, and 41 (36.6%) were treated only with IMV. The Brixia score among patients with a successful NIV trial was higher than among patients that failed it although it did not reach the statistical significance (12.1 ± 2.6 vs 10.9 ± 3.7 , p-value 0.12). Brixia score was obtained at the time of endotracheal intubation among patients that failed a NIV trial and among patients that were treated with IMV without a NIV (13.8 ± 2.8 vs 13.8 ± 2.5 , p-value 0.99). Patients who failed the NIV trial had a Brixia score of 10.8 ± 3.5 before the NIV which worsened to 13.6 ± 2.7 ($p = 0.002$) when tracheal intubation was performed.

Conclusion: Although the Brixia score was able to identify patients with a more severe degree of interstitial-alveolar infiltrates it has some limitation when used to guide the decision of the ventilatory strategy to adopt with COVID-19 patients.

Tracheal button as a safely artificial airway removal protocol during COVID 19 PANDEMIA in patients with percutaneous tracheostomy in ICU

O. Moreno Romero¹; MT. Cruces Moreno¹; M. Muñoz Garach¹; P. Fernandez Morales¹

¹Intensive Care Unit, Hospital Universitario Clínico San Cecilio, Granada, Spain

Correspondence: O. Moreno Romero
Intensive Care Medicine Experimental 2020, **8(2)**: 001275

Introduction: decannulation is an important step for our critical patients with a tracheostomy during the weaning process and its failure supposes a higher morbidity, mostly in terms of bronchoaspiration, specially in the time of isolation during Covid-19 pandemic, where the response to an emergency inside the box could be prolonged.

Objectives: First, to analyze the use of tracheal button during an artificial airway removal protocol in patients with tracheostomy and isolation with Covid-19 pneumonia in ICU. Second, to describe our complications, if present.

Methods: A prospective 3 month-study of all patients admitted to our ICU, which reconverted from usual 20 to a 40-bed unit, with COVID-19 pneumonia who needed invasive mechanical ventilation (IMV), a

percutaneous tracheostomy and a tracheal button during a maximum of 24 hours immediately after decannulating. Variables analyzed: Patient data (sex, age, SAPS II), complications of tracheal button, and from all patients (mean days of IMV, mean time of ICU stay and ICU mortality rate).

Results: We treated 49 patients with COVID-19 pneumoniae: men 35 (71%). Mean age 60,2 years (32-78). SAPS II of 50,8 (39-68). 44 patients underwent IMV (89%), 28 (63%) needed a percutaneous tracheostomy for weaning (22 (78%) men). In 9 patients (32%) we applied a tracheal button. Mean time of MV of 21,3 days (17-36). Global mortality rate Covid-19 patients in ICU 20%(10 patients), all mechanically ventilated: 6 as a limitation of therapeutic effort and 4 as multiple organ dysfunction/septic shock, none after removing artificial airway. Complication of tracheal button was mostly discomfort which needed removing it before 16 hours in 2 patients (25%).

Conclusion: The application of tracheal button is a safe technique of removing definitively artificial airway in isolated patients with Covid-19 infection. Discomfort was seen in 25% and needed an early removal. No serious complication was seen, although our sample is small.

Percutaneous Tracheostomy in ICU in the time of COVID 19 Pandemia

O. Moreno Romero¹; I. Cruz Valero¹; J. Tejero Aranguren¹; M. Muñoz Garach¹

¹Intensive care unit, Hospital Universitario Clínico San Cecilio, Granada, Spain

Correspondence: O. Moreno Romero
Intensive Care Medicine Experimental 2020, **8(2)**: 001280

Introduction: Percutaneous tracheostomy is an essential procedure for weaning in patients with SARS and invasive mechanical ventilation specially to minimize complications due to weakness of prolonged ventilation.

Objectives: First, to describe the characteristics of all percutaneous tracheostomies performed in our patients with new Covid-19 infection admitted to our ICU and performed by intensive care physicians. Second, to analyze the infection rate of the ICU workers after implementing these technique.

Methods: A prospective 3 month-study of all patients admitted to our ICU, which reconverted from usual 20 to a 40-bed unit, with COVID-19 pneumonia who needed invasive mechanical ventilation (IMV) and a percutaneous tracheostomy for weaning. All tracheostomies were performed by 2 intensive care physicians and 1 nurse, all with a “personal protection equipment” (PPE) and a percutaneous tracheostomy kit. Variables analyzed: patient data (sex, age, SAPS II), mean days of IMV, number of tracheostomies and the day it was performed, complications, mean time of ICU stay, mortality rate. Secondly, describe our ICU staff infection rate before and after initiating tracheostomies.

Results: We treated 49 patients with COVID-19 pneumoniae: men 35 (71%). Mean age 60,2 years (32-78). SAPS II of 50,8 (39-68). 44 patients underwent IMV (89%), 28 (63%) needed a percutaneous tracheostomy for weaning (22 (78%) men). Mean day of tracheostomy 11 (6-16). Mild haemorrhage as complication in 4 (14%). Global mortality rate Covid-19 patients in ICU 20%(10 patients), all mechanically ventilated: 6 as a limitation of therapeutic effort and 4 as multiple organ dysfunction/septic shock. Mean time of ICU stay in ventilated patients, 20,8 days (5-43). Global mortality rate in ICU 19,6%(10 patients). None of the staff was infected after initiating this technique. Infection rate during first period: 8 workers from a total of 135 (6%): 3 doctors, 5 nurses.

Conclusion: A percutaneous tracheostomy in ICU during covid-19 infection can be performed safely for the patient and our workers with only 6% of infection rate in workers and none after initiating the technique. 64% needed tracheostomy as a weaning protocol with a mean day of perform of 11 days. Our ICU mortality rate was 19%.

001287

Optimal Timing of Tracheostomy Insertion - Mechanical Ventilation RequirementsC. Cox¹; N. Bandla¹¹Critical Care, University hospital of north Midlands, Stoke-on-Trent, United Kingdom**Correspondence:** C. Cox*Intensive Care Medicine Experimental* 2020, **8(2)**: 001287

Introduction: Percutaneous Tracheostomy on Intensive Care is an established practice [1]. Timing of Tracheostomy with regards to the duration of ICU stay is well researched [2]. But the optimal timing of Tracheostomy with regards to the degree of ventilatory support is not well researched. The French Tracheostomy guidelines [3], suggest that the patients that are severely hypoxemic (PaO₂/FiO₂ < 13.3 Kpa with a PEEP of >10 cm H₂O) are not suitable for an airway procedure as this can significantly worsen their clinical situation. The general consensus among the ICU clinicians is that it is safe to perform a Tracheostomy when FiO₂ is < 50% with a PEEP < 10 cm H₂O.

Objectives: Our aim was to determine the optimal time of Tracheostomy in relation to the degree of ventilatory support. It was observed that patients have suffered episodes of desaturation and increased ventilatory requirements following the procedure, demanding a review into the clinical practice. We reviewed the pre-procedural ventilatory requirements and post procedural ventilatory requirements at 6, 12, 24 and 48 hours after the procedure.

Methods: We performed a retrospective analysis of the mechanical ventilation data in a university hospital adult intensive care unit and a major trauma centre over a 3-month period. The review is performed using the electronic notes of patients that underwent a percutaneous tracheostomy.

Results: A total of 51 patients were eligible to be reviewed. The mean age is 59 years with an age range of 20-81 years. Out of hospital cardiac arrest, Community Acquired Pneumonia, Traumatic Brain Injury were the three main admission diagnoses. Poor neurological recovery and facilitation of respiratory weaning were the two main indications for Tracheostomy. The mean day for insertion was day 9 of mechanical ventilation.

24 hours prior to tracheostomy insertion the mean PEEP among 51 patients was 7 and the mean PF ratio was 32 Kpa. There were deviations from the general safety consensus e.g.: one patient with a PEEP of 14 and another patient with a PF ratio of 17kpa at the time of procedure.

Following tracheostomy, ventilator settings and oxygenation were reviewed at 6 hours, 12 hours, 24 hours and 48 hours. There was no significant deterioration in the PF ratios and the degree of ventilatory support among our patients at 6 hours, 12 hours, 24 hours and 48 hours after the procedure. Although, several episodes of short-lasting hypoxia and mucus plugging were noticed.

Conclusion: The retrospective analysis of the ventilatory data in a population of 51 mechanically ventilated patients revealed that percutaneous tracheostomy is reasonably safe with a PEEP of < 10 cm H₂O and FiO₂ of < 50%, when performed by experienced clinicians.

001460

A single centre retrospective cohort study of the survival differences associated with the timing of tracheostomy in patients ventilated for more than 14 daysT. Gordon¹; A. Waite¹; N. Main¹¹Critical Care, Royal Liverpool University Hospital, Liverpool, United Kingdom**Correspondence:** T. Gordon*Intensive Care Medicine Experimental* 2020, **8(2)**: 001460

Introduction: Tracheostomy is often performed to aid weaning from mechanical ventilation but the timing of tracheostomy has not been shown to confer a mortality benefit [1]. As practice in our department tends towards conventionally late tracheostomies, we aimed to determine whether there was a difference in outcomes for patients ventilated for > 14 days, who i) underwent tracheostomy on or before day 14 of their ICU admission; ii) underwent tracheostomy after 14 days; or iii) had prolonged intubation without tracheostomy.

Methods: We retrospectively reviewed the notes of patients admitted to the Royal Liverpool University Hospital ICU who were mechanically ventilated for > 14 days between January 2015 and January 2020. Patients admitted with a tracheostomy already in situ were excluded. Data collected included demographic information, APACHE II score, ICU length of stay (LOS), day of tracheostomy, and mortality on ICU and hospital discharge. The primary outcome was survival to hospital discharge. Patients who had a tracheostomy on or before day 14 are referred to as the 'earlier' group, whilst patients who had a tracheostomy after day 14 are referred to as the 'later' group. Statistical analysis was performed in IBM SPSS 25.0 using X2 tests (Fisher's Exact Test where appropriate), Kruskal-Wallis or Mann-Whitney U tests.

Results: In total 246 patients were ventilated for >14 days. Of these patients, 91 (37.0%) had an earlier tracheostomy, 66 (26.8%) underwent later tracheostomy and 89 patients (36.2%) were not tracheostomised. Median day of tracheostomy in the earlier group was day 11 (IQR 8-13) and in the later group day 18.5 (IQR 16.0-21.3, p<0.001). There was no difference in age or APACHE II scores between the two tracheostomy groups. Patients with a later tracheostomy had a longer LOS (later tracheostomy median LOS 35.8 days [IQR 30.8-48.0] vs earlier tracheostomy median LOS 28.0 days [IQR 22.5-42.30] vs no tracheostomy median LOS 23.6 days [IQR 18.5-29.2], p<0.001) and more days of mechanical ventilation (later tracheostomy median 31 days [IQR 24.0-41.3] vs earlier tracheostomy 25 days [IQR 19.0-34.0] vs no tracheostomy 19 days [IQR 16.0-23.5], p<0.001). In the earlier tracheostomy group, 73 patients (80.2%) survived to hospital discharge; in the later group, 41 patients (62.1%) survived; and of those who did not undergo tracheostomy, 48 patients (53.9%) survived (p<0.001).

Conclusion: Patients who were ventilated for >14 days had a better rate of survival to hospital discharge when a tracheostomy was performed within the initial 14 days of their ICU admission compared to later during their admission or not at all. Our study is limited by its retrospective nature and there may be confounding factors influencing the poorer outcomes in those patients who were tracheostomised after 14 days, not represented by the data collected. Further research is indicated to assess the impact of earlier tracheostomy on patient-focused outcomes such as ability to engage in rehabilitation.

Intensive Care Medicine Experimental 2020, **8(2)**: 001498

Introduction: Data on the functional outcomes of patients surviving an intensive care unit (ICU) admission for COVID-19 is sparse [1]. It is widely recognised that Speech and Language Therapists (SLT) have an essential role within ICU to support patients achieving optimal communication and swallowing function post critical care [2]. Patients diagnosed with COVID-19 were intubated and ventilated for prolonged periods, increasing their risk of post-extubation dysphagia [1].

Objectives: To evaluate the mean and median duration of commencing a normal diet in patients with COVID-19 who were tracheostomised and to compare this with data collected on tracheostomised patients referred to SLT in 2018, who were admitted to the same intensive care unit at a Tertiary Specialist Cardiothoracic centre.

Methods: During the period March to June 2020 (inclusive), SLT was referred and provided intervention to 30 tracheostomised COVID-19 patients. Data was contemporaneously collected regarding intubation, extubation, tracheostomy insertion and every SLT intervention, including diet changes.

This data was compared to data collected over a 5-month period in 2018, in which 31 cardiothoracic or cardio-respiratory tracheostomised patients were referred and seen by SLT.

This data was analysed retrospectively, in terms of the time taken to resume a normal diet post tracheostomy insertion.

Results: A total of 25 COVID-19 patients were seen for dysphagia intervention, by SLT, post tracheostomy. There were 22 male and mean age was 52. The mean time taken for tracheostomy patients to commence a normal diet was 13.2 days (Median 13.5).

This was compared to data from 2019, when 21 patients were seen for dysphagia intervention post tracheostomy insertion, by SLT. There were 8 males and the mean age was 61. These patients had a mean time to commence a normal diet of 14 days (Median 13.1).

Conclusion: These are small but comparable patient samples, that show that there does not appear to be a significant difference in the length of time taken to commence a normal diet in tracheostomised patients with COVID-19 patients, when compared to the "normal" cohort of patients seen at a Tertiary Cardiothoracic Centre in London, despite the differences in the mean age of the sample groups.

Intensive Care Medicine Experimental 2020, **8(2)**: 001527

Introduction: Guidelines for long-term ventilation agree that tracheotomy has several benefits for patient treatment [1]. However, during the coronavirus disease-19 (COVID-19) pandemic it is widely seen as an unsafe procedure with a high risk of infection [2,3]. However, as mentioned by Piccin et al., theoretical considerations might speak in favour of early tracheotomies also in COVID-19 patients, such as earlier and safer weaning in order to free ICU capacity as soon as possible and a reduced need for analgosedation, the drugs which were running out in many regions, including ours [4]. Most of these considerations are of theoretical nature, little clinical data is available on tracheotomy in COVID-19 patients. In our retrospective study, we evaluated tracheotomies performed on 16 COVID-19 patients to assess the risk of infection for HCWs, adverse events and the time, patients spend on a ventilator.

Methods: We evaluated tracheotomies performed on 16 COVID-19 patients as there is considerable disagreement if and how to implement tracheotomies in COVID-19 patients. All tracheotomies were performed bedside according to our standard protocol for dilatation tracheotomy. Tracheotomies were performed by experienced ICU physicians and trainees under supervision. Four Patients were on ECMO support during tracheotomy. Personal protective equipment (PPE) consisting of a protective gown, a N95 (FFP3) facial mask, goggles, visor and double layer of gloves was used in all procedures. Patients or legal representatives gave informed consent to the procedure. Infections on HCW were monitored by frequent nasopharyngeal swabs.

Results: Patients were in mean 61 years old (median age 60 ± 7 years; 15/16 male), mean BMI was 31.3 kg/m² (median 29.6 ± 6.9 kg/m²). Most frequent pre-existing medical condition was arterial hypertension. All procedures were percutaneous dilatation tracheotomies (PDT). Mean time between intubation and tracheotomy was 8.35 days, (median 7.5 ± 5 days). Mean time of mechanical ventilation after tracheotomy was 30 days (median; SD 24.5 ± 15.9 days). There was no procedure related complication or death due to tracheotomy. Mortality in COVID-19 patients undergoing tracheotomy was 6 out of 16 (37.5%). No SARS-CoV2 infections were recorded in tracheotomy-performing healthcare workers (HCW) or other team members.

Conclusion: Tracheotomy in COVID-19 patients is almost identical to patients without COVID-19. The only difference is the PPE during the intervention. Tracheotomy is a safe procedure in COVID-19 for both patients and HCW under PPE. Given the shortness in ventilators and medication that are reported from some areas, it might be feasible for safe and forward patient management during COVID-19.

Intensive Care Medicine Experimental 2020, **8(2)**: 001602

Introduction: During the Covid-19 pandemic an unprecedented number of patients have required intensive care unit (ICU) admission and prolonged ventilation, posing a significant threat to availability

of resources. Early tracheostomy could benefit this cohort in terms of reduction of duration of mechanical ventilation, length of ICU stay (LOS), delirium and laryngeal injury [1]. However, professional societies advocated the delay of tracheostomies or discouraged them altogether given the expected increase in risk of aerosol-generating procedures (AGP) [2-3]. We performed tracheostomy in an effort to deal with predicted pandemic related resource shortages and to reduce ICU weakness and hospital stay.

Objectives: To compare patient characteristics, tracheostomy complications and evidence of viral transmission to staff.

Methods: Prospective, single centre, service evaluation project. We set out a multidisciplinary approach to tracheostomy insertion, both surgical and percutaneous, the principal aim of which was staff safety. Selection for tracheostomy criteria were defined as: $\text{FiO}_2 \leq 50\%$, positive end-expiratory pressure (PEEP) ≤ 10 for at least 24hrs prior to procedure, unready for trial of extubation and likely need for prolonged ventilation. We performed modified surgical and percutaneous tracheostomies aiming to reduce aerosolisation. This involved personal protective equipment (PPE) as per Public Health England (PHE) guidelines with sterile gown and gloves donned over the PPE. The modified percutaneous technique included using 3 drapes and use of muscle relaxation/paralysis and ventilation pauses. Following tracheostomy, we documented complications and outcomes. We surveyed the operators regarding evidence of infection.

Results: Tracheostomy was performed in 33 out of the 74 patients that were admitted in our ICU. 14 were percutaneous and 19 were surgical. Patients were predominantly male (63.6%), median age was 64 (IQR:58-68). Tracheostomy was performed after 7.5 days (median, IQR:5-12) from intubation and after 10 days (median IQR:7-14) of symptoms prior to ITU admission. We have not seen a significant difference in tracheostomy cuff leak nor wound infection/breakdown associated with either insertion technique. There was an increase in $\text{PaO}_2:\text{FiO}_2$ ratio from 23.1 (median, IQR:19-26) prior to the procedure to 26 (median, IQR: 19-35) after. Mortality was 20.6% (7 patients). 26 patients (78.8%) have been discharged home. There were no episodes of absence of staff with COVID-19 like illness and operators performing tracheostomy all had negative antibodies.

Conclusion: We have demonstrated that earlier tracheostomy in stable COVID-19 pneumonitis patients, with modifications to insertion technique, is feasible. We have not seen increased complication rates or instances of staff infection with COVID-19 during the study period. Earlier insertion during the pandemic may allow for improved resource allocation and reduction in upper airway complications related to prolonged oro-tracheal intubation.

Intensive Care Medicine Experimental 2020, **8(2)**: 001621

Introduction: The Covid-19 pandemic has placed an extraordinary burden on critical care medicine globally. Supportive care continues to be mainstay of treatment.¹ At the time of the study two thirds of Covid-19 patients who required critical care in the UK had mechanical ventilation within 24 hrs of admission.² Due to changing guidelines, there was little evidence on the appropriate mode (surgical vs bedside) of tracheostomy for patients admitted to Intensive care unit. Some studies suggested that early tracheostomy was associated with better outcomes³ than late tracheostomy.⁴

Objectives: This is a prospective observational study looking at possibility of doing percutaneous tracheostomy in Covid19 patients admitted in a tertiary hospital intensive care unit requiring invasive mechanical ventilation.

Methods: The present study involved review of covid-19 patients who underwent tracheostomy during their stay in our intensive care unit from 18th of March 2020 to 29 th of April 2020.(6 weeks). Data related to demographic parameters, duration of ventilation with Endotracheal tube, day and type of tracheostomy from time of ICU admission and outcome were reviewed.

Results: 20 patients underwent planned tracheostomy during the study duration with 15 males (75%) and 5 female patients (25%). The overall mean age was 55.1yrs; for males 57.13 and for females 49.20% had normal BMI, 20% pre obese and 60% were obese. Mean days of ventilation with ET tube was 13.15 +/- 6.53. Earliest tracheostomy was done on day 8 of ICU admission and latest was on day 30 of ICU admission. Median day of tracheostomy was Day 14. 11 (55%) patients underwent percutaneous tracheostomy in the ICU while 9 (45%) patients underwent surgical tracheostomy in operation theatre. Of the 9 surgical tracheostomy patients, 2 were difficult percutaneous tracheostomy that were subjected to surgical tracheostomy. 8 patients were discharged to ward, 9 patients continue to be ventilated and 3 patients died during the study.

Conclusion: This study shows that percutaneous tracheostomy can be safely done on Covid 19 patients in an Intensive care unit with adequate planning and preparation. Nevertheless, a surgical tracheostomy should be considered when necessary.

Intensive Care Medicine Experimental 2020, **8(2)**: 001435

Introduction: Fluid overload has been associated with increased morbidity and mortality in critically ill patients.

Objectives: To assess the efficacy and tolerance of a rationalized diuretic strategy to treat fluid overload after shock in patients undergoing mechanical ventilation.

Methods: The IRIHS study (NCT 02345681) was a single-blind, randomized-controlled study performed in 4 intensive care units (ICUs) in France, from May 5th 2015 to February 2nd 2019. Patients were eligible in case of fluid overload defined as in-ICU weight increase $\geq 3\%$, mechanical ventilation ≥ 24 hours, and hemodynamic stabilization (vasopressors drugs discontinuation > 6 hours; dobutamine $\leq 10 \mu\text{g}\cdot\text{kg}^{-1}\cdot\text{mn}^{-1}$). Patients were randomized into diuretic group (intravenous furosemide, twice a day, maximum daily dose of 250 mg from randomization until successful extubation), or a control group without furosemide. The primary outcome was the fluid balance, defined as weight variation, from randomization to successful extubation. The main secondary outcome was the safety of diuretic.

Results: 171 patients were randomized, 5 patients who did not satisfy the inclusion criteria were excluded and thus, 166 included in analysis: 77 in the diuretic and 89 in the control group. The primary outcome was available in 144 (84.2%) patients. In the complete cases analysis, fluid balance was $1.4 [-2.5;4.5]$ kg in the diuretic group and $6.4 [0.5;11.2]$ kg in the control group ($p < 0.001$). In the multiple imputation analysis, fluid balance was significantly decreased in the diuretic group ($\beta = -4.8$ 95%CI $[-7.3;-2.5]$, $p < 0.001$). Eleven (14%) patients died in ICU in the diuretic group, and 16 (18%) patients in the control group ($p = 0.5$). The rates of kidney failure were respectively 55 (63.2%) and 55 (73.3%) in the diuretic and the control group ($p = 0.2$).

Conclusion: In this multicenter randomized-controlled study, diuretics decreased the fluid overload of critically ill patients as compared to a no-diuretic policy.

Intensive Care Medicine Experimental 2020, **8(2)**: 001447

Introduction: Lung protective ventilation is the cornerstone of the ventilatory management of COVID-29 related ARDS (C-ARDS). Lung recruitment maneuvers (RM) and their related optimum PEEP setting are frequently used as adjuvant interventions. However, as lung collapse does not seem to be an important pathophysiologic component, these interventions may be less effective in C-ARDS.

Objectives: To study the role of RM and individualized PEEP settings as adjuvant lung protective interventions in the management of ventilated C-ARDS patients. We specifically analyzed the obtained PEEP levels and the effects on lung mechanics.

Methods: Retrospective analysis of all registered RM followed by a decremental PEEP titration performed in C-ARDS patients performed during the peak of the COVID pandemic in a teaching tertiary hospital ICU. Maneuvers were registered either by electrical impedance tomography (EIT- Enlight 1800, Timpel) or a sequential automated recruitment maneuver (Servo-u, Maquet CC). We compared individual PEEP levels determined during a decremental PEEP trial by global (Cg)

or regional (Creg) compliance. Cg was defined by the maximal global compliance and Creg by the point of minimum overdistension and collapse as measured by EIT(1). We also analyzed differences in PEEP individualization between supine and prone positioning. After checking for normality of the data distributions means were compared using t-test for independent variables.

Results: The analysis includes a total of 90 registered RM-PEEP titrations (60 in supine and 30 in prone) in 19 patients (4.6 RM per patient). Recruitment pressures (mean \pm SD) were $48 \pm 4/33 \pm 4$ cmH₂O (inspiratory pressure/PEEP). Obtained individualized PEEP levels were 10.5 ± 2.2 cmH₂O for Cg and 8.8 ± 2.3 cmH₂O for Creg ($p < 0.05$).

Respiratory system compliance, plateau and driving pressures improved after RM and PEEP setting from 37.1 ± 14.2 to 42.5 ± 13.8 ml/cmH₂O $p < 0.001$; 24.9 ± 3.6 to 22.7 ± 3.1 cmH₂O $p < 0.001$ and 13.8 ± 3.1 to 11.5 ± 2.8 cmH₂O $p < 0.01$, respectively. There were no differences between supine and prone position in individualized PEEP levels (Cg 10.6 ± 3.2 vs 10.2 ± 3.33 and Creg 8.9 ± 3.1 vs 8.6 ± 3.6) and respiratory system compliance was better in supine than in prone (41.9 ± 13.8 vs 42.8 ± 16.8 $p < 0.05$) respectively. At the determined Cg and Creg PEEP levels lung protective ventilation resulted in a percentage overdistension of 10 ± 7.9 and $4.5 \pm 3.4\%$ and collapse of y 3.4 ± 3.6 and $4.5 \pm 2.5\%$ of the total lung respectively as measured by EIT. Small changes in the applied PEEP levels resulted in important changes in the percentage overdistension and/or collapse.

Conclusion: Lung recruitment and individualized PEEP titration was an effective adjuvant lung protective intervention. It allowed to adjust and minimize PEEP in each individual patient and at different stages during the evolution. The individualized PEEP levels according to Creg were lower with less overdistension but more collapse than the ones according to Cg.

Intensive Care Medicine Experimental 2020, **8(2)**: 001457

Introduction: In line with NHS England guidance [1], during the first wave of the COVID-19 pandemic where appropriate all patients admitted to hospital, irrespective of COVID-19 status, were assessed for frailty, using the Rockwood Frailty Scale as part of a holistic assessment.

In this retrospective cohort study, we aimed to assess the impact of frailty, age and comorbidities in patients with COVID-19 requiring invasive ventilation.

Methods: We retrospectively reviewed case notes of all patients admitted to the Royal Liverpool University Hospital Accident and Emergency (A&E) Department, between March 23rd and April 23rd 2020 with a positive COVID-19 RT-PCR result. Routine data, including demographic data, comorbidity data and Rockwood Frailty Score, were extracted. We assessed the predictive value of age, comorbidities and Rockwood Frailty Scores for disease progression to requiring invasive ventilation. Receiver operating curves were generated to illustrate sensitivity and specificity for each variable to predict the need for invasive ventilation.

Results: Patients with a diagnosis of COVID-19 who progressed to invasive ventilation were younger with a median age of 58.5 [53.23;

59.81] years compared to 72 [58.25; 81] years ($p < 0.001$). The majority of patients invasively ventilated had a Rockwood Frailty Score < 3 (85%). Patients who required invasive ventilation were less likely to suffer from comorbidities including COPD, asthma, hypertension, chronic kidney disease, hepatic disease, diabetes mellitus, atrial fibrillation, malignancy or hypercholesterolemia and were less likely to have a history of myocardial infarction or stroke ($p < 0.01$).

Area under the curve for age was 74.2%, and 87.1% for Rockwood Frailty Score. For comorbidities, AUCs were between 47% and 59%, indicating a low predictive value.

Conclusion: Patients presenting to our A&E Department with a higher Rockwood Frailty Score were less likely to be admitted to ICU and to be invasively ventilated. Similarly, the age of patients on ICU was significantly lower than for patients presenting to A&E who had confirmed COVID-19. Our results are in line with large databases [2] that demonstrate that during the COVID-19 pandemic frail patients and those requiring support in their activities of daily living have been less frequently admitted to ICU compared to patients with viral pneumonia in non-pandemic situations. During pandemics, shortness of ventilators may become a reality, supporting the need for careful planning and triaging of patients requiring invasive ventilation to identify those who will need scarce resources early during their hospital admission.

Intensive Care Medicine Experimental 2020, **8(2)**: 001535

Introduction: The surge of patients with COVID19 severe acute hypoxemic respiratory failure has put resources at their limits.

Objectives: To describe how severely hypoxemic patients were managed with noninvasive and invasive respiratory support in the Catalan ICU network between 15 March and 15 April.

Methods: Consecutive patients admitted between 15 March and 15 April in 26 ICUs, who tested positive for SARS-CoV-2 (RT-PCR in a nasopharyngeal swab) and had severe acute hypoxemic respiratory failure, presenting with bilateral infiltrates in the chestX-ray and requiring invasive mechanical ventilation. Follow-up time was till ICU discharge.

Study was approved by the Ethics Committee of the coordinating center (HospitalUniversitari Sant Pau, Barcelona).

Results: A total of 1388 patients required invasive mechanical ventilation and overall mortality rate was 35% (491/1388). Most common single modes of oxygenation before intubation were facemask with oxygen reservoir in 39% patients (538/1388), of whom 182 died (34%), and high flow nasal cannula in 22% patients (308/1388), of whom 88 died (29%); $p = 0.12$ for mortality differences.

Once intubated, the most frequent ventilator mode was volume assist-control ventilation and was used in 1236/1388 patients (89%). The most frequently used ventilators were conventional ICU machines in 66% patients (915/1388), and anesthesia machines in 12% patients (169/1388). The anesthesia machines were used when conventional ICU ventilators were lacking. Patients ventilated with ICU machines had an ICU mortality of 34% (308/915) whereas those ventilated with anesthesia machines had a 47% mortality (79/169), $p = 0.002$. ECMO was employed in 31 patients (2,2%), 28 ECMO VV and 3 ECMO VA. Tracheostomies were performed in 28% patients (524/1388), of whom 26% (137/524) died.

Length of stay and duration of ventilation (mean \pm standard deviation)				
	All (n=1388)	Alive (n=897)	Dead (491)	p (alive vs dead)
Hospital stay pre-ICU, days	2.38 \pm 3.5	2.25 \pm 3.2	2.62 \pm 3.8	ns
ICU stay, days	20.1 \pm 14.9	22.2 \pm 15.5	16.4 \pm 12.7	<0.001
Hospital admission to intubation, days	2.74 \pm 3.5	2.6 \pm 3.2	3.02 \pm 3.97	<0.05
ICU admission to intubation, days	0.47 \pm 1.2	0.48 \pm 1.07	0.43 \pm 1.51	ns
Duration of mechanical ventilation, days	17.5 \pm 13.8	18.3 \pm 14.2	16.02 \pm 12.7	0.003
Intubation to tracheostomy, days	13.8 \pm 6*	13.5 \pm 6.1**	14.5 \pm 5.7***	ns

*n=524, **n=387, ***n=137

Conclusion: COVID19 mechanically ventilated patients consumed a substantial amount of resources, were often tracheostomized and their ICU length of stay was prolonged.

Intensive Care Medicine Experimental 2020, **8(2)**: 001538

Introduction: SARS-CoV-2 infection leads in the most severe cases to a profound respiratory failure that requires admission to the intensive care unit (ICU) and mechanical ventilation. Two different phenotypes have been proposed: H (HIGH elastance-right to left shunt ratio-lung weight-recruitability) and L (LOW elastance-VA/Q ratio-lung weight-recruitability) (ref 1. Gattinoni).

Objectives: To describe the incidence, clinical differences and outcomes of phenotype H and L patients with SARS-CoV-2 infection (COVID-19) who are admitted in an ICU of a third-level hospital with extracorporeal membrane oxygenation (ECMO) support capacity.

Methods: We retrospectively collected and analysed data from all COVID-19 confirmed patients, admitted to the ICU of a third-level hospital in Spain between 15th February and 15th June 2020. We categorised patients into two phenotypes, L and H, and compared their clinical and epidemiological variables as well as ventilation related parameters. The data are expressed as mean \pm standard deviation, median \pm interquartile range, and compared using T-test, Wilcoxon rank test, Chi-square test and Fisher's exact test as appropriate.

Results: A total of 87 COVID-19 confirmed patients were included out of which 79 (93%) received invasive mechanical ventilation. 77% males, mean age 60 ± 12 , median BMI 27 Kg/m^2 (IQR 25-32), mean APACHE-II 17 ± 6 . 13 patients needed VV-ECMO support (61% survival). Overall hospital mortality was 38%. Comorbidities: hypertension 30%, diabetes 14%, ischemic heart disease 5%, asthma 8%, COPD 3%. The incidence of H phenotype was 40%, L phenotype 32% and in 28% of the patients it was not possible to determine. Comparison of ventilation related parameters between both groups are expressed in Table 1.

	H-Phenotype (n=32) (mean \pm sd) (median, IQR)	L-Phenotype (n=25) (mean \pm sd) (median, IQR)	p
PaO ₂ /FiO ₂ day 1	171 (114, 216)	161 (134, 209)	>0.05
PaO ₂ /FiO ₂ day 3	195 (146, 263)	200 (144, 236)	>0.05
PaO ₂ /FiO ₂ day 5	176 (156, 240)	189 (142, 218)	>0.05
PaO ₂ /FiO ₂ day 10	184 \pm 68	217 \pm 73	>0.05
PEEP day 1 (cmH ₂ O)	15 \pm 3	11 \pm 2	<0.01
PEEP day 5 (cmH ₂ O)	10 \pm 3	11 \pm 2	
Days of mechanical ventilation	15 (8, 30)	11 (6, 24)	>0.05
Tidal volume/ideal weight day 1 (ml/kg)	7 (6, 7)	7 (6, 7)	>0.05
Tidal volume/ideal weight day 10 (ml/kg)	7 (6, 8)	8 (7, 8)	<0.05
Use of prone position (%)	68	60	>0.05
Number of prone sessions	2.6 \pm 2	2.8 \pm 1	>0.05
Mortality ICU (%)	33	29	>0.05

Conclusion: Out of all admitted patients, only 72% of them could be classified into one of the proposed phenotypes.

Patients with H phenotype were treated with a higher PEEP level on the first day of mechanical ventilation, but with a similar tidal volume. Tidal volume was significantly higher in L phenotype patients on day 10.

No differences in PaO₂/FiO₂ ratio, days of mechanical ventilation and the use of prone position was observed between groups.

Intensive Care Medicine Experimental 2020, 8(2): 001563

Introduction: COVID-29 related ARDS (C-ARDS) has specific pathophysiological features that include a relatively higher compliance as non C-ARDS of similar severity and a pulmonary vascular thrombosis diathesis together with a severe early hypoxemia. Given these features inhaled nitric oxide (iNO) could have a potential adjuvant role in the ventilatory management of C-ARDS.

Objectives: To study the effects of iNO on the relative change in pulmonary perfusion and on gas exchange in C-ARDS.

Methods: Retrospective analysis C-ARDS patients with severe ARDS treated with iNO delivered via the SoKINOXTM device (Air Liquide). The relative distribution of pulmonary blood flow before and after the administration of iNO was determined by EIT (Enlight, 1800 Timpel). Perfusion data were obtained by means of a bolus infusion of 10 ml of hypertonic (7.6%) Saline solution during a brief apnea period maintaining the same PEEP level(1). Ventilator settings before and after iNO were maintained unchanged so that no changes in the regional distribution of ventilation were expected. At least one blood gas before and after iNO, although at different time periods in relation to the start of iNO therapy, were obtained. Due to the low number of patients and measurements no statistical analysis was performed in this descriptive study.

Results: A total of 8 patients were included in the analysis. After a few dose response trials performed in the first patients average lowest iNO dose resulting in the maximum change in perfusion was 15 ppm. Changes in the relative distribution of ventilation were <1% for all studied regions. The response to iNO was very variable both in terms of the distribution of perfusion and gas exchange with no clear defined pattern. Only four patients responded according to oxygenation with an average increase in PaO₂/FiO₂ of $40.5 \pm 17.7\%$. When analyzing the changes in the distribution of perfusion in vertical gravitational axis, iNO predominantly shifted perfusion to the ventral (non-dependent) lung half in 3 patients ($13 \pm 6.95\%$ shift) and to the dorsal (dependent) lung half in 5 patients ($8.4 \pm 4.1\%$ shift). This corresponded to a decrease of $5.5 \pm 4.4\%$ in PaO₂/FiO₂ and an increase of $13.7 \pm 17.7\%$ in PaCO₂ and an increase of $29.9 \pm 28.3\%$ in PaO₂/FiO₂ and a decrease of $2.3 \pm 14.5\%$ in PaCO₂ in those predominantly shifting perfusion to ventral and to dorsal regions respectively.

Conclusion: The response to iNO in C-ARDS patients was highly variable and required higher than usual doses. In responding patients iNO caused a redistribution of pulmonary blood flow to dorsal non-dependent regions.

Intensive Care Medicine Experimental 2020, 8(2): 001568

Introduction: Patients with the most severe forms of SARS-CoV-2 infection develop a profound respiratory failure that, during the global pandemic, has forced hospitals to increase their ICU-bed capacity. Spaces with ICU-level monitoring, such as post-anesthesia care units or operating rooms have been used as temporary ICU beds (extended-ICU). Moreover, collaboration between professionals in the

departments of critical care, anesthesiology and other medical specialties has been necessary in order to attend all critical care patients. (ref. 1, 2).

Objectives: We aim to determine the differences in ventilation related variables between patients admitted to the ICU and patients admitted to the extended-ICU in a third-level hospital in Spain between 15th February and 15th June 2020.

Methods: We retrospectively collected and analysed data from all COVID-19 confirmed patients admitted to a third-level hospital in Spain and needed intensive cares, between 15th February and 15th June 2020. We categorised the patients into two groups: admitted to ICU and admitted to extended-ICU. We compared ventilation related parameters between groups. The data are expressed as mean \pm standard deviation, median \pm interquartile range, and compared using T-test, Wilcoxon rank test, Chi-square test and Fisher's exact test as appropriate.

Results: A total of 87 COVID patients are included, out of which 79 (93%) received invasive mechanical ventilation. 77% males, aged 60 ± 12 , BMI 27 Kg/m^2 (IQR 25-32). Mean APACHE-II 17 ± 6 . 13 patients needed VV-ECMO support (61% survival). Overall hospital mortality was 38%. Comorbidities: hypertension 30%, diabetes 14%, Ischemic heart disease 5%, asthma 8%, COPD 3%.

Ventilation related parameters are expressed in Table 1.

Table 1

Variable	ICU (n= 45)	Extended-ICU (n = 42)	P
Mechanical ventilation free days	1 (0, 4)	0 (0, 2)	<0.05
Tidal volume/ideal body weight day 1 (ml/kg)	7 (6, 8)	7 (6, 8)	>0.05
Tidal volume/ideal body weight day 5 (ml/kg)	7 (6, 8)	7 (6, 8)	>0.05
Tidal volume/ideal body weight day 10 (ml/kg)	8 (7, 8)	7 (6, 8)	>0.05
PaO ₂ /FiO ₂ day 1	167 (109, 221)	185 (142, 222)	>0.05
PaO ₂ /FiO ₂ day 5	183 (128, 240)	190 (147, 232)	>0.05
PaO ₂ /FiO ₂ day 10	205 \pm 79	167 \pm 69	<0.05
Driving pressure day 1 (cmH ₂ O)	12 (10, 14)	14 (12, 20)	<0.05
Driving pressure day 5 (cmH ₂ O)	12 \pm 3	15 \pm 4	<0.05
Driving pressure day 10 (cmH ₂ O)	12 (10, 14)	14 (12, 20)	>0.05
Plateau pressure day 1 (cmH ₂ O)	23 \pm 3	26 \pm 4	<0.05
Plateau pressure day 5 (cmH ₂ O)	23 \pm 3	25 \pm 3	>0.05
Plateau pressure day 10 (cmH ₂ O)	22 \pm 4	23 \pm 7	>0.05
Use of pre-intubation non-invasive ventilation (%)	17	23	>0.05
Extubation failure (%)	5	7	>0.05

Conclusion: Patients admitted to the extended-ICU had less mechanical ventilation free days.

Patients treated in extended-ICU had worse oxygenation, expressed as PaO₂/FiO₂ ratio than patients treated in ICU.

Patients admitted to extended-ICU had higher driving pressure and higher plateau pressure during the first days of treatment, when compared to patients admitted to ICU.

There were no differences between groups in the use of pre-intubation non-invasive ventilation or in the extubation failure.

Intensive Care Medicine Experimental 2020, **8(2)**: 001569

Introduction: Approximately 5% of coronavirus disease 2019 (COVID-19) are admitted to intensive care unit (ICU) for acute hypoxemic respiratory failure (AHRF). Whether invasive mechanical ventilation (IMV) should be used as first line therapy over non-invasive ventilation (NIV), high flow nasal cannula (HFNC), continuous positive airway pressure (CPAP) and oxygen by mask, is debated.

Objectives: The aim of the study was to assess a non-biased effect of Early-IMV in COVID induced AHRF on day-60 mortality.

Methods: Data from consecutive COVID-19 patients admitted in 11 ICUs of the French OutcomeRea™ network were prospectively collected. Patients with AHRF (PaO₂/FiO₂ < 300 mmHg) within 2 days of ICU admission and not referred from another ICU were included. The study compared day-60 mortality between patients who were administered IMV within 48 hours of ICU admission (Early IMV group) and patients who did not (non-Early IMV group). We used a Cox proportional-hazard model with ponderation with inverse probability of Early IMV weighting (IPTW) to model the risk of death at day 60 (HR > 1 in favor of death).

Results: Of the 306 included patients, the median age (IQR) age was 61 (52-69) years, 241 were males (78.8%), 175 (57.2%) had at least one comorbidity; the median SAPSII and PaO₂/FiO₂ were 33 (25-44) and 133 (96-186) mmHg, respectively. On admission, 105 (34.4%) patients received IMV, 26 (8.4%) NIV, 122 (39.8%) HFNC, 21 (6.8%) CPAP, and 32 (10.4%) oxygen by mask. Ultimately, the Early and non-Early IMV groups included 149 and 157 patients; and Day-60 mortality was 40.9% and 22.9%, respectively. Between the Early and non Early IMV group the rates of ICU-acquired pneumonia and bacteremia were 71 vs 29 (P < 0.01) and 15 vs 8 (P < 0.01); the median ICU length of stay 15 (10-22) vs 8 (5-15) days (P < 0.01), respectively. In the IPTW analysis, day-60 mortality remained higher in the Early than in the non-Early IMV group (IPTW_{SHR} = 1.78, CI 95%, 1.16 to 2.71, p < 0.01). Similar results were observed in a sensitive analysis using Multivariate Cox survival model (Table).

Variables	HR	CI 95%	pvalue
Early IMV	1.67	[1.04-2.67]	0.03
Time from symptoms to ICU admission	0.75	[0.48-1.19]	0.22
Chronic cardiac failure	1.76	[1.11-2.78]	0.02
Chronic respiratory failure	2.06	[1.19-3.59]	0.01
Chronic renal failure	1.59	[0.88-2.87]	0.12
Immunosuppression	2.11	[1.1-4.04]	0.03
Age (per 1 year increase)	1.05	[1.02-1.07]	<0.01
SOFA without respiratory	1.2	[0.75-1.91]	0.44
T ^o > 39°C	1.81	[1.15-2.85]	0.01
Lymphocytes < 800	1.4	[0.9-2.17]	0.13

IMV: Invasive mechanical ventilation; SOFA: Sequential Organ Failure Assessment

Conclusion: In ICU patients admitted with COVID-19 -induced acute hypoxemic respiratory failure, Early-IMV increases day-60 mortality and should not be used as first line respiratory support.

Intensive Care Medicine Experimental 2020, **8(2)**: 001575

Introduction: Expiratory muscle weakness leads to difficult ventilator weaning. Maintaining their activity with functional electrical stimulation (FES) may therefore improve outcome. We studied feasibility and efficacy of breath-synchronized expiratory muscle FES in a mixed ICU ("Holland study") and pooled data with our previous work [1] ("Australian study") to analyze effects in a larger and more heterogeneous group.

Methods: *Holland:* Twenty patients with contractile response to FES received active or sham expiratory muscle FES (30-min, twice-daily, five days/week until weaned). Endpoints were respiratory muscle thickness, feasibility, and ventilation duration. *Pooled:* Data on clinical endpoints from the Holland and Australian studies were combined (N = 40), including ventilation duration and ICU length-of-stay. Plasma cytokines (day 0, 3) were analyzed to study the effects of expiratory muscle FES on systemic inflammation.

Results: *Holland:* 272 sessions were performed (sham/active: 103/169, compliance: 91.1%). No FES-related serious adverse events were reported. Respiratory muscle thickness was not different over time and between groups. *Pooled:* At day 3, there was a between-group difference in total expiratory muscle thickness favoring the active group (treatment difference (95% confidence interval); 2.25 (0.34, 4.16) mm, P = 0.02). Plasma cytokine levels indicated that early FES did not induce systemic inflammation. Median ventilation duration and ICU length-of-stay were 10 vs. 52 (P = 0.07), and 12 vs. 54 (P = 0.03) days for the active vs. sham group. 3/20 patients died in the active group, vs. 9/20 in the sham group (P = 0.08).

Conclusion: Expiratory muscle FES is feasible in selected ICU patients. This might be a promising intervention within a respiratory muscle-protective ventilation strategy. A next step would be to test whether this approach could improve weaning outcome.

Intensive Care Medicine Experimental 2020, **8(2)**: 001195

Introduction: Optimized external expiratory resistances improve lung mechanics, reduce tidal expiratory flow limitation (EFL) and prevent expiratory lung collapse in injured lungs (1).

EFL is associated with an increased mortality in acute respiratory distress syndrome (ARDS) patients (2, 3). To detect and avoid EFL can have important consequences on patients outcome.

Whether EFL can be detected by electrical impedance tomography is still unknown.

Objectives: EFL is expected to affect regional expiratory flow and consequently regional variation of expiratory electrical impedance. We hypothesized that changes in regional expiratory flow and EFL, consequent to different expiratory resistances and positive end-expiratory pressure (PEEP) levels, can be detected as changes in expiratory electrical impedance of the thorax.

Methods: Ten anesthetized and mechanically ventilated pigs underwent lung lavages to reach mild ARDS with a PO₂/FIO₂ ratio of 250 mmHg at PEEP of 5 cmH₂O. During the experiment the pigs breathed spontaneously during continue positive airway pressure. Three PEEP levels (12, 3 and 0 cmH₂O) and four external expiratory resistances were tested (labeled as R0, R1, R2, R3). The electrical impedance signal was simultaneously acquired. The impedance signal was analyzed breath-by-breath at 5 time-points of the expiratory phase (end-inspiration, first, second, third and fourth quartile of the expiration) and separately for dependent and not-dependent lung regions.

Results: In absence of additional expiratory resistance (R0), a significant difference in electrical impedance was observed in non-dependent lung regions at different PEEP levels. High PEEP corresponded to a slower decrease in impedance throughout expiration.

Applying additional expiratory resistances (R1-R3), the differences in electrical impedance related to PEEP disappeared and showed a trend closer to the one observed at high PEEP and R0.

Conclusion: A change in the time course of the expiratory impedance at PEEP 0 cmH₂O was interpreted as sign of expiratory flow limitation. Addition of expiratory resistances contrasts the appearance of this pattern. Electrical impedance tomography can indirectly detect phenomena of expiratory flow limitation in injured lungs during spontaneously breathing ventilation.

A Novel System of "Split Ventilation" Using Electronically Controlled Valves Can Be Used to Deliver Modified Lung Protective Ventilation in a Porcine Model of Acute Respiratory Distress Syndrome

J. Clarke¹; P. Geoghegan¹; G. Hogan¹; A. Keogh¹; H. Marsh¹; G. Curley¹

¹Department of anaesthesia and critical care medicine, Royal College of Surgeons in Ireland, Beaumont Hospital, Dublin, Ireland

Correspondence: J. Clarke

Intensive Care Medicine Experimental 2020, **8(2)**: 001369

Introduction: During surges in demand for ventilator capacity, demand may outstrip supply. Split ventilation has been suggested as a

temporising measure for individual hospitals to cope with such surges in demand. Optimising split ventilation may be important in the ongoing pandemic of SARS-CoV-2 and the associated high prevalence of acute respiratory distress syndrome. We developed a low cost electronically controlled system for delivering split ventilation, provisionally termed the Combiventilate system.

Objectives: 1) To demonstrate that an electronically controlled split ventilation system could be used to delivery independent volume-controlled ventilation to two test lungs under conditions of varying resistance, compliance and leak. 2) To demonstrate that in a porcine model of acute respiratory distress syndrome, the Combiventilate system could deliver independent modified lung protective ventilation. 3) To show that in a porcine model of ARDS, markers of ventilator induced lung injury were similar in Combiventilate ventilated animals and single ventilated animals. 4) To demonstrate that with minimal training, critical care staff could independently operate the Combiventilate system in simulated clinical scenarios.

Methods: We performed benchtop testing of the Combiventilate system using linear test lungs to ensure it's ability to provide differential ventilation and accommodate for changes in respiratory mechanics. We established a porcine model of acute respiratory distress syndrome by administering intrabronchial hydrochloric acid. We compared ventilation using the Combiventilate system to traditional individual ventilation in both injured and uninjured animals (n = 30). Groups were: individually ventilated uninjured (n = 5), individually ventilated injured (n = 5), Combiventilate managed uninjured (n = 10) and Combiventilate managed injured (n = 10).

We compared between group differences in the ability to deliver lung protective ventilation and meet gas exchange targets over a period of 6 hours of mechanical ventilation. We also compared immunological and histological markers of ventilator induced lung injury between groups. We performed benchtop simulations of clinical scenarios to verify that, with minimal training, clinical staff could set up and operate the Combiventilate system under conditions simulating common clinical scenarios.

Results: The Combiventilate system was able to deliver individualised volume-controlled ventilation in benchtop testing with linear test lungs. In a porcine model of ARDS, the Combiventilate system was able to facilitate similar adherence to modified lung protective ventilation as compared to individual traditional ventilation. Immunological and histological markers of ventilator induced lung injury were similar in the Combiventilate managed groups compared to the traditionally ventilated groups. In benchtop simulations, clinical staff were able to set up and operate the Combiventilate system with minimal training.

Conclusion: Performance of the Combiventilate system in benchtop testing and in a large animal model of ARDS supports the ability to deliver modified lung protective ventilation. Similar degrees of ventilator induced lung injury as observed in the Combiventilate group as compared to the individually ventilated group. These data are promising and support further efforts to develop and investigate this system for use in humans as a temporising measure when surge demand exceeds capacity for individualised ventilation.

Documentation of Plateau Pressures and the incidence of High Plateau Pressures in Mechanically Ventilated Patients with ARDS secondary to COVID-19

L. O'Gorman¹; G. Murphy¹; C. Power¹

¹Intensive care medicine, Tallaght University Hospital, Dublin, Ireland

Correspondence: L. O'Gorman

Intensive Care Medicine Experimental 2020, **8(2)**: 001187

Introduction: Elevated Plateau Pressures in mechanically ventilated patients with ARDS have previously been shown to increase the time needed for liberation from mechanical ventilation, increase the length of ICU stay and increase hospital mortality (1,2). International

guidelines for the management of ARDS, including ARDS secondary to COVID-19, reflect these findings and recommend maintaining plateau pressures of less than 30 cmH₂O (3).

Objectives: 1. To assess how frequently Plateau Pressures were recorded in mechanically ventilated patients admitted with ARDS secondary to COVID-19.

2. To investigate the incidence of elevated plateau pressures in mechanically ventilated patients with ARDS secondary to COVID-19.

Methods: This was a retrospective audit of all patients with ARDS secondary to COVID-19 admitted to the ICU over a three month period (06/03/2020 - 06/06/2020) who required intubation and mechanical ventilation. Data was collected from patient's medical notes, including both paper charts as well as digital documentation. Data was also collected from patient's flow charts. Data was only collected on days during which the patient was mechanically ventilated on a Pressure Regulated Volume Control (PRVC), Pressure Control (PC) or Volume control (VC) mode of ventilation. Elevated plateau pressures were defined as a pressure greater than or equal to 30 cmH₂O.

Results: 24 patients were admitted to the ICU with ARDS secondary to COVID-19 during this time period. They spent a cumulative total of 428 days intubated and ventilated in ICU during this time. The total number of days spent on a PRVC, PC or VC mode of ventilation was 262. This was broken down as 250 days on PRVC, 8 days on PC and 4 days on VC. In total, plateau pressures were recorded on 47% of days while on a PRVC, PC or VC mode of ventilation (124 of the 262 days). There was a documented contraindication to recording plateau pressures on 2 out of the 262 days. Of the recorded plateau pressures, 29.8% were greater than or equal to 30 cmH₂O (37 of the 124 measurements).

Conclusion: We found that for mechanically ventilated patients with ARDS secondary to COVID-19, plateau pressures were not being measured routinely and were frequently found to be above the threshold limit recommended by international guidelines. This could have implications for patient's length of ICU stay, duration of mechanical ventilation as well as hospital mortality.

Flexible Fiberoptic Bronchoscopy performed by intensive care physicians in patients under Invasive Mechanical Ventilation

O. Moreno Romero¹; M. Muñoz Garach¹; A. Carranza Pínel¹

¹Intensive care unit, Hospital Universitario Clínico San Cecilio, Granada, Spain

Correspondence: O. Moreno Romero

Intensive Care Medicine Experimental 2020, **8(2)**: 001278

Introduction: Flexible fiberoptic bronchoscopy (FOB) has become an important tool for the diagnostic and management of complications in critically ill ventilated patients, specially since ICU physicians can perform this technique with low incidence of complications.

Objectives: First, to describe the etiology and complications of performing a flexible fiberoptic bronchoscopy (FOB) by intensive care physicians in patients under invasive mechanical ventilation (IMV) in our intensive care unit. Secondly, to check whether there was a significant modification of treatment due to the results of FOB.

Methods: Retrospective study in a 24 month period (from January 2018 until December 2019) of all FOB performed by intensive care physicians in our patients under IMV. Variables analyzed: data of patients

(sex, age, APACHE II), cause for IMV (primary respiratory, septic shock, cardiovascular, neurological), cause for implementing the bronchoscopy (atelectasis in US, suspected orotracheal tube obstruction, evaluation of tracheostomy, suspected tumor, diagnostic bronchoalveolar lavage), complications, change in treatment.

Results: In 24 months we performed 167 FOB in 397 patients under IMV. Male 55%. Mean age $58 \pm 16,3$ y. Mean APACHE II 19 ± 8 . Cause of IMV: primary respiratory 135 (34%), septic shock 118 (30%), neurological 45 (11,3%), cardiovascular 44 (10%), other 55 (13,7%). Causes: atelectasis 48 (28,7%), orotracheal tube obstruction 11 (6,6%), evaluation of tracheostomy 25 (15%), suspected tumor 7 (4,2%), diagnostic BAL 76 (45,5%). Complications: mild haemorrhage 16 (9,6%), supraventricular tachycardia 8 (4,8%), transient hypoxemia 12 (7%), transient bronchospasm 8 (4,8%). A significant change in treatment was implemented in 56 (33%). No mortality related to FOB.

Conclusion: The performing of flexible bronchoscopy in patients under IMV by intensive care physicians is a safe technic in our units. Complications are mild and in approximately 25% of patients. A change in treatment was made in 33%, mostly due to microbiological findings in BAL, diagnostic of tumors and limitation of therapeutic effort.

Contrafluran as an alternative scavenger for NO and NO₂ in ICU

R. Knafelj¹; V. Z.; A. Kokovec¹

¹University medical center Ljubljana, MICU, Ljubljana, Slovenia

Correspondence: R. Knafelj

Intensive Care Medicine Experimental 2020, **8(2)**: 001327

Introduction: Inhaled Nitric oxide (iNO) is used during mechanical ventilation as salvage therapy for refractory hypoxemia in ARDS, as (selective) pulmonary vasodilator in pulmonary hypertension and in right heart failure. At therapeutic levels for adults (up to 30 ppm) residual NO and its metabolite NO₂ are released in the surrounding from the ventilator expiratory port and must be scavenged. With prolonged use (> 12 h) dedicated NO/NO₂ scavenger filter causes additional resistance due to moisture accumulation and leads to expiratory flow limitation. Sevoflurane demonstrates numerous advantages over intravenous sedation and is preferred sedation agent in our ICU.

Objectives: Since volatile agents used for sedation in ICU also require scavenging we tested NO scavenging capacity of commonly used Contrafluran[®] filter.

Methods: Breathing circuit (Elisa 800VIT, Löwenstein Medical, Germany) with NO delivery/measurement system (NO-A, EKU Elektronik GmbH), Anaconda (Sedana Medical, Sweden) and Contrafluran (ZeoSys Medical, GmbH) was assembled according to manufacturer's recommendation and hospital standards. All measurements were performed during volume control ventilation (Vt 450 mL, FiO₂ 0.5, PEEP 10, RR 20/min) first without sevoflurane co-administration and then with sevoflurane at a rate of 10 mL/h. In 20 benchmark tests concentrations of NO and NO₂ were measured in different parts of the breathing circuit (**Figure 1**). Statistical analysis was performed using Student t-test (Numbers, MacIntosh).

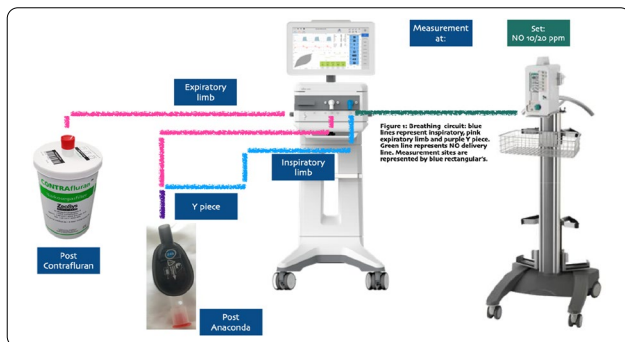

Figure 1 Breathing circuit. Blue lines represent inspiratory limb, pink represent expiratory limb and purple Y-piece. Green line represents NO delivery line. Measurement sites are represented by blue rectangular.

Results: In table:

Measured NO (blue) and NO ₂ (in orange) (ppm) at:	Set NO 10 ppm	Set NO 10 ppm + sevo	Set NO 20 ppm	Set NO 20 ppm + sevo
Inspiratory limb	9.7±0.6 / 0.01±0.03	8.5±0.4 / 0.01±0.02	20±0.5 / 0.04±0.07	19.8±0.6 / 0.0±0.03
Y piece	8.6±0.4 / 0.01±0.02	8.5±0.4 / 0±0	18.7±0.9 / 0.01±0.03	18.8±1.2 / 0.02±0.03
Post Anaconda	5.7±0.6 / 0±0	5.7±0.5 / 0±0	14.6 ±0.8 / 0±0	14.7±1.1 / 0±0
Expiratory limb	4.7±0.5 / 0.2±0.07	4.5±0.4 / 0.19±0.05	13.2±0.6 / 0.19±0.09	13.5±1.4 / 0.09±0.1
Post Contrafluran	0.1±0.1 / 0±0	0.1±0.1 / 0±0	0.1±0.1 / 0±0	0.1±0.1 / 0±0.02
Filter resistance	1.9	1.9	1.9	1.9
Filter resistance after 12 h	1.9	1.9	1.9	1.9

Conclusion: iNO concentration varies within the breathing circuit as a consequence of a Flow-by, mixture of inspired and expired gasses at Y piece and scavenging effect of Anaconda. Special caution must be practiced when interpreting the results of measured iNO values. Addition of sevoflurane does not interfere with NO/NO₂ measurements. Contrafluran filter is an excellent alternative to standard scavenger filter for NO/NO₂, scavenging >99.91% NO and 100% NO₂ at 10 and 20 ppm respectively. There was no increase in respiratory system resistance and intrinsic PEEP formation over time, while using Contrafluran filter.

Implementation of protective lung ventilation and its association with mortality, Focus on driving pressure

Y. Michael¹; Z. Goldik¹; A. Eden¹

¹Department of anesthesiology, critical care & pain medicine, Lady Davis Carmel Medical Center, Haifa, Israel

Correspondence: Y. Michael

Intensive Care Medicine Experimental 2020, **8(2)**: 001392

Introduction: Lung protective ventilation (LPV) strategies should guide ventilatory care throughout the ICU stay. We evaluated whether mechanical ventilation followed LPV guidelines throughout the mechanical ventilation period, with emphasis on the driving pressure (ΔP) and their association with 28 and 90 day mortality.

Methods: Retrospective study included 124 patients admitted to ICU in the Lady Davis Carmel medical center, Haifa, Israel, during 2019, who were mechanically ventilated for at least 48 hours. Ventilatory data was collected every 10 minutes for up to 28 days of mechanical ventilation in the ICU. We investigated the degree of compliance with the LPV guidelines and its association with mortality at 28 and 90 day post discharge.

Results: Analysis of the data per patient (mean ± SD) revealed ΔP of 15.5 ± 3.6 cmH₂O, Vt of 7.6 ± 1.4 ml/kgpbw and end inspiratory pressure of 23.2 ± 4.5 cmH₂O. The median prevalence per patient of ΔP > 14 cmH₂O was 58% of their ventilation period, Vt > 8 ml/kgpbw was 38% and of end inspiratory pressure > 30 cmH₂O was 2% of the ventilation period. Fifty-one patients (41%) died within 28 day and 56 patients (45.2%) within 90 day post discharge. Mean ΔP and amount of time spent with ΔP > 14 cmH₂O were significantly correlated with mortality at 28 day post discharge from ICU: OR = 1.13, 95%CI (1.02-1.26), p = 0.021; and, OR = 1.02, 95% CI (1.003-1.03), p = 0.015 respectively. At 90 day, the time spent with DP > 14 cmH₂O (more than 50% of measurements) was associated with increased mortality OR = 2.58 95%CI (1.2- 5.4), p = 0.012, but the mean ΔP was not. An increase in the frequency of elevated ΔP (quartiles) was associated with increased mortality (figure). No correlation was found between either Vt or end inspiratory pressure and mortality.

Conclusion: LPV was not always implemented, it is especially shown with the high frequency of elevated ΔP values. ΔP was significantly associated with mortality regardless of whether the patient had ARDS or not. To validate these results, further studies are needed.

Intensive Care Medicine Experimental 2020, **8(2)**: 001476

Introduction: The COVID-19 pandemic has seen a surge of patients with acute respiratory distress syndrome (ARDS) in intensive care units. Although early reports suggested that COVID-19-associated ARDS has distinctive features that set it apart from historical ARDS, emerging evidence indicates that the respiratory system mechanics of patients with ARDS, with or without COVID-19, are broadly similar.¹ Prevalence of ARDS among COVID-19 patients has been reported to be up to 17%.² Among the introduced treatment methods for management of ARDS patients, prone position can be used as an adjuvant therapy for improving ventilation in these patients.³

Objectives: The aim of this study was to describe our experience with prone position in SARS-CoV2 positive patients. We also compared the patients who survived with those who died to understand if there were any 28-day mortality predictors.

Methods: We retrospectively studied the patients who tested positive for SARS-CoV2 admitted in Hospital Beatriz Ângelo (HBA) ICU from April to June of 2020. Demographic data, comorbidities, severity scoring scales, PaO₂/FiO₂, days on mechanical ventilation, number and hours of prone position, complications, days at Intensive Care Unit and deaths were extracted from medical records and were submitted to statistic description and analysis.

Results: There were 62 patients positive for SARS-CoV2 admitted in HBA ICU from April to June of 2020, and 39 were mechanically ventilated. Twenty patients (32%) were placed in prone position, 65% were males. The mean age was 63 years old (minimum 31 and maximum 83). In relation to the severity criteria, the medium APACHE II score was 13 points and SAPS II was 37 points.

Half of the patients (10) registered a severe ARDS (P/F \leq 100) when admitted in the ICU and had had symptoms for 8 days before IOT. In six patients there was a HNFC trial, without success.

These 20 patients fulfilled on average 5 periods of prone ventilation and the mean of prone ventilation hours were 94. The patients were ventilated for 32 hours on average before prone position. The first prone position lasted a mean of 20 hours.

These patients were intubated on average 15 days. Fifty percent were extubated for NIV and in 5 patients was performed a tracheostomy. There were complications like accidental extubation (2), exteriorization of a central venous catheter (1), facial edema (1) and pressure ulcers (5).

These patients have been in the ICU for 20 days on average, with a 20 percent mortality rate in the ICU plus 5% in the hospital < 28 days.

When we compare the patients that survived with those who died, the latter were older (60 years vs 71), had worse SAPS II (34 vs 46) and APACHE II (12 vs 16), more days of symptoms until intubated (7 vs 12) and hours of ventilation until prone position (25 vs 53). On the other hand, we found that patients that survived had an inferior initial p/f ratio (118 vs 170).

Conclusion: Even before SARS-CoV2 pandemic we knew ARDS is an inflammatory process, with long hospitalization and significant mortality. From our experience, this study seems to show that the sooner the patients are intubated and placed in prone position, the best the outcome. Further research is needed.

Intensive Care Medicine Experimental 2020, **8(2)**: 001490

Introduction: The main respiratory dynamics of invasively ventilated COVID-19 patients are still not well known.

Objectives: In this prospective cohort we aimed to observe the characteristics of the respiratory system of COVID-19 patients under invasive mechanical ventilation and evaluate their relationship with mortality.

Methods: Patients admitted to our ICU with COVID-19 (confirmed SARS-CoV-2 infection in nasal or pharyngeal swab specimens) and invasively ventilated for more than 24 hours were enrolled. Demographics and laboratory values were recorded at baseline. Respiratory variables such as tidal volume, plateau pressure, PEEP, static compliance, driving pressure were recorded daily under passive conditions and median values were analyzed. Data are expressed as median (IQR) of numbers (%).

Results: 48 patients (33 male) were enrolled between 01 March 2020 and 01 July 2020. All patients had ARDS. Median age was 64 years (58-72). Mortality was 60% at day 28. Survivors were significantly younger than nonsurvivors. Plateau pressure, driving pressure and static compliance significantly differ between survivors and nonsurvivors. Other laboratory values were comparable. (Table 1).

Characteristics of patients			
Variable	Nonsurvivors	Survivors	p value
Age, years	66 (62-73)	61 (46-67)	0.021
APACHE II	21 (15-33)	19 (11-21)	0.06
SAPS	53 (38-79)	47 (40-56)	0.26
PaO ₂ /FiO ₂	140 (96-190)	136 (92-229)	0.84
Vt/kg, ml	8 (7-8)	7 (6-9)	1
Pplateau, cmH ₂ O	31 (28-33)	28 (24-30)	0.01
PEEP, cmH ₂ O	11 (8-14)	10 (9-12)	0.73
Pdriving, cmH ₂ O	20 (14-23)	15 (12-18)	0.008
Cst, ml/cmH ₂ O	29 (21-36)	37 (30-50)	0.008

Conclusion: COVID 19 related ARDS seems to have similar characteristics as other forms of ARDS. Lung protective ventilation with low plateau and driving pressures may be related with lower mortality.

Prediction model of endotracheal obstruction, in patients with severe pneumonia due to COVID 19, analyzing ventilatory parameters using intelligent computation

G. Pérez-Acosta¹; J. Navarro-Mesa²; L. Santana-Cabrera¹; J. Blanco-Lopez¹; C. Suárez-Araujo³; J. Martín-González¹

¹ICU, C.H.U. Insular-Materno Infantil, Las Palmas de Gran Canaria, Spain; ²Idetic, Universidad de las Palmas de Gran Canaria, Las Palmas de Gran Canaria, Spain; ³Iuctc, Universidad de las Palmas de Gran Canaria, Las Palmas de Gran Canaria, Spain

Correspondence: G. Pérez-Acosta

Intensive Care Medicine Experimental 2020, **8(2)**: 001617

Introduction: Patients admitted to the ICU with severe COVID-19 pneumonia present clinical complications during their admission, such as endotracheal obstruction due to accumulation of secretions. This problem often requires urgent endotracheal tube change and manual ventilation, both of which are health risk procedures for the generation of aerosols and constitute a potential life-threatening risk for the patient.

The model based on Machine Learning (ML) techniques and intelligent computing, using the signals produced by the respirators, constitute fundamental tools for the extraction of common patterns related to obstruction, and for the creation of prognostic and therapeutic prediction systems.

Objectives: To study the possibility of predicting the appearance of endotracheal obstruction in patients with COVID-19 pneumonia, using neuronal computing techniques, integrating the different respiratory variables during hospital admission into a model.

Generate a predictive model that follows the time course of patients with COVID-19 pneumonia undergoing mechanical ventilation and predict the appearance of endotracheal obstruction well in advance.

Methods: Descriptive, observational study using data mining in 22 patients with Pneumonia due to COVID-19, where 16 of them presented an episode of endotracheal obstruction during their admission to the IMU. Compilation of the respiratory variables Peak Pressure, Plateau Pressure, Medium Pressure, Resistance and Compliance, collected at least every 15 minutes during the entire intensive care admission. The recording of signals during the hours prior to the development of the obstruction is studied, representing the signals collected synchronously and in parallel. To develop a neural computing model, using data mining techniques, to analyze the existence of specific temporal patterns that help early detection of endotracheal obstruction, hours before it occurs.

Results: Based on the designed predictive model, changes in the respiratory mechanical signals collected by the system during admission to the ICU that precede the development of endotracheal obstruction are detected, with an average anticipation of 47 hours.

The model's output (black line) provides information about lung mechanics, from patient admission to endotracheal obstruction (green line). Image 1 shows common patterns of changes in lung mechanics prior to obstruction. The blue line indicates the start of abnormal changes in the registry, thus indicating the start time of the alert against possible obstruction. In the studied patients, changes in the pulmonary mechanics are observed with an average 47 hours before the episode of endotracheal obstruction.

Conclusion: We demonstrate that the application of computational intelligence techniques and data mining on lung mechanical signals studied, show promising results in the early detection of endotracheal obstruction.

This is of great value for the prevention of this complication during ICU admission, being useful in reducing the mortality of COVID-19 patients and reducing biosanitary risk.

Correspondence: G. Pérez-Acosta

Intensive Care Medicine Experimental 2020, **8(2)**: 001633

Introduction: The current COVID-19 pandemic has caused a high percentage of patients who require critical management due to acute hypoxemic respiratory failure with the need for mechanical ventilation. This situation implies a high vital risk in addition to possible respiratory complications such as obstruction of the endotracheal tube. This complication occurs suddenly from the first week of admission, it is a medical emergency due to the impossibility of ventilation of the patient and implies a high risk of contagion for the health workers due to exposure to aerosols.

Data mining and Artificial Intelligence (AI) techniques are a fundamental tool to create patient profiles, study their common characteristics and help predict the evolutionary development of this disease.

Objectives: Design and develop a computational predictive model to study the evolution of patients with COVID-19 pneumonia with

mechanical ventilation. Analyzing the clinical variables that help predict the development of endotracheal obstruction over time.

Methods: We recorded the clinical variables (heart rate, systolic blood pressure, diastolic pressure, mean pressure, oxygen saturation, and temperature) of all patients at least every 15 minutes during the entire intensive care admission. The variables were The set of variables were studied, represented in graphs synchronously and in parallel. Through data mining and the development of neural networks, a computational model was generated that helps early detection of endotracheal obstruction.

Results: In our unit, of the 22 patients with COVID-19 Pneumonia who required mechanical ventilation, 72.7% had at least one episode of endotracheal obstruction. 100% of these events took place after 7 days of admission.

The predictive model detects changes in the clinical variables studied that precede the endotracheal obstruction with an average advance of 42 hours.

In the Image 1, the changes observed in the clinical variables precede the development of endotracheal obstruction (green line). It shows common patterns of disturbances in the studied signals prior to obstruction. The blue line shows the start of abnormal registry changes indicating the time.

In the studied patients, clinical changes are observed with an average 42 hours before the endotracheal obstruction.

Conclusion: The use of signal recording of clinical variables, studied techniques using data mining and RNN techniques, show promising results in the early detection of endotracheal obstruction, being of great value for the prevention of this complication during ICU admission, reducing mortality of the Covid-19 patients as well as the risk for the health workers.

Intensive Care Medicine Experimental 2020, **8(2)**: 001214

Introduction: Continuous Positive Air Pressure (CPAP) treatment is used when approaching patients with dyspnoea in the prehospital (PH) setting¹. Despite being one of the best treatment strategies for this clinical condition, CPAP is an aerosol generating procedure. Therefore brought insecurity to the emergency PH teams and challenges to maintain its application. In order to promote its safe use the Department of Emergency Medicine (DEM) of the National Institute for Medical Emergency (INEM), modified the procedure promoting security.

Objectives: To analyse prehospital CPAP use in two homologous periods, before and during the COVID-19 pandemic.

Methods: A case series of CPAP used by Lisbon Immediate Life Support ambulance (SIV- ambulance staffed nurse), before and during COVID-19 pandemic will be compared. For this purpose, patients records between 1st of March and 30th July 2019 and the same period in 2020 were extracted from the ITEAMS clinical record (INEM Tool for Emergency Alert System), concerning the application of dyspnoea protocol^{3,4} where CPAP is recommended.

Results: Between 1st of March and 30th July 2019, dyspnoea protocol was applied in 121 patients, resulting in 11 uses of CPAP (9%). For the same period in 2020 (COVID-19 pandemic period), dyspnoea protocol was applied in 80 patients, resulting in 4 CPAP applications (5%). However, it should be considered that at the beginning of the pandemic in Portugal the use of CPAP was discouraged. Only after 28th of April 2020, when a safer method of CPAP was suggested, nurses felt comfortable and secure to use this treatment.

Between 1st of May and 30th July 2020, dyspnoea protocol was applied to 39 patients, resulting in 3 CPAP uses (7.7%), compared to the same period in 2019 when dyspnoea protocol was applied in 66 patients, resulting in 4 CPAP uses (6%).

Conclusion: The use of CPAP in PH is essential to maintain quality of care for patients with dyspnoea. Its use was decreased at the beginning of the pandemic in Portugal but measures were implemented promoting the safe use of CPAP. The results demonstrate the maintenance and even an increase in the use of CPAP compared to the same period in 2019 (7.7% in 2020 vs 6% in 2019). Until now, no staff member of the SIV Lisboa ambulance had COVID-19. This analysis refers to one out of the 40 SIV ambulances with nurses in Portugal, which is not sufficient to national extrapolation of data.

Predicting the response to high flow nasal cannula as first-line respiratory support in the patients with pneumonia covid-19 and acute respiratory failure

M. De Alba Aparicio¹; S. Carcel Fernandez¹; C. López Martin¹; M. Porras Pantojo¹; C. De La Fuente Martos¹; JM. Serrano Simón¹

¹Intensive Care Unit, Hospital Universitario Reina Sofia, Córdoba, Spain

Correspondence: M. De Alba Aparicio

Intensive Care Medicine Experimental 2020, **8(2)**: 001261

Introduction: Experience from the use of high-flow nasal oxygen (HFO) in acute hypoxemic respiratory failure (AHRF) (1), indicates that this method of respiratory support may reduce the invasive mechanical ventilation requirement of patients with COVID-19, depending on the degree of V/Q matching, and may be an appropriate therapy when conventional oxygen therapy does not provide sufficient respiratory

support. However, its application is controversial, particularly for the risk of aerosolization.

Objectives: To describe the characteristics and identify prognostic factors in response to the application of HFO as first line of respiratory support of patients Covid-19 with AHRF.

Methods: Analysis of prospectively collected data of 41 patients with pneumonia Covid-19, confirmed by RT-PCR assay, admitted to our polyvalent ICU of tertiary hospital (34 bed), from 22 March to 5 May 2020. Patients with moderate AHRF (PaO₂/FiO₂ 100-200 at admission) were included. Excluded patients were < 18, immediate mechanical ventilation (MV) criteria, hypercapnia or given HFO as a tool to weaning from MV. The HFO was applied using Philips V60[®] ventilator and Fisher & Paykel[®] MR850 device, flow 40-60 L/min, FiO₂ for SpO₂ ≥ 92%. We compared baseline characteristics, physiological, prognosis parameters, and Rox index in the first 12 h, as ratio of SpO₂/FiO₂ to respiratory rate (2), according to success or failure HFO. For statistical analysis we used U-Mann-Whitney or Fisher test as appropriate. Prognosis of success of HFO was calculated as sensitivity and specificity, relative risk (RR) (95% CI) and ROC curves for ROX index. The literature determines the cut-off point at 12 h at 4,88.

Results: Among 41 patients with AHRF Covid-19 admitted to the ICU, 20 (48.78%) were intubated on admission. Altogether 21 (51.22%) patients were eligible for HFO, 15 (71.43%), were defined as success which was regarded as no escalation to non-invasive ventilation, MV, ECMO or death within 28 days after commencement of HFO. Characteristics patients are shown in Table 1, the two group were well matched, only SOFA scores shown significant difference in failure HFO. Overall ICU mortality: 11 (26.83%), MV vs HFO: 8 (19.5%) vs 3 (7.3%) (p = 0.015). Parameters related to outcome see Table 2. ROC analysis for ROX index showed an AUC of 0.889 (95% CI 0.697 – 0.988). A cut-off ≥ 5.57 was associated with the best index for success, sensitivity of 0.93 (95% CI 0.75-0.91), and specificity of 0.83 (95% CI 0.41-0.98), PPV of 0.94 and NPV 0.83. RR 6 (95% CI 1.47-24.42).

Table 1. Characteristics of the 21 patients covid-19 with HFO.

Parameter	Overall (N=21)	Success (N=15)	Failure (N=6)	P

	Respiratory	5 (26.3%)	3 (15.8%)	2 (10,5%)	0.520
	Immunosuppression	6 (31.6%)	2(10,5%)	4 (21,1%)	0.071

Table 2. Outcome of the 21 patients covid-19 with HFO.

Parameter	Overall (N=21)	Success (N=15)	Failure (N=6)	P
Duration HNFO, days	3 (2-5)	4 (3-5)	2 (1.75-2.25)	0.007*
Duration of stay ICU, days	6 (3-9)	4 (3-7)	8.75 (6.75 – 18.75)	0.026*
ICU mortality, n (%)	3 (14.3%)	0	3 (50%)	0.025*
Rox index 12h	6.60 (5.48-9.85)	7.84 (6.0-10.89)	4.88 (3.53-6.48)	0.007*

Conclusion: In our sample of Covid-19 patients, the Rox index at 12 h allowed us to predict with accuracy the response to HFO with a cut value of 5.57, similar to the cut value describe in the literature for other causes of moderate AHRF. SOFA index value could be helpful in selecting the patients who could benefit from HFO. Careful selection of patients to whom HFO is applied as first-line treatment is necessary, since those who fail and delay intubation have high mortality and higher stay in ICU. Data need to be confirmed in wider population.

Intensive Care Medicine Experimental 2020, **8(2)**: 001277

Introduction: COVID-19 pandemic is an international health problem. Declared a worldwide pandemic by World Health Organization (WHO) in February 2020, the main complication causes severe acute respiratory syndrome (SARS-CoV-2) progressing to hypoxemia, requiring high oxygen fractions and invasive ventilation. The growing number of patients requiring invasive ventilatory support and the limited number of mechanical ventilator overload of the health systems. Alternative ventilatory support strategies are need for these individuals with COVID-19.

High-flow nasal cannula (HFNC) get attention as an alternative resource of ventilatory support for patients with severe hypoxemia.

Objectives: The primary outcome this study was to evaluate the proportion of patients that HFNC avoided tracheal intubation.

Methods: We realized a retrospective observational study of the patients that received HFNC as ventilatory support for treatment of acute respiratory failure because COVID-19.

Results: This study analyzed a total of 16 patients who used high flow nasal cannula (HFNC) for treatment of hypoxemic acute respiratory failure on patients with COVID-19, between the patients, we analyzed a subgroup of 5 patients who received combined therapy. For the purposes of this we classified combined therapy as HFNC and noninvasive ventilation (NIV). The rate of success for avoid tracheal intubation was 69% on HFNC group and 100% on combined therapy group, the average time of use of therapy was 4 days versus 6 days respectively, we also analyzed the time of duration on hours that was 92,8 (SD ± 64,7) hours versus 134,4 (SD ± 84,2) hours respectively. This study verified that the most of patients presented the worst radiologic pattern but doesn't seem influenced on outcome.

Conclusion: High-flow nasal cannula was feasible, and it seems to be an efficient in avoid tracheal intubation in patients with COVID-19. The effect of HFNC in COVID-19 survival should be further investigated in a large prospective study.

Face mask CPAP to Treat Acute Hypoxemic Respiratory Failure in COVID-19 Patients: characteristics and outcomesK. Belkhouja¹; W. Algarni¹; A. Alansari¹; B. Aljedaani¹; A. Hassan¹; M. Darwish¹; S. Omer¹; H. Al-Sharif¹¹Intensive care department, King Fahad Armed Forces Hospital, Jeddah, Saudi Arabia**Correspondence:** K. Belkhouja*Intensive Care Medicine Experimental* 2020, **8(2)**: 001399

Introduction: Acute hypoxemic respiratory failure and ARDS are common in COVID-19. The benefit of continuous positive airway pressure (CPAP), and associated risks of viral transmission through aerosolization, are unclear. Discouraging noninvasive ventilation (NIV) in the COVID-19 patient may increase the need for intubation and induce increased morbidity and mortality and led to rapidly saturation of resources and the availability of ICU bed. Some studies suggest that helmet CPAP can represent an effective alternative to improve the hypoxemia and decrease the risk of droplets' air-dispersion.

Objectives: To evaluate, the safety and efficacy of face mask CPAP in COVID-19 patients with acute hypoxemic respiratory failure.

Methods: Retrospective descriptive observational cohort study was conducted, from Mars 25, 2020, to July 28, 2020, in King Fahad armed forces hospital, Kingdom of Saudi Arabia. We included all adult patients with confirmed COVID-19 pneumonia and developed acute hypoxemic respiratory failure defined by PaO₂/FiO₂ less than 300 mmHg and required CPAP. We collected baseline data on demographics, clinical presentation, laboratory, arterial blood gas, ventilation setting, and the outcomes, mainly the rate of tracheal intubation, the rate of Health care workers (HCWs) contaminated by SARS-CoV2, the length of stay and the rate of mortality. The failure of CPAP was defined by the requirement of tracheal intubation. We determined by multivariate analysis, the independent predictive factors of CPAP failure.

Results: Of the 86 patients included in the study, the median (IQR) age was 62 (54-70) years and 58 (67.3%) were male. 78 patients (90.7%) had at least one comorbidity. The median (IQR) of SOFA score and APACHE II score were 4 (3-5) and 9 (7-13) respectively. The median time from first symptom to CPAP was 7.0 days. The median level of CPAP and FiO₂ were 10 cmH₂O and 0.5, respectively. The median (IQR) PaO₂/FiO₂ was 143 (120-169) and 13 patients (15.1%) had severe acute respiratory distress syndrome. The prone position with CPAP was performed in 31 patients (36%). The methylprednisolone was administered to 70 patients (81.4%) and empiric antibiotics to 83 patients (96.5%). The rate of failure of CPAP was 17.4% (15 patients) among them 3 patients was intubated within the first 24 hours of admission. The SOFA score at admission more than 4 [OR, 4.63; 95% CI, 1.11–19.33; P = 0.035] and PaO₂/FiO₂ at admission less than 140 mmHg (OR, 11.22; 95% CI, 2.44–51.61; P = 0.002), were independent risk factors of CPAP failure whereas the proning during CPAP (OR, 0.067; 95% CI, 0.01–0.41; P = 0.004) was a protective factor. One nurse caring for a patient was infected with SARS-CoV2. The median (IQR) length of stay was 9 (7-12) days and 6 patients (7%) had died.

Conclusion: The face mask CPAP as respiratory support for COVID-19 pneumonia with acute hypoxemic respiratory failure, is effective and safe. The rate of CPAP failure is less than 18% and the 3 predictive factors of failure were, SOFA score at admission, PaO₂/FiO₂ at admission and the use of prone position during CPAP.

CPAP helmet vs Invasive respiratory support in COVID-19 acute respiratory distress syndrome in elder patients: a monocentric retrospective studyM. Napolitani¹; F. Stefanini²; L. Bastia²; S. Russo³; I. Cuevas Cairo⁴; A. Pezzi⁵

¹Department of neurointensive care, Niguarda Hospital, ASST Grande ospedale metropolitani, Milan, Italy; ²Department of intensive care, Niguarda Hospital, ASST Grande ospedale metropolitano, Milano, Italy; ³Department of biomedical and clinical science "Isacco", University of Milan, Milano, Italy; ⁴Department of intensive care, San Carlo Borromeo Hospital, Milano, Italy; ⁵Department of intensive care, Ospedale Bassini, Cinisello Balsamo, Italy

Correspondence: M. Napolitani*Intensive Care Medicine Experimental* 2020, **8(2)**: 001495

Introduction: The recent COVID-19 pandemic has been dramatically aggressive in the region of Lombardy: the overwhelming number of patients who needed intensive care during the peak of the health emergency, exceeded the available resources. This crisis led to a revision of the usual admission criteria to the ICU: patients with a higher expectation of survival had priority access to ICU. Outside the ICU, the highest ventilatory care was CPAP helmet (up to 12 cmH₂O PEEP and FiO₂ 0.8). Looking backward to those daunting weeks, we noticed some anecdotal cases who survived in medical wards despite severe COVID acute distress respiratory syndrome (C-ARDS) without mechanical ventilation (MV).

Objectives: Hence, we retrospectively compared mortality rates between elder C-ARDS patients treated with MV vs CPAP helmet.

Methods: We retrospectively analyzed the outcomes of patients with severe C-ARDS. Two groups were made: first, CPAP group with elder patients (age 70-79) treated with CPAP helmet (with no access to ICU) with a refractory hypoxemia (P/F < 150 for more than 48 h regardless the administration of CPAP helmet); second MV groups, made of patients assisted with an endotracheal tube (ETT) and ventilated with positive pressures, aged 55-69, and elder ones, aged 70-78. Additionally, we collected the maximal d-dimer values per each patient before and after the placement of the ETT.

Results: We hospitalized 493 patients with covid respiratory distress syndrome. CPAP group (n = 22) had a lethality rate of 50%. The lethality of the MV group aged 55-69 (n = 31) was 52%, while about the elder CMV group (n = 13) 77% died. We found a significant increase (p value < 0.05) in plasmatic d-dimer after CMV begun: mean values pre - ETT (n = 15) 8362 µg/dl (CI ± 5987); mean values post - EET (n = 30) 21846 µg/dl (CI ± 10781).

Conclusion: Among patients with C-ARDS, we found only a slight difference in mortality between the population admitted to ICU (receiving MV) and the population not admitted (receiving CPAP helmet). Considering the thrombophilic condition caused by SARS COV2 infection, we raise the question if an aggressive invasive respiratory approach is advisable compared to a more gradual approach. However, we can not exclude that, in spite of similar hypoxemia, the ICU patients had a more severe clinical picture liable for the worse outcome. We acknowledge the limitations of our sample, but our results are interesting in light of a "less is more" strategy.

The impact of different levels of non-invasive ventilation on hemodynamics in healthy subjects

D. Vanhonacker¹; J. Jonckheer¹; E. De Waele¹

¹Intensive care, UZ Brussel, Jette, Belgium

Correspondence: D. Vanhonacker

Intensive Care Medicine Experimental 2020, **8(2)**: 001578

Introduction: Non-invasive ventilation (NIV) consists of respiratory support without the need for intubation. NIV has been used in a plethora of clinical situations such as acute pulmonary oedema, acute respiratory failure in patients with chronic pulmonary disease and obstructive sleep apnoea (1).

The application of positive pressure in the thoracic cavity has both positive and negative hemodynamic effects. It impairs the venous return to the right heart and the blood flow to the pulmonary arteries (reduced RV preload, increased afterload) but aids the flow of blood to and from the left ventricle (increased LV preload, decreased afterload) (2).

Objectives: The aim of this pilot trial is to investigate the impact of different levels of NIV on hemodynamics in a group of 5 healthy subjects.

Methods: The study protocol was approved by the ethical committee of UZ Brussel (B.U.N. 143201940980) and registered at clinicaltrials.gov (NCT04178694).

NIV (V60, Philips) was administered with an oro-nasal mask at an expiratory positive airway pressure (EPAP) of 4 cmH₂O and a pressure support (PS) of 0 cmH₂O. The subjects were allowed to adapt to the treatment for 5 minutes. Then, PS was gradually increased by 2 cmH₂O every 2 minutes until an inspiratory positive airway pressure (IPAP) of 12 cmH₂O had been reached and held for another 2 minutes.

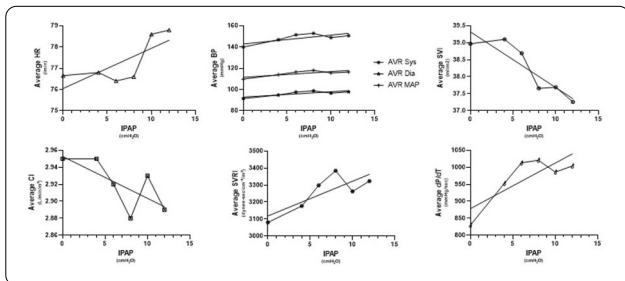

Non-invasive hemodynamic monitoring (Nexfin[®]) was used to monitor a range of hemodynamic parameters.

We analysed our data by simple linear regression with Graphpad Prism[®].

Results: Although the IPAP increased, the heart rate (HR) of the test subjects did not significantly rise (slope 0.189; R² 0.57; p 0.085). However, the diastolic blood pressure (DBP) significantly rose (slope 0.507; R² 0.68; p 0.043), the systolic (SBP) and mean arterial blood pressure (MAP) also went up but not significantly (slope 0.832; R² 0.60; p 0.070 and slope 0.536; R² 0.65; p 0.054).

The stroke volume index (SVI) dropped significantly at higher IPAP levels (slope -0.164; R² 0.82; p 0.014), the cardiac index (CI) diminished slightly but the change was not significant (slope -0.005; R² 0.52; p 0.108).

Both the systemic vascular resistance index (SVRI), a surrogate for afterload, and the dp/dt, which is a measure for LV contractility as it represents the ratio of pressure change in the LV during the isovolumetric contraction period, increased but not by a statistically significant amount (slope 20.42; R² 0.65; p 0.053 and slope 13.44; R² 0.65; p 0.051).

Conclusion: This pilot trial suggests that NIV induces hemodynamic changes in healthy volunteers. These changes appear to be related to the amount of IPAP applied.

Following a decline in venous return, a decreased stroke volume and cardiac output may trigger baroreceptors in the cardiovascular system. The activation of these receptors could augment sympathetic

tone, resulting in a blood pressure rise, an increase in HR, SVR and contractility.

A follow-up trial on a larger population is needed to confirm and validate these results.

Intensive Care Medicine Experimental 2020, **8(2)**: 001595

Introduction: The optimal management strategy for respiratory support in covid-19 remains unclear. A low threshold for invasive ventilation in patients with moderate to severe respiratory failure has been advocated by some. The use of NIV in MERS, a similar coronavirus, had a high risk of failure. In addition, the hypothetical risk of patient self-inflicted lung injury (PILI) raised concerns that CPAP may be detrimental in Covid-19. However, use of CPAP avoids associated morbidity of invasive ventilation and is less burdensome on healthcare resources.

Objectives: Primary: To establish the success of CPAP for respiratory failure secondary to covid-19; defined as avoidance of invasive ventilation, liberation from CPAP and discharge from hospital in those appropriate for escalation of care.

Secondary: 1. To establish incidence of intubation and ventilation following CPAP and compare mortality rates for patients for those that were invasively ventilated on admission to ICU compared to those that had a period of CPAP prior to invasive ventilation. 2. To identify associated factors of those patients on CPAP that required intubation and ventilation.

Methods: A single centre retrospective observational study of all patients managed with CPAP for respiratory failure secondary to Covid-19 from 10th March to 21st May 2020. Patients positive for SARS CoV2 RNA and those with a clinical diagnosis of covid requiring respiratory support were included. Further respiratory parameters were collected from a subset of 45 patients admitted between 16th March to the 3rd April 2020.

Results: 37 of 61 patients (60%) who received CPAP and were appropriate for escalation of care were managed successfully on CPAP alone. No patients that were appropriate for escalation died without escalation of care. Of those that required invasive ventilation (n = 24) mortality rates in those that had prolonged CPAP prior to invasive ventilation was not increased compared to those intubated immediately. In those where CPAP was the ceiling of care, outcome was poor; mortality rate 58% (19 of 33).

Table 1: Outcome of patients suitable for escalation who received CPAP

Outcome	Survival n (%)
CPAP only, n=37	37 (100%)
Invasive ventilation following <48hr CPAP, n=8	3 (38%)
Invasive ventilation following >48hr but <7 days of CPAP, n=11	5 (45%)
Invasive ventilation following >7 days of CPAP, n=5	4 (80%)
Immediate invasive ventilation without CPAP, n=8	5 (63%)
All patients managed initially with CPAP who were appropriate for escalation, n=61	54 (89%)

Table 2: Respiratory parameters of those who progressed to invasive ventilation compared to those that were managed successfully on CPAP alone.

SF = oxygen saturations / fraction inspired oxygen. ROX = ratio of pulse oximetry/FiO2 to respiratory rate

Variable	Invasive ventilation	Successful CPAP	p (Wilcox)
	Median [IQR]	Median [IQR]	
SF pre CPAP	120 [116-152]	153 [120-160]	0.08
ROX index pre CPAP	5.28 [3.54-6.22]	5.94 [5.32-7.15]	0.12
Change in SF during CPAP	30 [9.58-55.88]	40.83 [9.17-49.93]	0.94
Change in ROX during CPAP	1.2 [-0.16-1.83]	1.8 [0.35-4.16]	0.23
Days on CPAP	1.5 [1-3.5]	3 [1.25-5.75]	0.23

S:F ratios and ROX index were significantly lower in patients trialed on CPAP that went on to require invasive ventilation.

Conclusion: Patients with Covid-19 that present with respiratory failure could be managed with an initial trial of CPAP in a well controlled and monitored area. It is likely that a third of these will progress to needing invasive ventilation, but two thirds are likely to escape the need for intubation and ventilation. This has a tremendous impact on resource allocation, ICU bed days, length of stay, and complications associated with intubation and ventilation. SF ratio and ROX index may play a role in differentiating between patients that are likely to improve with CPAP alone and those that will require invasive ventilation.

Intensive Care Medicine Experimental 2020, **8(2)**: 001601

Introduction: Available data suggests that 5–20% of patients with Coronavirus Disease-2019 (COVID-19) develop acute hypoxic respiratory failure (AHRF) (1). Guidelines have given a weak recommendation for non-invasive positive pressure ventilation (NIPPV) as a preventive strategy for avoiding intubation in this scenario (2). As such, the procedure should only be considered in selected COVID-19 patients with AHRF and without major organ dysfunction.

Objectives: To assess the effect of NIPPV on the rates of invasive mechanical ventilation (IMV) and in-hospital mortality in a series of patients with COVID-19 and AHRF.

Methods: Consecutive patients from a single center with confirmed COVID-19 admitted between March 1st and July 20th, 2020 were retrospectively analyzed. Patients were stratified according to an 8-point ordinal scale recommended by the World Health Organization for use in clinical research among hospitalized patients with COVID-19, and only those with severe disease (score ≥ 5) were included (3). Clinical variables and the respiratory support strategy were correlated to IMV requirement and in-hospital mortality. Categorical data were expressed by percentages and continuous variables were represented by the median with the 25th to 75th percentile interquartile range (IQR). Multivariate logistic regression models were performed to

determine independent associations. A p value < 0.05 was considered significant.

Results: Nine two patients were included, of which 61.9% were male, with a median age of 72 years (IQR 60.5-84). Significant comorbidities were hypertension (48.9%), diabetes (25%), cardiovascular disease (CVD) (10%) and obesity (10%). Sixty nine (75%) patients received NIPPV for a median of 5 days (IQR 1-13.5), of which 44 (63.8%) did not require IMV. NIPPV was significantly associated with a lower frequency of IMV (36.2% vs 87%, $p < 0.001$), even when adjusted for age, sex, hypertension, diabetes, obesity and underlying cardiovascular disease (OR 0.08 [95% CI 0.02–0.3], $p < 0.001$). The overall mortality rate was 32.6% ($n = 30$), and was lower in those treated with NIPPV (26.1% vs 52.2%, $p = 0.02$). In the multivariate analysis, NIPPV remained associated with lower mortality (OR 0.25 [95% CI 0.08–0.84], $p < 0.001$), whereas age ≥ 75 years was predictive of death (OR 12.2 [95% CI 3.4–43.1], $p < 0.001$).

Conclusion: In a series of patients with COVID-19 and AHRF, NIPPV was significantly associated with a lower frequency of IMV and in-hospital mortality. Identifying patients who may benefit from NIPPV and determining predictors of failure from the intervention are key factors to adequately allocate resources and improve clinical outcomes.

Intensive Care Medicine Experimental 2020, **8(2)**: 001651

Introduction: High-flow oxygen therapy via nasal canula (HFNC) is a technique that delivers heated and humidified oxygen through short nasal prongs at high flow rates. Its great tolerability and positive results of its use in pneumonia, immunocompromised patients and ventilatory weaning have highlighted it as a first-line option for some of these conditions. Recent data show that it's the only non-invasive ventilatory technique that doesn't increase death space during ventilatory support, allowing for continuous air renewal, minimizing the risk of hypercapnia. HFNC allows to oxygenate critical patients with isolated hypoxemia, preventing intubation allowing the lung to heal. It is the only device that oxygenates critical patients without compromising communication or feeding. It's beneficial effect on the epithelial lining makes it an option even in chronic obstructive respiratory disease.

Our study illustrates a 14 months experience in a secondary care center, since HFNC acquisition. The team based their strategies on the local protocol that relied on starting with maximum temperature, O2 Flow and FiO2, and decrease support after 2 hours.

Methods: We performed a retrospective study with a descriptive analysis of HFNC's application in our Secondary Care Center Intensive Care Unit (ICU), from February 2019 through June 2020.

Results: In 14 months a total of 33 patients were treated with HFNC. The mean age was 63.5 years and 63.6% of the patients were male. The average duration of HFNC was 2 days. The major condition for its

use was acute respiratory failure (72.7%). In 18.2% it was used for ventilatory weaning. In 3 cases it was applied in patients with a do-not-intubate order. The most common diagnosis was community acquired pneumonia (54.2%). HFNC was successful in 51.5% of the cases, with pneumonia being the most common successful condition (58.8% of the successful cases). In the cases of failure, 25% had COVID-19 pneumonia, and 31.3% presented with associated multiorgan dysfunction. 50% needed invasive mechanical ventilation, while 25% proceeded successfully with non-invasive ventilation (NIV) with positive pressure. When HFNC was used for ventilatory weaning, 66.7% had a successful outcome.

Conclusion: Literature on HFNC includes a heterogeneous group of patients with diverse clinical diagnosis. It is increasingly applied in adults with hypoxemic respiratory failure with diverse etiologies. As observed in our report, diverse studies present pneumonia as the most common cause of respiratory failure in patients selected for HFNC. Some studies assessed the need of intubation after a HFNC trial and found that only 30% required intubation after failure of HFNC. In our study the “failure rate” was approximately 48.5%. HFNC delayed use in patients with advanced stage disease and multiorgan dysfunction might explain these results. The development of studies to determine which group of patients benefit the most from HFNC is imperative. The 25% patients with HFNC failure that progressed successfully to NIV raise the question whether they had a limitation for the technique that was not initially identified by the physician. The possibility of avoiding intubation in patients with severe hypoxemia worths the trial, even in cases with uncertain predicted responsiveness. It is fundamental to watch closely the evolution of these patients because, besides its benefits, HFNC shall not delay intubation when it is needed.

Intensive Care Medicine Experimental 2020, **8(2)**: 001285

Introduction: Patients with cancer are at risk of being admitted to the intensive care unit (ICU) with a mortality rate similar to that of the general ICU population (30-65%) (1). Prognosis factors are described for general ICU patients, while there is scarce information about such factors in critically ill patients with hematological malignancies. Hence, to provide better care for our patients, more information is needed.

Objectives: To describe the characteristics of patients with hematologic malignancies (HM) admitted to the ICU, and to determine the association between already known prognostic factors and mortality in our population.

Methods: A descriptive-analytical, cross-sectional study was done. Adult patients with HM admitted to the ICU from Jan 2008 – Dec 2018 at Hospital Universitario Fundación Santa Fe de Bogotá, Colombia, were enrolled. Demographics, disease stage, disease-specific parameters, laboratory results, hospital course, and outcomes were gathered from medical charts and analyzed using SPSS ver. 25.

Results: From the 185 patients enrolled, most were men (56.8%), the mean age was 63 years, and ICU admission was mostly due to cardiovascular causes (17.9%). Lymphoma (43.2%) and multiple myeloma (MM) (28.1%) were the most frequent hematologic diagnosis, and the majority were diagnosed recently (49.7%). More than half (~65%) were receiving acute treatment, either induction therapy (45%) or rescue therapy (18.3%). Around 29,1% of patients required vasopressors and 25,4% required mechanical ventilation, with a mean duration of 3.34 (1-21), and 5.45 (1-26) days respectively. Overall mortality was 31.3%, divided into ICU mortality of 21,6% and in hospital mortality of 9,7%.

Subgroup analysis for HM type showed a difference in mortality rates. Lymphoma patients had greater mortality (41.3%), followed by acute leukemias (29.3%), and MM (24.1%). Nevertheless, this difference was not statistically significant. On the other hand, mortality was more common in patients undergoing induction (24.48%) and rescue (22.41%) chemotherapy.

The bivariate analysis showed that male sex (OR:2.18,p:.022), previous diagnosis of non-hematological malignancy (OR:2.17,p:.043), neutropenia on admission (OR:2.11,p:.038), disseminated intravascular coagulation (OR:4.49,p:.012), alveolar bleeding, (OR:9,86,p:.03), requirement of mechanical ventilation (OR:5.99,p: < .001) and transfusion (OR:3.39,p: < .001) were associated with general mortality.

Binomial logistic regression showed that diabetic patients (B:1,638;OR 2,68;p = ,034), vasopressor requirement (B:2,83; OR 8,31;p = < ,001) and dialysis requirement (B:2,93; OR 8,602;p = ,001) were strongly associated with ICU mortality.

Conclusion: Mortality rates in our patients were similar to those already described, albeit on the lower end. Lymphoma patients and those in induction therapy had greater mortality compared to others. Also, hematological causes were the most common cause of admission for deceased patients. Lastly, in our population, the main predictors of mortality were diabetes, use of vasopressors and hemodialysis requirement.

Characteristics of oncohematological patients admitted to the ICU of the Virgen de las Nieves Hospital in 2018-2020

L. Hidalgo Manchado¹; A. Sánchez González¹; I. Guzmán Adum¹; R. De La Chica Ruano¹

¹Intensive care unit, Hospital Universitario Virgen de las Nieves, Granada, Spain

Correspondence: I. Guzman

Intensive Care Medicine Experimental 2020, **8(2)**: 001576

Introduction: The prognosis of malignant hematological diseases has changed in the past few years, making it increasingly frequent the admission of these patients to the ICU; but controversy continues regarding the real benefit of ICU admission in the long term.

Objectives:

- To describe the baseline characteristics of hematological patients admitted to our ICU.
- Identify factors likely associated with higher mortality in these patients.
- Description of mortality according to the main causes of ICU admission and comparison between them.

Methods: Observational, retrospective and analytical study that includes oncohematological patients admitted to the ICU between April 2018 and 2020. A database was created in SPSS with the baseline characteristics of the patients (demographic, comorbidities, underlying disease, transplantation of hematopoietic precursors, neutropenia), cause of ICU admission, cause of death, respiratory support and decision to limit life support treatment. They were then evaluated in terms of descriptive statistics with frequencies for qualitative variables and median, interquartile range for quantitative; Comparisons between groups were made using the Student's t test and chi square respectively.

Results: Of the 60 patients included, 25% were admitted in 2018, 46.7% in 2019 and 28.3% in 2020 so far, of which 28 (46.7%) are women and 32 (53.3%) men. Base disease: lymphomas 18 (30%), leukemias 36 (60%), myelomas 3 (5%), others 3 (5%), relationship with mortality (p = 0.54). Prior to admission, 3 (5%) had received autoHSCT, 24 (40%)

alloHSCT and 32 (53.3%) had not yet been transplanted; association with mortality ($p = 0.59$). 39 (65%) developed neutropenia, with no direct relationship to mortality ($p = 0.63$). The causes of ICU admission were: respiratory failure (56.67%), septic shock (26.67%) and loss of consciousness (11.6%), with no difference in mortality between them ($p = 0.6$). Regarding respiratory support, 45 (75%) required NIMV/HNFO and 33 (55%) IMV, the latter with higher mortality ($p = 0.003$). Total mortality in ICU 38 (63.3%), significantly higher than overall unit mortality (18.3%), $p = 0.001$. LTE was decided in 24 patients (40%).

Conclusion:

- The admissions of oncohematological patients in the ICU are increasing in the last years.
- The characteristics that were significantly related to a higher mortality were: age, invasive mechanical ventilation and SOFA score.
- The underlying disease, the cause for admission to the ICU, the HSCT, the presence of neutropenia and the requirement for NIMV did not present a statistically significant relationship with the mortality of these patients.
- ICU mortality in oncohematological patients, regardless of the cause of admission, is higher than the overall mortality in the ICU.

Early Carboxyhaemoglobin (COHb) Blood Concentration May Predict Outcome in Patients with Out of Hospital Cardiac Arrest (OOHCA)

T. Bucknall¹; O. Valencia²; G. Zilahi³

¹Foundation year doctor, St Peter's Hospital, Lyne, United Kingdom; ²Cardiovascular sciences research centre, St George's, University of London, London, United Kingdom; ³Intensive care, St George's Hospital, London, United Kingdom

Intensive Care Medicine Experimental 2020, **8(2)**: 001340

Introduction: Outcome prediction after Out of Hospital Cardiac Arrest (OOHCA) remains challenging with high cost and resource burden. Multimodal approach has been adapted in most hospitals as advised by the ESICM and ERC (1). Carbon Monoxide (CO) has recently gained interest as a molecule with wide ranging physiological properties (2). The potential for novel pharmacological intervention is vast and exciting (3,4). Most notably, CO plays an important role in apoptosis related cell death with ischaemic-reperfusion brain injury (5–7). We proposed that early CO measurement, using COHb as a surrogate marker, correlates with outcome in our OOHCA patient population.

Objectives: We retrospectively analysed Arterial Blood Gas (ABG) data to measure COHb blood concentrations in patients admitted from OOHCA for an initial 72-hr period. We evaluated COHb with regard to our long term follow up outcomes.

Methods: Retrospective data for 94 patients who were admitted to our Cardiothoracic Intensive Care Unit (CTICU) after OOHCA during 2016. Data collected included: ABG measurements for the 72hr period, demographic, and prognostic scores (Intensive Care National Audit & Research Centre (INARC) and Acute Physiology and Chronic Health Evaluation (APACHE II) and outcome measures (Death and cerebral performance score (CPC) in hospital and at 3-, 6- and 12-month intervals).

Univariate analyses of categorical and continuous data were performed to determine differences between Patients who died or remained alive following OOHCA. Tabulations of dichotomous or categorical variables for comparisons using Chi-square Test. The distribution of continuous variables was assessed for normality with Shapiro-Wilk Test, and Independent Samples Test or Mann-Whitney U Tests were used to compare both groups. The Receiver Operating Characteristic Curve analysis was required for survival, along with Multiple Logistic Regression analyses and graphical methods. Friedman Repeated Measures Analysis of Variance on Ranks was needed and Pairwise Multiple Comparison Procedures (Tukey Test) was used to isolate the group of samples that differ from the others.

Results: 94 patients were analysed, and the overall survival was 56%. 73% of the patients were male and median age was 65 years. Median age ($p < 0.001$), mean ICNARC score ($p < 0.001$), median APACHE II score ($p < 0.001$), median lowest pH ($p < 0.001$), and median lowest COHb concentrations in the first 5 hours ($p: 0.032$) were significantly different in the surviving population. Initial 5 Hour Median COHb $\geq 0.975\%$ had a sensitivity of 0.77 and specificity of 0.49 to predict survival in our OOHCA patient population with the AUC of 63%.

Conclusion: Initial COHb blood concentration measurements are predictive of overall survival in patients presenting to hospital with OOHCA. This may be explained by the cytoprotective effects of CO in ischaemic-reperfusion brain injury, but further larger scale evaluation of the association is planned and required.

Out-of-hospital cardiac arrest (OHCA) during the COVID-19 pandemic in Doha, Qatar

B. Albaroudi¹; O. Albaroudi¹; F. Mohammed¹; T. Salam¹; AM. Ahmad¹; A. Abdulrahman²; H. Tim¹

Intensive Care Medicine Experimental 2020, **8(2)**: 001574

Introduction: OHCA is a common disease with a high mortality with the commonest cause being ischaemic heart disease(1). Survival ranges from around 1-3% to 20-25%, suggesting that high quality care can have significant impact on survival(2). One small study reported a survival of 8.1% for Qatar(3). The COVID-19 pandemic caused by SARS-CoV-2, initially reported in China in December, 2019, and subsequently announced as a global pandemic by WHO on March 11, 2020. The first case of SARS-CoV-2 reported in Qatar was on 29th of February. More than 90000 cases of COVID-19 have been reported in Qatar since February 2020, with more than 145 deaths as of mid-July, 2020. The risk of viral transmission from patients in OHCA to health care workers saw changes in practice recommended in international guidelines. Cardiopulmonary resuscitation (CPR) and endotracheal intubation according to the centers for disease control and prevention (CDC) are aerosolizing procedures and should be performed using full personal protective equipment (PPE), moreover few hospitals told

their healthcare worker not to perform CPR or ventilation in patient suspected to have Covid-19 diagnosis unless they are wearing full PPE (5, 6). Public behavior also changed due to either the restrictions on public movement to reduce viral transmission or the fear from coming to hospital with COVID-19 cases with many countries reporting falling in ED attendances (7). In Qatar all outpatient clinics moved on line with possible difficulties for the patients to obtain medications and investigations, arguably reducing the quality of care provided. Our ED saw only small falls in public attendance and the cardiac catheterization rate remained stable. All these previously listed factors and changes have unknown consequences on the incidence and survival of OHCA with possible direct or indirect impact on the quality of care. Previous publications have highlighted an increased incidence of OHCA and reduced survival during the Covid-19 pandemic. Given these differences, we collected data on the incidence and survival of OHCA in our population.

Methods: Date collection: We developed a dedicated Covid-19 OHCA guideline and set up a dedicated team to teach this in our ED. In order to ensure rapidly emerging knowledge and to be translated into clinical care we set up a dedicated team to collect data on non-traumatic OHCA management and outcomes. We met weekly and adjusted our care according to local data, international guidelines and emerging knowledge on both transmission risk and treatment. The data in this report was collected using PAROS (Pan Asian Resuscitation Outcomes Study) which relay on Ustein complaint data. The Ustein criteria are a standardized data set used internationally to collect data on OHCA(4). Data was collected prospectively during Covid-19 outbreak from mid-March till mid-June 2020 (12 weeks period). Retrospective data was collected from the electronic medical records in the same period extending from mid-March till mid-June 2019 (12 weeks period) using the same template. Both periods data (2019 and 2020) was analyzed for the following: incidence, location of arrest, gender, age, first assessed rhythm, survival to hospital admission, survival to hospital discharge. Comparison graphs were established to show the deference between 2019 and 2020 of the same yearly periods. Setting: Qatar has a population of 2.8 million with around 90% being non-nationals and a median age of 32.3 years. Hamad General hospital emergency department (ED) is the largest ED in Doha, Qatar, with average ED visit > 1000 patients per day. It is co-located with a dedicated cardiac hospital and receives > 90% of cardiac arrests in Qatar. There is 24/7 PCI and an active ECMO service. eCPR was ceased during the pandemic to preserve the resource for Covid-19 related respiratory failure. Local policy sees around two thirds of OHCA transported to hospital. The project was registered along departmental guidelines with corporation level approval.

Results: The total number of non-traumatic OHCA during COVID-19 outbreak period in 2020 was 92 cases compared to 69 cases in non-outbreak period in 2019. The average weekly incidence of OHCA for outbreak period and the non-outbreak period were 7 and 5.3 respectively. survival to hospital admission (SHA) and Survival to hospital discharge (SHD) were in outbreak period (28.3%) and (11%) respectively, compared to the non-outbreak period where SHA (43.5%) and SHD (22%).

Conclusion: Two reports from Europe showed an increase the OHCA incidence during COVID outbreak. The first one in Lombardy, Italy (8) and the second one in Paris, France (9). There is an increase in OHCA incidence during COVID-19 outbreak in Qatar. This result might be partly related to the effect of COVID-19 outbreak. Unusual unexpected situation like Outbreak or a crisis might have an impact on health care system by direct or indirect ways. healthcare provider training and population education might mitigate that effect.

Intensive Care Medicine Experimental 2020, **8(2)**: 001190

Introduction: Weaning and tracheal extubation of post-operative ICU patients is a stressful procedure which triggers the sympathetic nervous system leading to potential deterioration of cardiac performance in patients with left ventricular dysfunction. This study was conducted to compare the efficacy and safety of Landiolol, a novel ultra-short-acting-beta-1 blocker with those of Esmolol in cardiovascular response during the extubation of patients with heart failure.

Methods: Thirty-nine patients with heart failure [LVEF (%): 36.6 ± 7.6, NYHA Class III/IV (n): 32/9] were randomly divided into two groups: Landiolol group of 19 patients and Esmolol group of 20 patients. Landiolol infusion at the rate of 4 µg/Kg/min and Esmolol infusion at the rate of 100/Kg/min was started as soon as the procedure of weaning began. Heart rate (HR) systolic arterial pressure (SAP) diastolic arterial pressure (DAP) mean arterial pressure (MAP) and cardiac rhythm were recorded every minute up to 30 min after the extubation of trachea.

Results: Mean age, LVEF, NYHA Class, Acute Physiology and Chronic Health Evaluation II and Sequential Organ Failure Assessment score were similar between the two groups. Landiolol produced a more rapid and substantial decrease in HR than Esmolol (-40 ± 20 vs -30 ± 16 bpm) without any deterioration of hemodynamics. Significant reduction of MAP was recorded in the Esmolol group.

Conclusion: Landiolol more rapidly and more potent reduced the HR than Esmolol. Significant reduction of MAP was recorded only in the Esmolol group.

Intensive Care Medicine Experimental 2020, **8(2)**: 001254

Introduction: Massive pulmonary embolism is a life-threatening complication of the patient admitted in intensive care unit (ICU) and the consecutive hemodynamic instability or cardiogenic shock is sometimes accompanied by unusual blood gas alterations. If hypoxemia and hypocapnia are usual, hypercapnia in embolic disease is rarely reported in the literature and is the result of increased dead space ventilation due to extensive embolic vascular obstruction.

Objectives: So the aim of this study was to hypothesize that the presence and persistence of hypercapnia during pulmonary embolism would be a marker of severity and of poor prognosis.

Methods: we retrospectively collected data from a group of 15 ICU patients (group 1) who presented hypercapnic pulmonary embolisms from 2017 to 2019 and compared them with those of a group of 15 patients (group 2) presenting pulmonary embolisms with normocapnia or hypocapnia, between 2012 and 2015. The number of patients with hypercapnic pulmonary embolisms being rare, we compared them with an identical number of patients presenting pulmonary embolisms with normocapnia or hypocapnia. The patients of the 2 groups were aged 68- + 7 years, weighing 75 + -6 kg, without previous cardiac or pulmonary pathology. The patients of the 2 groups were in spontaneous ventilation and breathed oxygen between 6 to 10 l/min. On admission to ICU, we monitored and recorded systolic arterial pressure (SAP) with a catheter inserted in radial left artery and evaluated with echocardiography, cardiac index (CI) and systolic pulmonary arterial pressure.(SPAP).We measured blood gases, lactate, BNP from the arterial wave line and finally we evaluated ICU mortality in each group.

Results: Statistical analysis was performed using Student 's t test. Results were expressed as mean +- standard deviation.

We observed that Pco2 (mmHg) in the group of patients presenting hypercapnic pulmonary embolism (group 1) was obviously different than in the group of embolism with hypocapnia (group 2), respectively 51.41+-4.10 vs 28.86+-1.18. P<0.0001. However, Po2 (mmHg) was not different between group 1 and group 2, respectively 74.33+- 4.8 vs 76.33+-1.87 P<0.14. SAP (mmHg) was in the group 1 significantly different of SAP of the group 2, respectively 79.2+-8.3 vs 102.06+-5.73 P<0.0001. Similarly, SPAP (mmHg) was different between group 1 and group 2 respectively 55.46+-2.50 vs 44.8+-1.78. P<0.0001. CI was different between group1 and group2, respectively 1.85+-0.09 vs 2.28+-0.14 P<0.0001. The value of BNP(Pg/ml) was more elevated in group 1 than in group 2 respectively 2888.33+-827 vs 1722+-291 P<0.0001. Similarly, Blood lactate concentration(mmol/l) was higher in group 1 than in group2, respectively 4.78+-1.14 vs 3.69+-0.77.P<0.005. ICU mortality, despite any therapeutic, was higher in the group 1 than in the group 2 respectively 50% vs 40%.

Conclusion: We can observe that massive pulmonary embolisms with hypercapnia seem to have a worse prognosis than those which are accompanied by hypocapnia or normocapnia.

The persistence of hypercapnia in a patient with previously healthy lungs indicates that 50% or more of the lung is underperfused and prompts the use of either thrombolytic therapy or surgical intervention.

Upper Gastrointestinal Bleeding (UGIB) in Latin America: Demographics, management and the role of AIMS65 predicting ICU mortality

SA. Prieto Garces¹; FS. Terán-Ibarra²; YE. Caballero-Díaz²; H. Gómez-Velasco²; LM. Sabogal-Angel²; LC. García-Medina²; A. Gómez-Aldana³; M. Álvarez-Gaviria⁴

¹Medicina crítica y cuidado intensivo, Fundacion Santa Fe de Bogota University Hospital, Bogotá, Colombia; ²Facultad de medicina, Universidad de los Andes, Bogotá, Colombia; ³Gastroenterología, Fundacion Santa Fe de Bogota University Hospital, Bogotá, Colombia; ⁴Cardiología, Fundacion Santa Fe de Bogota University Hospital, Bogotá, Colombia

Correspondence: S.A. Prieto Garces

Intensive Care Medicine Experimental 2020, **8(2)**: 001289

Introduction: Upper gastrointestinal bleeding (UGIB) is an emergency requiring prompt management to achieve favorable outcomes(1). It presents with hematemesis and/or melena (1), and may be followed by hemodynamic instability. Hemorrhagic gastritis and peptic ulcer disease make up for 75% of UGIB etiologies, while esophageal varices, esophagitis, duodenitis, and Mallory-Weiss syndrome represent the remaining causes (2).

However, in our population, knowledge about the epidemiological characteristics is scarce. Therefore, to correctly utilize our limited health resources, information regarding patients in our territory is needed.

Objectives: The objective is to characterize UGIB patients admitted into the intensive Care Unit (ICU) in a Latin American hospital and to determine the presence of prognostic factors associated with ICU mortality, in-hospital mortality and rebleeding.

Methods: An analytical, cross-sectional study, was carried out. UGIB patients admitted to the ICU between Jun/2013-Jun/2018 in a hospital in Bogotá, Colombia were enrolled. Demographics, comorbidities, clinical presentation, laboratory results, management, predictive scores, clinical course, complications and outcomes were retrieved and analyzed using SPSS ver.25. Descriptive analysis was done alongside a correlation matrix and binomial regression using outcomes such as rebleeding, ICU mortality and in hospital mortality, with a statistical significance of p<0.05. Rebleeding risk was according to Forrest classification.

Results: The study enrolled 321 patients, 62% were male and average age was 66.11 years. At admission, 75.7% were diagnosed with UGIB, black stools were present in 67% of patients, hematemesis in 31.8%, hematochezia in 17.1%, and ground-like vomit in 16.8%. Also, a significant number presented hypovolemic shock on admission (20.5%). Notably, 26.2% patients received chronic antiplatelet therapy, and 17.8% were anticoagulated.

For management, 99.1% received proton pump inhibitors and endoscopy was performed in 94.1% of patients. The main findings were peptic ulcer (44.9%), gastroduodenal erosions (17.4%), and esophagitis (10%). During endoscopy, 32.1% of patients underwent sclerotherapy, and 19.6% varicose veins clip ligation. Around 62.9% required red blood cell transfusion and 10% had intrahospital re-bleeding. Anticoagulation/anti-aggregation was restarted 6.34 days on average. Lastly, ICU mortality was 8% and average ICU stay was 4.93 days.

Logistic regression concluded that ICU mortality increases 7.39 times for males, 26 times if there are dementia, lung and/or liver comorbidities, 8.5 times if the person is anticoagulated and 5 times with each point of the AIMS65 (all of the above with a p= <0,05).

Conclusion: The demographic characteristics of UGIB patients in our hospital were similar to those reported on global literature. Also, rebleeding affects 10% of patients, a value lower than those reported (3). Lastly, this is the first study in south American literature that shows the usefulness of AIMS65 predicting ICU mortality of UGIB patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 001385

Introduction: Patients admitted to the Intensive Care Unit (ICU) for coronavirus disease 2019 (COVID-19) present an inflammatory state that conditions a high thrombotic risk. There are several studies about thrombotic events in patients with COVID-19 in ICU but they are limited in size and without report all thrombotic events.

Objectives: To determine the incidence of venous thromboembolic disease (VTE) in critically ill patients with COVID-19 and the correlation with D-dimer levels.

Methods: A prospective study of critically ill patients with severe SARS-CoV-2 pneumonia. Inclusion criteria: severe SARS-CoV-2 pneumonia confirmed by PCR and admission to the ICU. Exclusion criteria: ECMO, pregnant woman, puerperium, age < 18 years. The study included all patients admitted to the ICU who met the inclusion criteria and none of the exclusion on 15-16 April 2020. Ultrasound screening with venous compression bilateral in lower extremities was performed. Asymptomatic and symptomatic VTE was recorded [pulmonary thromboembolism (PE), deep vein thrombosis (DVT)] throughout the ICU stay, patient characteristics, blood test results, and results with 30 days follow-up. Categorical data are expressed as frequency (%). The quantitative data are expressed as mean (standard deviation) or as median (interquartile range 25-75). Categorical variables were compared using the chi-square test and Fisher's exact test. Continuous variables were compared with the T Student test or the Mann-Whitney U test. The association between D-Dimers and VTE has been calculated using the area below the curve (AUROC). Approved by the Ethics Committee of Clinical Research (PR (AG) 213/2020).

Results: On 15-16 April 2020, 118 patients [77% male, age mean 59.37 (10.20) years, BMI 30.5 (4.74), 100 (84.74%) with invasive mechanical ventilation] were studied. D-Dimer on the day of the ultrasound screening was 1575 (703.5-2963) ng/mL. VTE was prevalence of 30.5% (36/118). At 30 days of follow-up, the cumulative incidence of VTE was 35% (41/118): 31 DVT, 5 PE, 5 DVT + PE. There were 17 (14%) hemorrhages (4 major and 14 minor). The VTE was not more frequent in ventilated patients. Mortality was 13.6% (16 patients) without difference depending on the existence of thrombosis (5 patients in patients with VTE and 11 in patients without VTE, p ns). Elevation of the D-Dimer above 1500 ng/ml is related to thromboembolic phenomena (AUROC 0.77, p < 0.0001, 95% CI 0.62-0.82), sensitivity 73% and specificity 60%.

Conclusion: Patients admitted to the ICU for severe SARS-CoV-2 pneumonia are at high risk of VTE. The elevation of D-Dimers is related to VTE.

Intensive Care Medicine Experimental 2020, **8(2)**: 001434

Introduction: The availability of different mechanical circulatory support devices (MCSs) allows physicians to provide the most appropriate support to a wide range of clinical conditions.

Objectives: To analyze the different types of MCSs used in our Intensive Care Unit (ICU). Analyze the clinical characteristics of the patients who had removed their first device support and required a second device course.

Methods: Retrospective observational study from 2013 to 2019 in a third level ICU with heart transplantation program. We included all patients who required more than one device implantation. We examined demographic data, cause for VAD implantation, type of first (VAD1) and second (VAD2) device used, days of VAD support, ICU length of stay, in-hospital and ICU mortality. Absolute number and frequency described qualitative variables and median and interquartile range (IR) described quantitative variables.

Results: A total of 22 patients were included, 16 were male (72.7%), with a median age of 53.50 (34.25-60.50). The main reason for more than one device placement was post myocardial infarction cardiogenic shock 10 (45.5%) follow by descompensated chronic cardiomyopathy 6 (27.3%), postcardiotomy shock 1 (4.5%), non-ischemic cardiogenic shock 1 (4.5%), acute myocarditis 1 (4.5%), electrical storm 1 (4.5%), right ventricular dysfunction 1 (4.5%) and ischemic cardiomyopathy 1 (4.5%). VAD1 as bridge to transplant was performed in 11 patients (50%), bridge to decision in 8 (36.4%) and to recovery in 3 (13.6%). Different types of VAD implanted are shown in table 1. An average of 7 days of VAD1 support was reported (4.50 - 11.50[1]) and 7.5 days for VAD2 support (4.75 - 13.25). A second device placement was needed due to clinical deterioration as bridge to recovery 17 (77.3%), decision 3 (13.6%) and transplant 2 (9.1%). Median ICU stay of 32.50 days (16.50 - 44.75). ICU and hospital mortality of 36.4%.

Table 1. Types of VAD implanted.

	VAD1 (n = 22)	VAD2 (n = 22)
Central VA-ECMO	2 (9.1)	5 (22.7)
Peripheral femoro-femoral VA-ECMO	8 (36.4)	5 (22.7)
Peripheral femoro-axilar VA-ECMO	4 (18.2)	3 (13.6)
Right Centrimag		3 (13.6)
Left Centrimag	5 (22.7)	3 (13.6)
EXCOR	2 (9.1)	
EXCOR + Centrimag D		1 (4.5)
Biventricular Centrimag	1 (4.5)	
VV ECMO		2 (9.1)

Conclusion: In our cohort, post myocardial infarction cardiogenic shock was the main cause for placing more than one VAD. Femoro-femoral VA-ECMO was the most frequent device used. A second device placement increased to 59.1% the percentage of patients recovered.

001449

ECMO as a bridge to recovery: progress over the last decade

J. Navarro-Rodríguez¹; M. Mendoza-Prieto¹; S. Escalona-Rodríguez¹; N. Palomo-Lopez²; Y. Corcia-Palomo¹; L. Martin-Villen¹

Intensive Care Medicine Experimental 2020, **8(2)**: 001449

Introduction: Venous-arterial extracorporeal membrane oxygenation (VA-ECMO) is a temporary mechanical circulatory support (MCS) used as rescue therapy in patients with acute refractory cardiogenic shock. Its use as a bridge to recovery has been increasing over the last decade.

Objectives: To describe epidemiological and clinical features of patients with acute heart failure (AHF) admitted to our ICU that required VA-ECMO implantation as a bridge to recovery.

Methods: A retrospective study was performed from January 2011 to December 2019 in a third-level cardiovascular ICU. All patients with AHF that required VA-ECMO as a bridge to recovery were included. We collected demographic data, cardiovascular risk factors such as smoking, alcoholism, hypertension and diabetes mellitus, AHF etiology, ICU length of stay, ECMO cannulation techniques, days on ECMO, clinical outcomes and complications after ECMO implantation. Qualitative variables were described by absolute number and frequency; quantitative variables by median and interquartile range.

Results: A total of 40 patients were included, median age was 51.50 (40.25-60.75), 24 were males (60%). Smoking habits 21 (52.5%), alcoholism 6 (15%), hypertension 19 (47.5%) and diabetes mellitus 8 (20%). Past medical history of heart disease was detected in 26 (65%) patients being heart valve disease the most frequent in 8 patients (20%), followed by ischemic 5 (12.5%), congenital 4 (10%), idiopathic dilated 3 (7.5%), hypertrophic 2 (5%) and restrictive cardiomyopathy 1 (2.25%). Peripheral femoro-femoral cannulation was the most common technique in 22 (55%) patients, central ECMO in 10 (25%) and peripheral femoro-axillar in 8 (20%). Median time on ECMO was 6 days (3-11.25). Main causes of acute heart failure are shown in Table 1. The most frequent complications were pericannula bleeding 11 (27.5%) and mediastinal bleeding 14 (35%). Ventilator-associated pneumonia was reported in 15 patients (37.5%) under ECMO support and bacteremia in 13 (30%). Clinical outcomes are shown in Table 2. Median length of stay in ICU and in Hospital was 18 (7-38) and 51 (25-76) days respectively. Hospital mortality was 40%.

Table 1.

Etiology AHF (n = 40)	n (%)
Postcardiotomy shock	11 (27.5)
Ischemic cardiomyopathy	7 (17.5)
Right ventricle dysfunction	9 (22.5)
Acute myocarditis	5 (12.5)
Acute transplant rejection	3 (7.5)
Primary graft dysfunction	2 (5)
Non-ischemic chronic cardiomyopathy	2 (5)
Tachycardiomyopathy	1 (2.5)

Table 2. Clinical outcomes.

	n (%)
Recovery and weaned	20 (50)
Heart transplant	2 (5)
Second MCS device	2 (5)
Overall ICU mortality	16 (40)

Conclusion: ECMO is widely used in refractory cardiogenic shock as a bridge to recovery. Although the indications of implantation have

increased in the last years, ECMO is not free of risk, being infections and bleeding the most frequent complications.

Intensive Care Medicine Experimental 2020, **8(2)**: 001450

Introduction: Despite the differential characteristic of older patients, the results are not worse than in younger patients, so clinical decisions in these cases should be individualized.

Objectives: To assess the clinical, evolutive and prognostic characteristics of patients older than 70 years who underwent cardiac surgery for infective endocarditis.

Methods: We evaluated endocarditis patients from two hospital centers (Fundación Jimenez Diaz and Hospital Rey Juan Carlos in Madrid) operated by the same surgical team between 2010 and 2019.

Patients were divided in two groups according to age: GROUP 1 ≤70 years and GROUP 2 > 70 years. Any value of p < 0.05 is considered significant.

Results: We evaluated 103 patients, 50 of them older than 70 years (48.5%). Comparing the two groups (≤70 years vs > 70 years) we obtained:

Demographic data: Male sex (83% vs 50%; p < 0.001) and age (58.77 ± 9.36 vs 77.16 ± 4.49; p > 0.001).

Personal history: smoking (26.4% vs. 10.2%; p = 0.036), alcohol/drugs (7.5% vs. 0%; p = 0.05), arterial hypertension (45.3% vs. 71.4%; p = 0.008), COPD (17% vs. 10.2%; p = 0.320), Stroke (18.9% vs. 38%; p = 0.031), hypothyroidism (5.7% vs. 16.3%; p = 0.083), very reduced mobility (Barthel index < 50) (17% vs 30%; p = 0.118), non invasive mechanical ventilation (28.3% vs 12.2%; p = 0.045), previous cardiac surgery (18, 9% vs 55.1%; p < 0.001), coronary artery disease (7.5% vs 12.2%; p = 0.425).

Disease data: pre-surgery inotropic (34% vs. 14.3%; p = 0.021), moderate or severe LV dysfunction (20.8% vs. 10.2%; p = 0.143), arrhythmias (22.6% vs 40.8%; p = 0.048), cardiogenic shock (20.8% vs 6.1%; p = 0.032), prosthetic dysfunction (20.8% vs 51%; p = 0.001), emergency surgery (18, 9% vs 2%; p = 0.01), pre-intervention antibiotic (7.45 ± 7.15 vs 12.45 ± 10.99 days; p = 0.007) and days between diagnosis and surgery (5.05 ± 5.89 vs. 7.91 ± 8.05; p = 0.44), type of surgery (mitral valve 30.2% vs. 44.9%; aortic valve 39.6% vs. 28.6%; mitral valve and aortic 18.9% vs 20.4%; p = 0.362) and logistical EUROSCORE II (25.37 ± 21.23 vs 37.04 ± 20.50; p = 0.006).

Complications: atrial fibrillation (17% vs. 6.1%; p = 0.089), renal failure requiring temporary hemodialysis (18.9% vs. 8.2%; p = 0.116), mechanical ventilation > 96 hours (17% vs. 2%; p = 0.011), ICU admission days (13.22 ± 19.44 vs. 7.75 ± 9.88; p = 0.08), hospital discharge mortality (13.2% vs. 16%; p = 0.688).

Conclusion: There is a great number of elderly patients in our serie, predominantly male, smokers, alcoholic, with arterial hypertension, previous Stroke, and non invasive mechanical ventilation compared to younger ones. The orders present more pre-intervention complications with need os vasoactives and cardiogenic shock, arrhythmias,

prosthetic dysfunction, EUROSCORE II log and longer mechanical ventilation times.

001461

Prognostic value of Troponin increase in the first days of ICU admission due to Coronavirus

M. Rojas Amezcua¹; M. Guerrero Marin²; MC. Molina De la torre³; JA. Camacho Pulido⁴; C. Colmenero Aguilar²

¹Medicina intensiva, Hospital Cabra, Cabra, Spain; ²Medicina intensiva, Hospital of Jaen, Jaén, Spain; ³Intensive care, Hospital of Jaen, Jaén, Spain; ⁴Medicina intensiva, Hospital Universitario "San Agustín", Linares, Spain

Correspondence: C. Aranda Martínez

Intensive Care Medicine Experimental 2020, **8(2)**: 001461

Introduction: To asses in those patients admitted on the ICU for coronavirus the relationbetween mortality and some prognostic ratings evaluated at the admission and on the thirdday.

Methods: Prospective cohort study of patients with coronavirus admitted to the ICU at the HospitalUniversitario de Jaén, Hospital San Agustín de Linares and the Hospital Infanta Margarita deCabra.Continuous variables are expressed as median (25th percentile, 75th percentile) andqualitative variables with absolute and relative frequencies. U Mann Whitney was used forcomparison of continuous variables and X2 for qualitative variables. Discrimination wasassessed with the area under RO curve P <0.05 was considered as statistically significant (s.s).A specifically "R" program "randomForestSRC" was used to impute missing values.

Results: We have studied 52 admitted patients at ICU by coronavirus infection, 41 of them at Jaénhospital ICU, 11 at Cabra hospital.51 of the 52 patients were alive on the third day and they were evaluated. The average agewas 62 (58,71) years old. APACHE II at the admission was 12 (8.5, 16) points and SOFA 6 (3.8)points. SOFA on the third day was 7 (3.5, 9) points and the SOFA difference between the firstand third day was 0 (-2.0) points.

There weren't the value of troponin in 10 of the patients (less than 20% of the sample)and it was input by statistics methods. Ultrasensitive troponin at the admission was 20 (10,42)and on the third day was 19 (9,49). In 23 patients (46%) the determinations carried out on days1 and 3 were elevated. In 23 patients (45.09%) the determinations on the first and third dayswere elevated.

Patients who deceased (n = 19) showed higher number of troponin at the admission butthe differences weren't s.s. 26 (14,42) vs 17 (10,42), (p=0.47) and on the third day 35 (19,54)vs 13 (8,31), (p= 0.029). 31.58% of the 28 patients without troponin increment on the first andthird day, died, and 68.42% of the 23 patients in whom it was increased in the three days (p = 0.009).

Those patients who died (n = 19) had more SOFA at the admission 7 (4,8) vs 6 (3,7) points(p=0.20) but without being significant the differences. However, differences were statisticallysignificant on the third day in regard to SOFA 8 (7,9) vs 6 (3,8) points (p=0.003) and thedifferences between the first and the third day of SOFA -1 (-3.0) vs 0 (-1.25,1) points(p=0.007). Diifferences regarding APACHE II were also significant 14 (12,18) vs 10 (8,15) points(p=0.011).

For a better display of prognostic capacity of SOFA on the third day, patients wereclassified according to SOFA, if was less than 7 points (n=22) with a 9% of mortality or if was 7points or more (n = 29) with 59% of mortality (p < 0.0029).

Multivariate analysis with logistic regression shows that hospital mortality is relatedwith SOFA higher than or equal to 7 points OR on the third day: 12.78 (2.81,94.14) with anincrease of troponin on the first day. On the first day, OR: 4.09 (1.05, 17.79). Thediscrimination of the exemplar, evaluated with the area under ROC curve was 0.82 (0.72, 0.93).From the 22 patients studied (43% of the sample) with SOFA lower than 7 points and withoutan increase of troponin, just 2 of them died (9%).

Conclusion: In ICU patients, admitted for coronavirus, on the third day afteradmission to the ICU, most are alive and the increase of troponins on the first and third day isassociated with higher mortality. And if we add, to the said before, high SOFA on the third day,it allows us to select a group of patients with low mortality.

001473

Coronary artery bypass surgery in the last eight years

Intensive Care Medicine Experimental 2020, **8(2)**: 001473

Introduction: Despite appearance of other less invasive therapeutic alternatives for the treatment of coronary artery disease, surgery continues to be a safe technique with very good results in selected patients.

Objectives: Describe clinical and evolutive characteristics of the coronary artery bypass surgery.

Methods: Retrospective and descriptive study of the patients operated of coronary artery disease from January 2012 to June 2020, in two centers by the same surgical and Intensive Care Unit (ICU) team (Hospitales Fundación Jiménez Díaz y Rey Juan Carlos from Madrid).We collected demographics parameters (age, sex), EUROSCORE II, personal history of coronary artery intervention (interventional or surgery), type of surgery (urgent or not), surgical times, post-operative complications, length of stay on ICU and hospital, ICU re-entry and mortality. We made a quartile analysis according to the stay in ICU by hours and got four homogeneous groups on number, sex and age of the patients: GROUP 1 = < 24H; GROUP 2 = 24-48H; GROUP 3 = 48-72H; GROUP 4 = >72H.

Results: 724 patients. 84% males. Medium age of 65,5±10 years. Medium EUROSCORE 2 was 4.31±5.50. 19.75% had previous coronary artery intervention. Medium length of stay in ICU was 66±82 hours, 10±8 days on hospitalization floor and global hospital time was 14±9 days. The total mortality was 1.5%. Comparing the groups:

	GROUP 1	GROUP 2	GROUP 3	GROUP 4	p
ICU stay (hours)	<24	24-48	48-72	>72	
N	183	270	118	153	
Males (%)	87	83	86	82	0.502
Previous CI (%)	23	17	28.8	13.7	0.0007
Urgent Surgery	0	0.3	0.8	9.8	<0.001
Surgery with EC	79.2	81.1	85.6	85.7	0.494
EUROSCORE II	2.28 (1.42-3.65)	2.34 (1.33-3.96)	2.25 (1.40-4.87)	4.29 (1.94-9.92)	<0.001
EC time (hours)	96(77-114)	99(76-120)	101(85-125)	105(83-126)	0.0840
Ischemia time (hours)	60 (48-80)	61 (49-75)	62 (50-80)	64 (46-84)	0.949
MV time(hours)	4(3-5)	5(3-7)	6(4-11)	14(6-61)	<0.001
Complications (%)	16.39	20	31.4	67	<0.001
Cardiogenic shock(%)	0.5	1.1	0.8	6.5	0.002
IABP need (%)	0	0.4	2.5	13.7	<0.001
PMI (%)	0.5	1.1	1.6	5.8	0.002
ARF (%)	0.5	1.9	4.2	20.9	<0.001
ERRT need (%)	0	0.4	2.5	7.1	<0.001
Bleeding (%)	0.5	0	5.1	7.8	<0.001
Floor stay (days)	7(6-8)	7(7-8)	8(7-10)	13(9-18)	<0.001
Total stay (days)	10(8-14)	10(8-14)	11(8-16)	18(13-23)	<0.001
Mortality (%)	0.5	1.1	0	4.5	0.005

Conclusion: Coronary artery bypass surgery in our series has few complications, short ICU and hospital stay times and low mortality, considering that we have not a specific cardiologic ICU. Patients who require urgent surgery and spend in ICU >72 h, have worse results.

001624

Hypertension and antihypertensive treatment in patients with Covid19. Mortality analysis

I. Guzmán Adum¹; L. Hidalgo Manchado¹; R. Diaz Contreras¹; R. De La Chica Ruano¹

¹Intensive care unit, Hospital Universitario Virgen de las Nieves, Granada, Spain

Correspondence: I. Guzman

Intensive Care Medicine Experimental 2020, **8(2)**: 001624

Introduction: Since Covid19 was described, almost 17 million cases and more than 665000 deaths have been reported. Different theories regarding the increased mortality in patients diagnosed with high blood pressure that IECAs/ARAI as antihypertensive treatment have been postulated, the evidence of which has changed.

Objectives:

- To describe the general characteristics of the patients with Covid19 admitted in the ICU of the Virgen de las Nieves Hospital.
- To describe the association between mortality and the history of hypertension.
- To describe the relationship between the use of antihypertensives acting on the renin-angiotensin-aldosterone system and the mortality of patients with Covid19.

Methods: Observational, retrospective and analytical study that includes the 58 patients admitted to ICU by Covid19 between March and July 2020. A database was created in SPSS with the demographic characteristics of patients, comorbidities, antihypertensive treatment, SOFA at admission, APACHEII in the first 24 hours and type of respiratory support. They were subsequently evaluated in terms of descriptive statistics with frequencies, means, and standard deviation; Mortality-based comparisons were made using Student's T-test for quantitative variables and chi squared for qualitative variables.

Results: Of the 58 patients included, 79% were men and 21% women. Their mean age was 60 years (+/- 11), their main comorbidities were: hypertension (54%) 23 (39.66%) of whom were treated with ACEi/ARB, diabetes mellitus (35%), obesity (56%), COPD (28%), renal failure (9%). SOFA at admission 6.79 (+/- 2.68) with significant association with mortality $p = 0.006$. APACHE II in the first 24 h was 15.9 (+/- 6.68) association with significant mortality $p = 0.002$. IMV since admission 32 (55%) and combination of HFNO and then IMV 17 (29%), unrelated to mortality. ICU mortality 33%, hospital mortality 39%. Mortality of hypertensive patients 24.13% ($p = 0.23$) and of those taking ACEi/ARB is 13.79% ($p = 1$).

Conclusion:

- More than half of the patients admitted to the ICU for Covid19 are hypertensive, however this risk factor does not represent a significant increase in their mortality. Most of them also associate other cardiovascular risk factors.
- In accordance with what is described in the medical literature, hypertensive patients treated with drugs that act on RAAS do not present a higher mortality compared to those who take other types of antihypertensive medication.

Incidence of New Onset Supraventricular Arrhythmias in Septic Shock Patients and Its Impact on Outcome

S. Hegazy¹; T. Helmy²; A. Salam²

¹critical care medicine department, Alexandria Faculty of Medicine, Alexandria, Egypt; ²Critical care medicine, Alexandria Faculty of Medicine, Alexandria, Egypt

Correspondence: S. Hegazy

Intensive Care Medicine Experimental 2020, **8(2)**: 001233

Introduction: Sepsis is frequently associated with new-onset supraventricular arrhythmias (NOSVA). The identified predictors of SVA in sepsis include advanced age, renal failure, preexisting cardiomyopathy, history of hypertension, high SOFA score, and previous calcium channel blocker treatment.

Objectives: The aim of this study is to prospectively assess the prevalence of NOSVA during septic shock, identify the associated factors, and to evaluate its impact on hemodynamics and outcome of patients.

Methods: This prospective observational study enrolled 60 critically ill and mechanically-ventilated patients admitted to the critical care medicine department at Alexandria University Hospitals, screened with continuous 12-lead ECG for the occurrence of NOSVA, and assessed for hemodynamic tolerance and prognosis.

Results: The first group (SVA Group) included 24 patients who developed NOSVA. The second group (SR Group) consisted of 36 patients who didn't develop NOSVA. The deterioration in mean arterial pressure increased the prevalence of inotrope indication in SVA group. Serum creatinine was significantly higher in SVA group. Also serum calcium and magnesium were significantly lower in SVA group. Patients with SVA group had higher rate of mortality within 7 days from admission and higher duration on mechanical ventilation but the difference from SR group didn't reach the level of statistical significance.

Conclusion: New onset SVA is frequent and poorly tolerated during septic shock, and is associated with higher rates of inotrope use. Hypomagnesemia, hypocalcemia and elevated serum creatinine are considered as potential co-factors or causes for the development of NOSVA in septic shock patients.

Improving the Documentation of Emergency Anaesthesia in the ICU and Emergency Department

C. Docherty¹; E. Kerr¹; K. Bennett¹

¹Critical Care, NHS Lanarkshire, Wishaw, United Kingdom

Correspondence: C. Docherty

Intensive Care Medicine Experimental 2020, **8(2)**: 001206

Introduction: Emergency anaesthesia is frequently performed in ICU and Emergency Departments for critically ill patients. However, it has been demonstrated that there is a higher incidence of complications when performing emergency anaesthesia in these environments compared to the operating theatre. In our department we anecdotally noted that documentation of emergency anaesthesia was frequently of poor quality or had missing information. During the course of an ICU admission patients may require reintubation and details (such as grade of intubation, equipment and drugs used) regarding the initial procedure are essential for safe planning.

Objectives: The aim of our quality improvement project was to improve the documentation of emergency anaesthesia in the ICU and Emergency Department by implementation of a sticker.

Methods: A retrospective audit was performed of 40 consecutive patients who were intubated and ventilated in the emergency department or ICU. 17 key points for documentation were identified and data was collected as to whether or not these were documented: indication, intubator, airway assistant, monitoring, laryngoscope, airway, grade, tied at lips, manoeuvres, pre-oxygenation, apnoeic ventilation, adjuncts, opiate, anaesthetic agent, neuromuscular blocker, emergency drugs and critical incidents.

Following the audit an emergency anaesthesia sticker was introduced to act as an aide memoire and to improve efficiency of documentation. These were located in the ICU and emergency department. A

further prospective audit of 40 consecutive patients was performed to determine whether or not there was an improvement.

Results: Prior to the introduction of the sticker, the audit confirmed that documentation was inadequate. Use of monitoring was documented in 23% of cases and pre-oxygenation in 18%. Choice of laryngoscope was documented in 80% of cases, airway used in 78% and adjuncts in 23%. Of note in 13% of cases there was no documentation of drugs used either in the notes or on the kardex and 44% made no reference to whether or not any critical incidents occurred.

Following the implementation of the sticker uptake on use was 68% (27/40 cases). Where the sticker was used, documentation was noted to be improved. 100% documented monitoring, pre-oxygenation, laryngoscope, airway and drugs. 70% documented use of adjuncts and 93% documented whether or not a critical incident occurred.

Conclusion: Accurate and thorough documentation of emergency anaesthesia is not only important for medico-legal purposes but is also crucial to ensure that any future intubations are prepared for and managed as safely as possible. Implementation of an emergency anaesthesia sticker is a simple and cost effective intervention and this quality improvement project demonstrated that it delivers a significant improvement in the documentation of emergency anaesthesia in the ICU and emergency department. Further education within the department will be aimed at improving the uptake of use of the sticker.

Formulation and Implementation of a COVID-19 Modified Percutaneous Tracheostomy Checklist to Ensure Safety of Healthcare Workers and to Promote Good Medical Record Keeping

S. Ng¹; M. Watanabe¹; J. Mandeville¹; P. Shanmugasundaram¹; A. Manoras¹; T. Ali¹

¹Intensive care department, Stoke Mandeville Hospital, Aylesbury, United Kingdom

Correspondence: S. Ng

Intensive Care Medicine Experimental 2020, **8(2)**: 001234

Introduction: COVID-19 is considered an airborne pathogen by the WHO and Public Health England in the context of aerosol generating procedures. During the 2002 to 2004 SARS epidemic, healthcare workers were shown to be at a significantly increased risk of infection(1), with tracheal intubation posing the highest risk for transmission(2). Therefore, amid the current pandemic additional precautions have been introduced to minimise the risk of SARS-CoV-2 transmission. Medical record keeping plays an integral role in delivering safe patient care (3,4). Despite this, documentation is often given a low priority when additional demands are placed on doctors.

In an effort to improve patient and staff safety, and to promote a consistent procedural approach and good quality documentation among doctors, we implemented a modified COVID-19 percutaneous tracheostomy checklist and procedure note.

Objectives: This project aimed to assess the improvement in quality of documentation of percutaneous tracheostomy procedures performed by the ICU team after the implementation of the checklist.

Methods: We undertook retrospective audits of the documentation of percutaneous tracheostomy procedures on ICU during the whole of 2019 (n=14) and during the COVID-19 period up to June 2020 (n=11).

Following the first audit, we formulated and introduced a modified COVID-19 percutaneous tracheostomy checklist. The checklist not only includes 'Sign In', 'Time Out' and 'Sign Out' but also highlights key steps in the updated procedure guidelines, which were created through repeated simulation sessions. This formed part of a COVID-19 Tracheostomy Local Safety Standards for Invasive Procedures (LocSSIPs) to promote a more consistent technical approach amongst operating doctors.

Results: The initial audit from 2019 in our Trust demonstrated a poor quality of documentation. This issue was successfully addressed with implementation of the COVID-19 percutaneous tracheostomy checklist and procedure note. The second audit reported a significant improvement: 100% of percutaneous tracheostomy procedures were documented using the designated form, versus 50% in the first audit; 100% of equipment used were also recorded, up from 57.14% in 2019. A consistent improvement was also observed in the documentation of patient consent, post-operative instructions, and overall quality of documentation. Furthermore, doctors and theatre staff reported a reduction in concern when remembering the additional steps made necessary for personal protection.

Conclusion: The implementation of a checklist and procedure note not only helped to provide a consistent structured approach to the procedure and to documentation but also reduced anxiety among the healthcare workers. We strongly feel that the quality of documentation is a consistently overlooked element of good quality patient care and we find the improvement observed, even in the face of increased technical and human factors complexity, very encouraging.

Scaling a UK District General Hospital (DGH) Critical Care Unit by 400% during the COVID 19 Pandemic

R. Loveless¹; A. Falek¹; T. Samuels¹; A. Myers¹

¹Intensive care unit, East Surrey Hospital, Redhill, United Kingdom

Correspondence: R. Loveless

Intensive Care Medicine Experimental 2020, **8(2)**: 001237

Introduction: East Surrey Hospital is a DGH in South East England that serves a population of 535,000 and has 700 acute beds(1). The Critical

Care Unit has 8 level 3 beds and 8 level 2 beds. The unit is staffed by 10 consultants, 16 junior doctors (50% airway trained), and 84 nurses (1/3 have less than 2 years ICU experience). The trust has 17 ICU ventilators (including 4 transfer ventilators) and 29 anaesthetic machines offering only basic mandatory ventilation. COVID 19 required planning to accommodate an increase in patients with severe respiratory failure requiring mechanical ventilation.

Objectives: We aimed to increase level 3 bed capacity safely by 400%.

Methods: We identified 6 elements of our organisation requiring attention in order to facilitate rapid escalation in ICU capacity.

1. Footprint.

A 22 bed medical ward was converted into an additional ICU. At peak this unit had 17 ventilated patients. Theatre recovery was used for non-COVID patients.

2. Equipment.

17 ICU ventilators were supplemented by 21 anaesthetic machines. Anaesthetic machine gas analysers were used as EtCO₂ monitors ran out. Haemofiltration units were rotated between patients in 12 hour sessions. Midazolam sedation was used as supplies of propofol were compromised.

3. Infection Control.

Full PPE was used in all critical care zones during the pandemic. A patient gym became a donning area and temporary partitions created a one way system for doffing. Acquiring PPE was challenging nationwide, but the procurement department was proactive ensuring adequate supply.

4. Staffing.

An emergency rota was created that provided 24/7 consultants on site, with 9 ICU doctors at all times. 10 consultants and 24 trainees worked a 1 in 4 pattern, with 6 anaesthetic consultants joining critical care. Doctors with previous experience were redeployed to ICU. Anaesthetic consultants staffed 2 MERIT teams 24/7 for emergency intubations and transfers. 151 nurses were redeployed from Theatres and surgical wards. Patients were divided into "zones" of 3-4 patients, with 1 ICU nurse leading 3-4 non-ICU trained nurses. Physiotherapists, consultant and trainee surgeons formed proning teams.

5. Communication.

Two way radios allowed communication between units, doctors, charge nurses and the emergency department. A temporary bespoke electronic patient record (COVID SitRep) was designed using FileMaker(TM) and was used for patient tracking, handover and audit. A family liaison team updated each patient's family daily.

6. Clinical Management Protocols.

Protocols for airway management, CT transfers, admission investigations and proning ensured patients received the highest level of care.

Results: We had a maximum of 33 ventilated patients at any one time, across 3 geographically distant critical care units. Over the pandemic we treated 59 confirmed and 34 suspected COVID-19 patients in critical care, and performed 10 non-clinical transfers of ventilated patients. Our mortality for ventilated COVID 19 patients was 29%.

Conclusion: During the COVID 19 pandemic we delivered safe, effective care at 400% capacity. Using a robust education and management structure for new nurses, redesigning rotas to increase staffing and creating protocols using national guidance(2) ensured safe expansion. Our outcomes compare favourably with other institutions in the UK (ICNARC mortality of ventilated COVID 19 patients is 48%(3)). Feedback from patients, staff and families was positive. Structures are in place for psychological support for staff and patients, which aim to mitigate the effects of an unprecedented time.

Family communications – lessons learned during the Covid-19 outbreak

S. Dunin De Skrzywno¹; E. Gravel¹; L. Davies¹; M. Cuartero¹

¹St. Mary's Intensive Care Unit., Imperial College Healthcare NHS Trust, London, United Kingdom

Correspondence: S. Dunin De Skrzywno

Intensive Care Medicine Experimental 2020, **8(2)**: 001243

Introduction: The importance of good communication in an Intensive Care Unit (ICU) is being increasingly recognised.[1] Effective communications improves families' trust in the medical team clinical ability and decision making, as well as their own psychological well being.[2]. The COVID19 pandemic is an unprecedented health crisis which has reshaped our way of practicing medicine and communicating with our patients and families. The growth rate of the COVID19 virus led to restrictions and subsequently banning of all visitors to hospital wards and ICU. At the height of the pandemic, communication between medical staff and families could only be through phone or video calls.

Objectives: To assess communication with families at the height of the pandemic in a UK based intensive care unit. This was measured against standards set by senior nursing staff and our consultant body prior to the pandemic. Standards set were for patient families to be contacted by nursing staff daily, and medical staff every 48 hours.

Methods: We conducted a retrospective case note review of all patients admitted to the Adult Intensive Care Unit (AICU) or Recovery Intensive Care Unit (RICU) between the 16th and 31st of March 2020 at St Mary's hospital. Only COVID19 positive, or clinically suspected cases were included in this study.

Family Communication notes, Nursing documentation as well as Daily Documentation notes were reviewed on the critical care software system IntelliSpace Critical Care and Anaesthesia (ICCA).

Key clinical characteristics of patients were recorded including age, length of ICU admission, if mechanical ventilation was used, level of care on admission, and whether any End of Life (EoL) care was in place. Documented family discussions were reviewed and classified as either: First meeting within 48 hours, Update or Follow-up, Clinical deterioration or DNACPR discussion. The date and clinical staff leading each communication was recorded.

Results: A total of 32 patients were admitted with positive or clinically suspected COVID19, and 331 communications were recorded. The mean length of stay in ICU was 17.3 days, and the mean age was 54 years old. Mechanical ventilation was used in 29 (91%) of our cohort. 12 (38%) patients died in the unit, 15 (47%) were discharged to a ward. Among our cohort, 16 (50%) had a DNACPR in place, and 10 (31%) had an EoL care pathway in place.

Nursing staff met our standard of contacting families daily in 1 (3%) patient, and doctors of contacting families every 48 hours in 6 (18%) patients. 5 (18%) patients had no documented family discussions with a doctor, 3 (9%) had no documented conversation with a nurse and 2 (6%) had no documented discussions with any healthcare professional.

Family discussions within 48 hours of admission were made in 25 (78%) of our cohort, with nursing staff initiating 18 (72%) of these conversations. The median time to a first documented discussion with family for nurses was 1 day, and 4 days for doctors.

Junior Doctors led 8/10 (80%) of documented DNACPR discussions, and 25/58 (43%) Clinical Deterioration discussions. Consultant discussions were held with families in 2/10 (20%) patients on an End Of Life care pathway.

Conclusion: At the height of the pandemic, nurses and doctors did not meet the standards set for family communication. Nursing staff initiated family discussions within 48 hours of admission, and Junior Doctors were leading difficult discussions with families. Agreed guidelines on the regularity of family communication during a pandemic, and the level of Nurse/Doctor expected to communicate needs to be developed. Further training is needed to support Junior Doctors in conducting difficult discussions if a further spike is to occur.

Tracheostomy in Intensive Care: Delays between decision and procedure

A. Gupta¹; J. Gosling²

¹Anaesthesia and Intensive Care, Chelsea and Westminster NHS trust, London, United Kingdom; ²Anaesthesia, West Middlesex University Hospital, Isleworth, United Kingdom

Correspondence: A. Gupta

Intensive Care Medicine Experimental 2020, **8(2)**: 001246

Introduction: Tracheostomy is usually performed for patients with prolonged stays on mechanical ventilation and/or embarking upon a slow wean from mechanical ventilation.

Objectives: The aims of this audit were to identify the length of, and reasons for, delays in performing tracheostomy once a decision made to proceed and to determine the adequacy of documentation of delays. If a delay in carrying out tracheostomy is encountered, whether planned or unforeseen, the reason for delay should be documented for each day tracheostomy is delayed beyond 2 days after a decision. The two standards employed in this audit are therefore; 75% of patients should receive a tracheostomy within 2 days of decision to proceed and if tracheostomy is delayed beyond 2 days, 100% of the days in question should have a documented reason for the delay.

Methods: Retrospective review of patients undergoing either percutaneous or surgical tracheostomy during ICU stay between September 2015 and September 2016. We recorded 1) technique of tracheostomy 2) number of days between decision to perform tracheostomy (classed as Day 0) and the procedure itself, where there were more than 2 days between decision and procedure, the number of days for which a reason for the delay was documented.

Results: A total of 21 tracheostomy episodes were recorded during the audit period, of which 12 were percutaneous and 9 surgical. 2 patients had unsuccessful percutaneous attempts followed by successful surgical tracheostomies. Overall, 12/21 patients (57%) had their tracheostomies performed within 2 days of the decision to proceed. Only 1 additional patient had procedure within 3 days of decision; the remaining 8 patients waited 4 or more days.

There was no significant difference between the delays in the percutaneous and surgical groups, although both patients with a delay of 8 days required surgical tracheostomies.

	Mean	Median
Overall	3.0	2
Percutaneous	2.3	2
Surgical	4.1	4.5

Table 1 - Days Delay (by type of procedure)

The reasons documented were:

Liver USS
ENT review required (x 2)
ENT not available (x 2)
Atrial fibrillation causing compromise
Coagulopathy requiring reversal
Anaesthetist not available
Family discussion

Table 2 – Documented reasons for delays in tracheostomy

Conclusion: The unit did not meet the standards for either timely performance or documentation of reasons for delays, with rates of 57% (standard 75%) and 18% (standard 100%) respectively. Possible reasons for this were availability of experienced anaesthetic and ENT. Clinical limitations e.g. coagulopathies or anti-coagulant treatment, or a general instability and low reserve to tolerate procedure. It was difficult to comment on the appropriateness of delays by a sizeable minority of patients because of the poor standard of documentation. Possible reasons for incomplete documentation include insufficient time on ward round or at the end of shifts, lack of or misunderstanding of reasons for delays and attributing little importance to such documentation.

Intensive Care Medicine Experimental 2020, **8(2)**: 001259

Introduction: Limited evidence indicates that mortality rates of elderly patients treated in the intensive care unit (ICU) vary widely across Europe.

Objectives: The aim of this study was to evaluate the variation in short-term mortality among patients ≥ 80 years old admitted to European ICUs.

Methods: We used data from two multicenter prospective cohort studies which enrolled very old intensive care unit patients (VIPs) between the years 2016 and 2019 in 20 European countries. The primary outcome was mortality within 30-days from admission to the ICU. Nine clinical variables were adjusted for in multilevel logistic

regression models. Country was included in the model as a random effect and categorized healthcare expenditure per capita (<2500\$, 2500-5000\$, >5000\$) was a country-level variable.

Results: The median age in the sample of 8257 consecutive patients was 84 years (IQR: 81-86) and the median Sequential Organ Failure Assessment score was equal to 6 points (IQR: 4-10). Crude mortality in participating countries ranged from 10.6% to 50.0% in the ICU and from 21.9% to 54.4% in 30-day follow-up. After adjusting for patient-level variables, the proportion of individual variation in mortality attributable to systematic differences between countries was equal to 3% at discharge from the ICU and 2% in 30-day follow-up. Lower healthcare expenditure per capita was associated with higher ICU mortality, but we did not find evidence that a similar relationship exists in 30-day follow-up.

Conclusion: Systematic differences between patients, not countries, largely explain the variation in short-term mortality among European countries. Lower healthcare expenditure is associated with higher mortality in the ICU, but the direction and magnitude of this relationship is less certain in 30-day follow-up.

001265

Beta-D-Glucan testing in the ICU: A single-centre experience

D.O. Hamilton¹; S. Waite¹; A. Howard²; I. Welters¹

¹Critical Care, Royal Liverpool and Broadgreen University Hospitals NHS Trust, Liverpool, United Kingdom; ²Department of microbiology, Royal Liverpool and Broadgreen University Hospitals NHS Trust, Liverpool, United Kingdom

Correspondence: D.O. Hamilton

Intensive Care Medicine Experimental 2020, **8(2)**: 001265

Introduction: Invasive fungal disease is a common cause of morbidity and mortality in Intensive Care Units (ICU) worldwide [1]. A Beta-D-glucan (BDG) test has a high negative predictive value and can be used to exclude invasive fungal disease in appropriate populations [1,2].

Objectives: To describe the prevalence and clinical outcomes of patients treated with empirical antifungals and to identify how BDG testing is utilised in the ICU at the Royal Liverpool University Hospital, a tertiary academic teaching hospital.

Methods: We performed a retrospective observational study of all patients treated with anti-fungal medication between December 2018-December 2019 utilising medical notes, microbiological data and prescription charts. Patients treated for oral or genital candidiasis or with prophylactic antifungals were excluded.

Financial estimates were made by analysing the prescriptions of patients with no positive fungal culture, excluding those with haematological malignancy or oesophageal perforation, for whom empirical anti-fungal use is appropriate, and assuming an eight-day turnaround time for testing.

Results: One-hundred-and-six patients received anti-fungal medication over 107 admissions to ICU during the specified time period. Sixty-two (58%) admissions were male, the mean age was 56 and 63% were admitted from surgical specialties, most commonly Upper Gastrointestinal or Hepato-pancreato-biliary. The inpatient mortality was 28.9%.

Fifty-seven (53%) patients had a positive fungal culture, 3.9% of the 1480 admissions in the study period. The most common species cultured was *Candida albicans* (n=25), followed by *Candida glabrata* (n=15). The most commonly infected sites were: intra-abdominal fluid (n=25); blood culture (n=11); and urine (n=6). There were four blood stream infections due to central venous catheters. The median number of days patients were treated with antifungals was 16 [IQR 11-28].

Of the 49 patients with no positive fungal culture, only 6 (12%) had a BDG test sent, which were all negative. The mean number of days for a BDG result to be available was 8.3 ± 3.3 days. We estimate that applying BDG testing to appropriate patient cohorts would save 142 days of anti-fungal use and approximately €12,300 per year.

Conclusion: It is common for no fungal species to be identified in patients who are started on empirical antifungals. BDG testing is

under-utilised in our ICU and improving its uptake and speed are important measures for both antifungal stewardship and fiscal management.

'Training for ICU Crash Course (TICC)': Rapid, modifiable cross-skilling course for staff redeployed to Intensive Care Units in response to the COVID-19 pandemic

D. Sureshkumar¹; V. Blackburn¹; E. Hardman¹

¹Anaesthetics/ICU, Whittington Hospital, London, United Kingdom

Correspondence: D. Sureshkumar

Intensive Care Medicine Experimental 2020, **8(2)**: 001270

Introduction: The COVID-19 pandemic has seen a unique response arise in hospitals, one feature of which has been the rapid redeployment of healthcare workers of all stratifications to intensive care units (ICUs) across the country. This posed a sudden and unfamiliar challenge of a high-acuity environment to many staff, who have had little or no prior ICU experience. In the Whittington Hospital ICU, staff expressed uncertainty about assessing and managing patients, but opportunities for bedside teaching were limited due to workload, staffing ratios and communication challenges due to personal protective equipment (PPE). This teaching programme was designed to deliver high quality, relevant information for navigating ICU, appropriate to different healthcare backgrounds of staff recruited at short notice. The aim was to provide basic but thorough cross-skilling swiftly, in a structured and standardized way, to enhance confidence amongst newly deployed staff and to improve patient safety in an unprecedented situation¹.

Objectives: The overall objective was to increase the competence of as many staff as possible – both medical and auxiliary – who were redeployed to the Whittington ICU. Further aims were to improve staff confidence in assessing and managing an intensive care patient by 25% following delivery of 'Training for ICU Crash Course' ('TICC') programme, and provide with the relevant learning supplementation appropriate to level. Lastly, to provide bedside checklist resources for basic management as an aide-memoir, for improved communication under difficult circumstances and amongst unfamiliar teams.

Methods: TICC comprised of a standalone session delivered as a tutorial with accompanying slides away from the bedside so staff did not have responsibility for clinical care and were not hindered by wearing PPE. It consisted of a set of slides using a standardised systems (ABCDE) approach which was tailored to the audience background, and augmented by practical demonstration of simple equipment such as arterial lines, three way taps and giving sets. Participants were all healthcare workers with 6 months or less experience in Intensive Care, or any current ICU recruit who felt that they would benefit from attending.

The learning supplement consisted of two stratified checklists appropriate to level (one targeted at doctors, one at auxiliary staff), given as handouts at the end, in the format corresponding to the course. The bedside resource was a further corresponding laminated checklist, with a wipe-clean tick box function, for use in PPE on the unit. It was designed to improve coordination, efficiency and safety in the patient's multi-person team by keeping track of jobs and assessments, again according to the system taught.

Feedback including confidence levels by system, usefulness of content and format was collected immediately before and after teaching by an anonymous questionnaire. Further feedback was obtained several weeks later by an online questionnaire to assess retention and confidence.

Results: The course was delivered to 47 members of staff who were working in the Whittington Hospital ICU including doctors (foundation doctor level to medical registrars), registered nurses, physiotherapists, healthcare assistants, medical and nursing students, other healthcare workers (e.g. speech and language therapists, podiatrists). Of the students, 74% (35/47) had no previous ICU experience. The topics that people identified as being the most anxious about were airway and breathing. Immediately after the course, confidence levels in assessing an ICU patient were improved by 39%, increasing from a mean score of 2.5/5 to 3.5/5. 2 months following the course, participants confidence levels were 36% greater than prior to the course. Students reported feeling most confident in assessing breathing, and the most useful topics were determined to be either airway, or the whole session A-I. Qualitative feedback on the usefulness of the learning materials distributed post-tutorial was highly positive, with a constructive influence on team coordination.

Conclusion: The teaching session was designed to be both achievable and rapid to implement, while still being fully modifiable as to be appropriate for a variety of audiences. It was successful in this aim and in providing a basic standardised structure for novice workers on ICU. Increased confidence levels of healthcare staff were reported in high risk areas (e.g breathing assessment) which is a vital skill for safely managing patients with COVID-19 pneumonitis. In particular, qualitative feedback suggested it helped to maintain safety standards and team co-ordination when ICU nursing ratios were low. This course has the potential to rapidly cross-skill staff from a variety of backgrounds to improve staff confidence and wellbeing, team co-ordination and efficiency. Ultimately improving patient safety in rapid response to a novel, chaotic and highly challenging situation.

Intensive Care Medicine Experimental 2020, **8(2)**: 001271

Introduction: The COVID 19 pandemic brought a significant increase in workload for healthcare workers (HCW) around the world (1). This fact was especially relevant in the ICU where adverse events could be caused by this burden. The Safety Huddle (SH) is a strategy designed to mitigate this risk (2), mostly focusing on increase in situation awareness, communication skills and psychological safety for HCW. It has not been tested in the current COVID-19 scenario.

Hospital Sao Lucas is a 210-bed general private hospital in the city of Rio de Janeiro – Brazil. Before the pandemic, the hospital had 75 ICU beds. After the beginning of COVID-19 in the city of Rio de Janeiro, the number of ICU beds was increased to 100 beds, of which 79 beds dedicated exclusively to COVID-19 patients. As part of the Quality and Safety department improvement initiatives, two-tier safety huddle was implemented in a 60 bed ICU.

Objectives: The aim of the present study is to test if the feasibility, HCW impact and clinical outcomes associated with SH implementation in the context of COVID-19 pandemic.

Methods: The first level SH was led by the shift nurse and involved the bedside team of the corresponding shift. The second level was conducted with representants of each ICU (senior doctor or nurse), heads of nurse, respiratory therapy, medical director and quality and safety. Most of participants were in remote contact with each other, including the leader of the 2nd tier.

An anonymous electronic survey consisting of perceptions was launched for HCW, 5 weeks after the beginning of the safety huddle.

A before and after analysis was performed for the critically ill patients. Outcome for COVID 19 was retrieved from the EMR, using current definitions.

Results: Safety huddles were performed daily, including weekends, from 7thMay, until now. The duration was approximately 10 min in the first level and 60 minutes in the second level.

Three hundred and twenty (35%) two out of 906 HCW answered the survey of whom 181 (56%) RN and nurse assistants, 87 (27%) respiratory therapists and 54 (17%) other professionals (including 4 physicians). The main findings are described in the Table 1.

Question	Agreement rate
Do you believe that Safety Huddle brings positive results?	97%
Do you believe that Safety Huddle has a positive effect in your daily routine?	92%
Do you feel comfortable in sharing your perceptions and doubts during the Safety Huddle?	89%
Do you believe that structural improvements were implemented because of the Safety Huddle?	91%

Table 1. Proportion of respondents in a HCW survey concerning the perceptions of Safety Huddle

From 16th March 2020 to 15th July, HSL discharged 452 patients, of whom 255 (56%) stayed in the ICU for some time. The main clinical outcomes, before and after the beginning of SH are described in table 2.

Characteristics and clinical outcome	Before SH (n = 91 patients)	After SH (n = 164 patients)	P value
Age - years (±SD)	69.0	70.2	0.59
SAPS3 - points (±SD)	58.4	57.7	0.70
Use of MV - n (%)	55 (60)	96 (58)	0.76
Hospital LOS - days	14.6	26.0	0.03
Hospital death n (%)	46 (50)	49 (30)	<0.01
SMR (±SD)	1.51	1.00	<0.01

Conclusion: Safety Huddle is feasible during COVID-19 pandemic crisis and is associated with positive perception among healthcare workers and better clinical outcomes for critically ill patients.

001346**Improving wellbeing and reducing anxiety among core trainees in ICU via feedback led intervention**A. Holmes¹; B. Greatorex²¹Anaesthetics and Intensive Care, NHS Highland, Inverness, United Kingdom; ²ICU, NHS Highland, Inverness, United Kingdom**Correspondence:** A. Holmes*Intensive Care Medicine Experimental* 2020, **8(2)**: 001346

Introduction: Prioritising staff wellbeing improves the health of staff and patients¹. In the latest GMC survey almost 25% of trainees reported burnout². This can be particularly prevalent for trainees working in critical care³. A key contributor to anxiety is uncertainty⁴, which renders core anaesthetic trainees vulnerable as they transition into intensive care. In contrast to anaesthetic practice – which sets a standard using the initial assessment of competence⁵ – there is no benchmark for trainees starting in ICU. Trainees may assume high levels of responsibility with little experience and distant senior support out of hours.

Objectives: To identify the anxieties experienced by trainees prior to starting on the ICU on-call rota, to gain their perspective on what could have reduced these anxieties, and to use this information to deliver targeted training to alleviate these concerns for future trainees. To assess the impact of our intervention.

Methods: A survey was sent to all trainees who had completed core anaesthetic training within our hospital over the past two years, detailing their experiences of transitioning onto the on-call ICU rota in CT2. The results were assessed and a targeted one-day ICU boot-camp was developed to address the areas in which trainees had felt vulnerable. This was delivered to two trainee cohorts over two years prior to them going on-call. Surveys were distributed before and after the boot-camp to assess changes in anxiety and perceived preparedness. A pre and post-course quiz was included to provide objective information on improvements in knowledge. Further information was collected on the on-going concerns of trainees and how they felt these could be addressed.

Results: Our initial survey highlighted that trainees had not felt adequately prepared for transitioning onto the on-call rota, with preparedness being scored as 3.8/10 (0–6.5; n = 7). Specific issues highlighted were variation in length of shadowing in ICU (0–4 weeks; mean 1.1); and inconsistencies in experience during shadowing. 86% of trainees stated that they would have liked a standardised introduction to ICU. After implementation of our boot-camp, 100% of trainees reported reduction in anxiety and increase in preparedness for transitioning onto the ICU on-call rota (n = 7). Test scores improved from 51% to 87.5%. Feedback has highlighted a need for additional simulated critical incidents and more real-life exposure to ICU referrals.

Conclusion: Understanding the anxieties of trainees is invaluable in improving their experience. A simple survey can be a useful way to gain insight and to design relevant interventions. From our initial work, we designed a simple yet effective ICU training day that improved trainee performance and confidence. Based on our ongoing feedback we plan to design a database of simulation scenarios to facilitate teaching, and to implement a CT1 bleep for trainees to carry prior to their ICU block alerting them to ICU referrals so they can attend in a supernumerary capacity.

001388**vCreate: a new communication tool during COVID-19 within adult critical care**A. Thomson¹; H. Jordan²; M. Wheelhouse¹; J. Tait³; A. Graham¹; S. Rodgers⁴; C. McCulloch³; L. Mackinnon³; J. Tocher⁴; K. Nunn¹; A. Abu-Arafeh¹; E. Wilson³¹Western general hospital, intensive care medicine, NHS Lothian, Edinburgh, United Kingdom; ²Intensive care medicine, NHS Lothian, Edinburgh, United Kingdom; ³Royal infirmary of edinburgh, intensive care medicine, NHS Lothian, Edinburgh, United Kingdom; ⁴University of edinburgh, NHS Lothian, Edinburgh, United Kingdom**Correspondence:** A. Thomson*Intensive Care Medicine Experimental* 2020, **8(2)**: 001388

Introduction: The COVID-19 pandemic brought unprecedented challenges to critical care units across the world. Significant restrictions on hospital visiting hugely impacted the way in which we communicate and interact with families. Effective communication, usually in the form of family meetings and bedside updates, improves family understanding, clinical decision making and the psychological well-being of family members.¹ We found that the absence of face-to-face communication heightened anxiety and distress for families and the critical care team. A lack of physical presence resulted in many families struggling to comprehend the severity of their relatives' condition. In particular, end of life discussions was extremely difficult to cope with. In order to improve communication and patient care we implemented a new secure method of asynchronous video communication called vCreate[®] (Windsor, Berkshire).

Methods: This study was conducted in two critical care units in Edinburgh, during and slightly after the acute phase of the COVID-19 peak in the UK. vCreate has been used in the UK neonatal critical care setting but was an entirely new concept for adult critical care. It provides a means to send regular visual updates via pre-recorded videos and photos to document patient progress, both positive and negative. This virtual connection has enabled us to record and share key moments in a patient's journey: videos prior to intubation, treatments such as proning and has been used by our physiotherapy and rehabilitation team. In addition, we have developed vCreate to allow relatives to send personal videos and photos to be shared with the patient. To evaluate the impact of vCreate and its acceptability as a new communication tool, a family survey was conducted.

Results: 36 patients and their families have benefitted from the service with 163 videos and 111 photos being sent. The initial responses from 10 families who used the service is illustrated in Figure 1. Of these 10 families, 9 strongly agreed that using vCreate improved their connection with their relative, 7 strongly agreed that vCreate improved communication and 8 strongly agreed that vCreate helped them to understand their relatives' situation.

All 10 families responded that they would recommend the use of vCreate to other families.

Conclusion: Initial feedback has been overwhelmingly positive and has shown vCreate to be an effective additional communication tool, improving family and patient connection, communication and understanding of the patient's condition and prognosis. A full evaluation is underway to determine the overall impact of video communication with families, using vCreate. Based on this initial success we will continue to use this technology. Both hospitals are tertiary referral centres, and so vCreate could provide an invaluable communication link for many patient groups whose families live remotely, even once hospital visiting returns to normal.

Use of a Proning Protocol in Intensive Care during the COVID-19 Pandemic

S. Qandil¹; F. Holbrook¹; R. Medlock¹; T. Ali²

¹Intensive Care, Buckinghamshire Healthcare NHS Trust, Stoke Mandeville, United Kingdom; ²Intensive care department, Stoke Mandeville Hospital, Aylesbury, United Kingdom

Correspondence: S. Qandil

Intensive Care Medicine Experimental 2020, **8(2)**: 001408

Introduction: Prone positioning has been used since the 1970's and is well recognised to provide benefit in patients with acute respiratory

distress. 1, 2 The PROSEVA trial demonstrated the significant mortality benefits of prone positioning when used within 36 hours of ICU admission with severe ARDS. 3 Robust evidence for proning in COVID-19 infection is not yet published. However, it has been observed as a useful therapeutic tool.

Protocols can optimise and standardise clinical practice, during the COVID-19 pandemic period protocols may help maintain good clinical practice. 4,5 In our District General Hospital we have developed a protocol specific to proning and supinating intubated COVID-19 patients.

Objectives: Ascertain how frequently proning was utilised during a four-month period across our trust. We also aimed to identify any complications related to proning that occurred during this time period.

Methods: We reviewed all electronic and paper records of any patient admitted to our ICUs between 01/03/20 - 30/06/20. We also reviewed incident report forms for this time period.

Results: Seventy-Two patients tested positive for COVID-19 during this period. Patient demographics include mean age of 60.6 years old, range 21 to 86 years, 49 (68%) of all patients were male. Twenty-eight (39%) patients with COVID-19 died. Twenty-six patients (36%) were proned during their admission. Fifty-five proning attempts were made, ranging from one to six times per patient, 50% of these patients were only proned once. For those that were proned, the average length of ICU admission was 26.4 days vs 8 days for non-proned patients. Forty-two percent of the patients that were proned did not survive, compared to 37% of the patients that were never proned.

There were five complications attributed to proning - this was 19.2% of proned patients, and 9.1% of all proning attempts. This included one shoulder subluxation and one brachial plexus injury. Optic neuropathy/retinal haemorrhage were identified in two further patients. One patient developed pressure sores on their ear and clavicle.

Conclusion: Patients that were proned were more likely to die from COVID-19, this likely indicates the disease severity. Fewer patients experienced complications than those identified in previous studies. 2, 6, 7 Meticulous use of our proning protocol helped to minimise the risk of the most common complications and is in line with national guidance and standards 6. A clear protocol also facilitated teams cross-skilling from other specialties into an unfamiliar environment.

ICU bed occupancy in Ireland during COVID-19 surge; impact on ICU mortality

R. Dwyer¹; B. Moran¹; F. Treanor¹; M. Baggot¹; T. Mitchell²; P. Flanagan²; J. O'donnell²; K. O'donnell²

¹NOCA, RCSI, Dublin, Ireland; ²Hpsc, Dept of Health, Dublin, Ireland

Correspondence: R. Dwyer

Intensive Care Medicine Experimental 2020, **8(2)**: 001409

Introduction: ICU bed capacity is relatively low in Ireland (255 beds at baseline, 5.2 ICU beds/100,000 population). The COVID-19 pandemic had the potential to overwhelm ICU capacity leading to a high mortality rate. We documented (i) ICU bed occupancy in Ireland during the surge in COVID activity in March – May 2020 and (ii) mortality for COVID-19 patients in ICU in Ireland up to July 6th 2020. We referenced this to mortality in ICU in the UK in the same period as documented by the Intensive Care National Audit and Research Centre, UK (ICNARC)¹.

Methods: The National Office of Clinical Audit (NOCA) collected data on ICU bed occupancy during March-May 2020. Data were entered on a web portal by all ICU's twice daily, with support and validation by NOCA. A Census documented ICU bed capacity (i) on March 13th, at baseline and (ii) on May 1st, after the expansion of capacity to cope with COVID-19.

The Health Protection Surveillance Centre (HPSC) published weekly data on outcomes in COVID patients admitted to ICU in Ireland. ICNARC publish data for the United Kingdom (UK) (except Scotland) weekly (1).

Results: ICU bed capacity in Ireland increased by 39% from 255 at baseline to 354 beds at peak surge capacity. The peak number of patients in ICU during this period was 255 and the peak number of COVID patients in ICU was 176. Numbers of non-COVID patients decreased significantly, to a low point of just 62 patients. Thus total numbers of patients in ICU in Ireland remained less than the baseline number of ICU beds. This was due to (i) a smaller number of COVID patients admitted to ICU than expected and (ii) a major decrease in non-COVID patients in ICU. Numbers of patients in ICU nationally remained significantly below the total number of beds available after the expansion of capacity for COVID.

ICU mortality for COVID patients in Ireland was lower than that reported in other countries, including the UK (Table 1). This was noted for (i) all ICU admissions with COVID and (ii) for ICU patients undergoing invasive ventilation.

ICU mortality for COVID patients in Ireland was lower than that reported in other countries, including the UK (Table 1). This was noted for (i) all ICU admissions with COVID and (ii) for ICU patients undergoing invasive ventilation.

	Ireland	UK(1)
COVID-19 ICU admissions / 100,000 population	8.9	16.0
Age on admission (yrs, median)	60	60
% of ICU admissions invasively ventilated	66%	72%
ICU mortality – all COVID admissions to ICU	17%	40%
Hospital mortality – all COVID admissions to ICU	20%	47%
ICU mortality in COVID patients invasively ventilated	26%	49%

Table 1. Outcomes of (i) all COVID admissions to ICU and (ii) COVID patients who underwent invasive ventilation

Conclusion: The demand for ICU beds remained within the available capacity because of (i) fewer COVID admissions to ICU, relative to the UK and (ii) decreased numbers of non-COVID patients in ICU. This was associated with a lower ICU mortality rate than the rate reported for the UK which has a comparable healthcare system.

Intensive Care Medicine Experimental 2020, **8(2)**: 001412

Introduction: Organization and Rebuild intensive care unit (ICU) during pandemic case surge such as COVID-19 is essential for preventing the collapse of healthcare system and excessive damage.

Objectives: We developed new ICU for COVID-19 in the secondary-level, non-teaching, public provincial hospital.

Methods: The administration of Gyeonggi province in the Republic of Korea raised the fund for reconstructing ICU and equipping medical resources for COVID-19, such as high flow nasal cannula (HFNC), mechanical ventilator (MV), critical care ultrasound system, continuous renal replacement machines, etc. Collaborating the tertiary-level, teaching, public central hospital, one intensivist, and ICU nurse master prepared the educational plan including simulation workshop, device demonstration.

Results: After two weeks of preparedness, the confirmed COVID-19 critically ill patients from the long term care facilities were admitted to the new ICU due to respiratory failure enough requiring HFNC or MV support. Invasive monitoring via arterial lines and maintaining critical care medication via central venous lines were done by collaboration dispatched one intensivist with local house staffs. Currently, five COVID-19 critically ill patients were admitted, two discharged with survival, one transported to the tertiary hospital, remained still admitted in the new ICU.

Conclusion: We reported the first experience of the organization and rebuild the new ICU for COVID-19 via collaboration in one public sector.

Intensive Care Medicine Experimental 2020, **8(2)**: 001436

Introduction: Show the results for the year 2019; from the ICUWW team; which is a reactive and proactive team that performs assessment, assistance, monitoring and procedures activities for critical/semi-critical patients outside the scope of the Intensive Care Unit (ICU). Responsible for the early detection and treatment of those who are admitted and present clinical deterioration regardless of where they are, the ICUWW is also in charge of monitoring the patients assessed in the previous 24 hours by the ICU on-call team and it also follow fragile patients after discharge from the ICU. We the results we want to evaluate if it is justified the implementation of this team.

Methods: Descriptive study from January to December 2019; that shows the results of the evaluations made by the ICUWW. Variables are described as means, \pm standard deviation or percentage. Chi square (X²) and Mann-Whitney test for continuous variables were used to compare categorical variables.

Results: In 2019, a total of 1,289 patients were treated by the ICUWW team, who underwent 2,059 interventions, 798 were men (61.9%) and 491 (38.1%) women, with an average age of 61.7 years. The average attention time was 158 minutes, with a follow-up of 1 to 12 days (average 1.26). 553 patients (42.9%) had medical pathology, 624 (48.4%) surgical and 112 (8.7%) trauma. 25.21% of the patients were evaluated in the Emergency Department, 15.4% in the Digestive Surgery service, and the rest in other services. In 54.4% of the occasions the attention was in response to a direct call; 6.9% follow-up was of patients assessed in the previous on-call team and who had not been admitted to the ICU; 17.1% of the evaluations were for CVC placement; 3.8% follow-up of fragile patients after ICU discharge. 30.2% of the care resulted in admission to the ICU, 24.7% were attended for management and 33.5% did not require admission, due to lack of criteria or due to proper management of patients at risk. 5.35% underwent limitation of the therapeutic effort (LTE) after evaluation. Of the fragile patients who were followed-up at discharge, 8.8% required readmission to the ICU.

Conclusion: With the number of patients evaluated and the number of interventions made (active and reactive); continuing with ICUWW team for our hospital or a similar hospital is justified.

001446**Optimising family communication during a pandemic: do video calls have a role?**

S. Jeyabraba¹

¹Critical care, University Hospital Lewisham, London, United Kingdom

Correspondence: S. Jeyabraba

Intensive Care Medicine Experimental 2020, **8(2)**: 001446

Introduction: This survey aims to evaluate whether communication with families was affected by the coronavirus (COVID-19) pandemic and whether video call software mitigated these difficulties.

In 2011 the NHS Outcome Framework recognised “ensuring people have a positive experience of care” as a key domain of quality. In critical care, family members play a crucial role in the care and decision making process. Meeting the emotional and practical needs of family

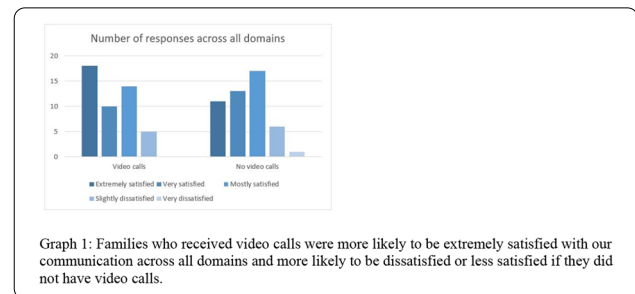

members is essential to delivering good quality care. Family Satisfaction in the Intensive Care Unit FS-ICU has been developed and validated for assessing families’ satisfaction with care and communication. The coronavirus pandemic has placed unforeseen constraints on all aspects of critical care including communication with patients’ family members. Due to the need to limit coronavirus spread, family visitations have been limited if not absent across the country. In order to allow families to communicate with their inpatient relatives, we acquired tablet computers with the TouchAway application. Furthermore, doctors on our ICU made a daily phone call to each family.

Methods: An anonymous, retrospective survey was sent to all families affected by the visitor restrictions during the coronavirus period from early March until the present. The questionnaire utilized was based on the FS-ICU questionnaire, and was modified to focus on communication with doctors and include questions regarding video call use between families and patients.

Results: 24 responses were received. Half of the cohort who responded to the survey had access to video calling. The answers to each domain have been categorised into satisfied and not satisfied and presented in the table below.

Domain	Satisfied	Not satisfied
Frequency of communication	83 (20/24)	17 (4/24)
Ease of getting information and adequate explanations	88% (21/24)	12 (3/24)
Honesty of information	96% (23/24)	4% (1/24)
Consistency of information	79% (19/24)	21% (5/24)
Ease of video calling	91% (10/11)	9% (1/11)
Frequency of video calls	67% (8/12)	33% (4/12)
Video calls help to stay connected	100% (12/12)	0% (12/12)

Table 1: Results by selected domain, divided by satisfaction

Graph 1: Families who received video calls were more likely to be extremely satisfied with our communication across all domains and more likely to be dissatisfied or less satisfied if they did not have video calls.

We also included an opportunity in the survey for free text comments regarding improving our communication and the use of video calls. Many families were very positive; “daily phone call from ICU for update was a lifeline for my family” and that doctors were thorough and honest with them regarding their relative’s condition. There was also feedback that some families did not receive consistent phone calls particularly around time of admission.

Families were very grateful for the opportunity to video call, which helped them appreciate how unwell their relative was and helped them feel connected with their relative and the staff. They commented the application was easy to set up. Families who were not able to use video calls, also said that they would have liked to use this service and all agreed that even outside of pandemic restrictions, it would be a useful addition.

Conclusion: This survey has shown that during a pandemic, we can effectively communicate with patients’ relatives. The utilisation of video calls in critical care has been a welcome addition to our services while families are unable to visit their loved ones. The future benefits of using this technology remain enormous; particularly during further COVID-waves.

Correspondence: A. Waite

Intensive Care Medicine Experimental 2020, **8(2)**: 001452

Introduction: The COVID-19 pandemic poses massive strains on healthcare systems worldwide. In a recent report from the UK, approximately 17% of hospitalised patients required intensive care unit (ICU) admission. Efficient triage of patients with COVID-19 at the time of hospital admission will support local resource planning. There is an urgent need for prediction models that use commonly available clinical measurements to estimate the risk of patients requiring respiratory support and ICU admission.

We aimed to compare physiological observations between patients who require invasive mechanical ventilation and those who do not using the first available data after presentation of patients to our Accident and Emergency Department to allow rapid triaging.

Methods: We retrospectively reviewed case notes of all patients admitted to the Royal Liverpool University Hospital between March 23rd and April 23rd 2020 with a positive COVID-19 RT-PCR result. The chosen time period reflects the peak of the pandemic in North West England. Routine clinical data including demographic data and initial admission physiological data were extracted. We assessed the predictive value of admission physiological parameters including heart rate, oxygen saturations, required fraction of inspired oxygen (FiO₂), mean arterial pressure, temperature and National Early Warning Score (NEWS) by generating Receiver Operator Characteristics.

Results: 455 RT-PCR positive COVID patients were included in our analysis. In univariate analysis, patients requiring mechanical ventilation had lower admission oxygen saturation (87% vs 93%, $p < 0.001$), higher respiratory rate (27 vs 22 bpm, $p < 0.001$), lower estimated P/F ratio (46 vs 35, $p < 0.001$) and were more tachycardic (102 vs 93 bpm, $p < 0.001$). Mean arterial blood pressure was not significantly different (93 vs 90 mmHg, $p = 0.44$). Temperature was comparable between groups (37 vs 37.5°C, $p = 0.55$). When physiological parameters were combined into the NEWS score, patients requiring mechanical ventilation had a significantly higher NEWS (6 vs 4 $p < 0.001$). Following logistic regression, oxygen saturations and estimated P/F ratio predicted need for mechanical ventilation with an area under the curve of 77% and 73% respectively.

Conclusion: Our study identifies a number of physiological parameters which predict the need for invasive mechanical ventilation. Physiological markers associated with hypoxia, including lower admission oxygen saturations, higher respiratory rate and lower estimated P/F ratio show potential to predict the need for invasive ventilation. Patients with COVID-19 were relatively haemodynamically stable with comparable mean arterial pressures between patients requiring mechanical ventilation and those who do not. In the UK it is common practice to combine physiological parameters into the NEWS, however, for patients with COVID-19 the NEWS was not superior in predicting those patients requiring mechanical ventilation.

001466**Decision-making on escalation of treatment to invasive ventilation: A critical review of referrals during the COVID-19 pandemic**

M. Crews¹; E. Morgan¹; A. Ardeshtana¹; BW. Johnston¹; AAC. Waite¹; ID. Welters¹

¹Intensive care unit, Royal Liverpool University Hospital, Liverpool, United Kingdom

Correspondence: A. Waite

Intensive Care Medicine Experimental 2020, **8(2)**: 001466

Introduction: Invasive ventilation to treat respiratory failure may become a scarce resource during pandemics, necessitating critical review to allocate ventilators and intensive care beds to patients likely to benefit most from this intervention.

Demographic characteristics and differences in functional state between patients who were declined escalation to invasive mechanical ventilation compared to those who were admitted to critical care for this intervention during the COVID-19 pandemic have not been well described so far.

In this retrospective cohort study we analysed data from 83 patients who were referred to critical care specialists with the question as to whether they should be admitted to critical care for invasive ventilation in case of clinical deterioration.

Methods: Data for all patients admitted to Royal Liverpool University Hospital between March 23rd and April 23rd 2020 with a positive COVID-19 RT-PCR result who were referred to and reviewed by a consultant intensivist were analysed. Outcome of the critical care review was documented as "suitable for escalation to invasive ventilation if required" or "ward level care only". Frailty scores, comorbidities, demographic data and laboratory results were reviewed for the day of hospital admission. Univariate statistics were performed using χ^2 tests for categorical and Mann-Whitney-U test or T-test for independent samples for metric data.

Results: 83 patients were included in the analysis. 53 patients were assessed as suitable for escalation to invasive ventilation, while treatment was limited to ward level care in 31 patients. Patients in whom escalation was deemed appropriate had lower Rockwood frailty scores (2.5 ± 1.3) compared to patients declined for escalation of care (4.3 ± 1.4 , $p < 0.001$). Patients offered escalation were significantly younger (63.8 ± 11.5 years) than patient who were not offered escalation (54.0 ± 12.2 years, $p < 0.001$). Markers of infection on admission to hospital did not differ between patient groups, indicating that the severity of infection did not influence decision making. Ischemic heart disease, COPD, malignancies, liver disease and chronic kidney disease were documented significantly more often for patients deemed unsuitable for escalation of care ($p < 0.001$). In contrast, comorbidities that showed no significantly different distribution between groups included diabetes, asthma and hypertension.

Conclusion: Patient factors that influenced decision making of critical care specialists as to whether treatment offered should include invasive ventilation included frailty, comorbidities such as heart, kidney or liver disease and patient age. Although not directly investigated in this study, age correlated with the occurrence of these comorbidities and with frailty. Mortality of COVID-19 increased with age. Further research is required to fully understand the decision-making process for offering escalation of care in pandemic situations with limited critical care capacity.

001480**The ICU without walls (ICUWW) team. A reactive and proactive service, created for the care of critically ill patients outside the ICU**

J. Monclou¹; M. Vallverdú¹; JJ. Trujillano¹; N. Montserrat¹; J. Prados¹; S. Iglesias¹; S. Carvalho Brugger¹; M. Miralbes Torner¹; JG. Jiménez²; J. Caballero-López²

²Intensive care department, University Hospital Arnau de Vilanova, Lleida, Spain

Correspondence: J. Monclou

Intensive Care Medicine Experimental 2020, **8(2)**: 001480

Introduction: The ICUWW team is conformed by intensivist doctors who carry out activities from 8 am to 8 pm, accompanied by a nurse with training in critical patients from 10 am to 5 pm, Monday through Friday. Its activity has 2 components. The first is that of the ICU, which is reactive to any need of the hospital (care of critically ill patients, assistance in CPR, assessment of multiple trauma patients, etc..) and other that is proactive; which focuses on the follow-up of fragile patients after discharge from the ICU or who have previously been evaluated by on-call doctors or by the ICUWW team.

Objectives: Show some comparative data about the care provided by the ICUWW team for the years 2018 and 2019, in a hospital of 400 beds in Lleida, Catalunya, Spain.

Methods: Descriptive study from January 2018 to December 2019; that shows the results of the evaluations made by the ICUWW. Variables are described as means, \pm standard deviation or percentage. Chi square (X²) and Mann-Whitney test for continuous variables were used to compare categorical variables.

Results: In 2018 the ICUWW attended 932 patients, with a total of 1496 interventions. 63% were men and 37% women, with an average age of 61 years. The average time of attention was 81 minutes with one average follow-up of 1.36 days. 52% had medical pathologies, 38.2% surgical, and 9.8% traumatic. The 29.7% were assessed at the emergency department, 13.2% at the digestive surgery unit, and the rest in other areas. 49.3% of the attention was made by a direct call; 5.6% was a follow-up of patients assessed in the previous ICU night shift, 11.4% required central venous catheter placement, 5.7% were the follow-up of fragile patients after the ICU discharge. The 17.2% required admission to ICU, 13.5% did not require admission. 8.5% underwent limitation therapeutic effort (LTE). Of the patients that required follow-up (N = 193), 20.7% needed more than 2 days; 14% admission to ICU, and the rest avoided the admission. Only (N = 53) 24.5% of the patients with a follow-up after the discharge from ICU required re-entry.

In 2019, a total of 826 patients were treated by the ICUWW team, who underwent 2,060 interventions; 289 patients with scheduled admissions were also evaluated and 174 CVC insertions were performed. 61.9% were men and 38.1% women; with a mean age of 61.7 years old. The average attention time was 158 minutes, with an average follow-up of 1.26 days. 42.9% had medical, 48.4% surgical, and 8.7% trauma pathology. 25.2% of the patients were evaluated in the emergency department, 15.4% in the digestive surgery unit, and the rest in other services. 30.2% required admission to the ICU, 24.7% were attended for management and support and 33.5% did not require admission. 5.35% underwent therapeutic effort limitation (LTSV) after evaluation. Of the frail patients who underwent follow-up at ICU discharge (N: 45), 8.9% required readmission to the ICU.

Conclusion: With these data, we show the evolution of the ICUWW. Our goal is to improve the team. Try to make better monitoring of fragile patients, and identify critically ill patients earlier. Those are the task for the next years.

001484

Audit of Twice Daily Consultant Reviews on the Intensive Care Units at Buckinghamshire Healthcare NHS Trust

E. Leadbeater¹; M. Taquet¹; N. Fry¹; T. Ali¹

¹Stoke mandeville hospital, Buckinghamshire Healthcare NHS Trust, Stoke Mandeville, United Kingdom

Correspondence: E. Leadbeater

Intensive Care Medicine Experimental 2020, **8(2)**: 001484

Introduction: This audit retrospectively repeats a closed loop on an audit assessing adherence to the GPICS standards of 100% patients receiving twice-daily consultant review (1). An initial audit was carried out before trust wide implementation of a daily management proforma, which contains a pre-printed section for evening ward rounds. The loop was closed after implementation, showing a modest. As staff have become more used to the proforma, the audit was repeated to re-assess documentation.

Methods: A retrospective case notes review was carried out using 'Evolve', an electronic record of scanned handwritten notes. All patients across both sites (site A and site B) were audited over pre-selected

days. The days were chosen such that a selection of consultants would be reviewed; 1 day a week, 8 days apart between 2nd December 2018 and 7th January 2019. This allowed for approximately 2 years since the previous data collection, during which, the proforma had been used exclusively. A patient was deemed to have been reviewed by a consultant if the consultant themselves had documented an assessment or if a doctor had documented the consultant name into the notes. Data were recorded using a simple spreadsheet. Slightly differently to the previous audit, we reviewed whether a specific bed space in the ICU had been reviewed as opposed to a particular patient.

Results: During the assessment period, a total of 87 patient episodes were assessed. An episode was either a morning or an afternoon review. Notes were not available for 14 of those episodes on Evolve. These were included for the data analysis as 'consultant review not documented'. Where a bedspace was empty or a patient was stepped down, no episode was recorded.

Prior to implementation of the proforma, trust-wide 24% patients had a twice daily consultant review documented, immediately post introduction, 35% patients had a twice daily review and two years later, 33% patients had a twice daily review.

- 29 patients had two documented consultant reviews daily (25 site A 4 site B).
- 25 patients had documented morning reviews only (21 site A 4 site B).
- 7 patients had documented evening reviews only (6 site A 1 site B).
- 26 patients had no documented reviews (16 site A 10 site B).

This table compares % patients with documented consultant reviews at both sites for morning and afternoon episodes pre and post introduction of the proforma and the repeat audit.

SITE A	Pre	Post 1	Post 2
Twice	21%	45%	37%
None	17%	20%	24%
AM	57%	33%	31%
PM	5%	2%	8%
SITE B	Pre	Post 1	Post 2
Twice	31%	11%	21%
None	4%	21%	53%
AM	65%	68%	21%
PM	0%	0%	5%
Overall	Pre	Post 1	Post 2
Twice	24%	35%	33%
None	14%	21%	30%
AM	59%	43%	29%
PM	3%	1%	8%

Conclusion: The GPICS standards of 100% of patients having twice daily documented consultant reviews has not been met long after introduction of the ward round proforma. Trust wide, the number of twice-daily reviews have decreased from 35-33%. There has been an improvement across both sites for evening reviews.

The reason for the drop may be as simple as the consultant presence on the ward round not being documented.

Recommended actions:

- departmental presentation of audit findings to encourage more meticulous documentation.
- to further encourage use of the daily management sheet on ward rounds.
- inclusion of the proforma as part of the paperwork pack when a patient is admitted to the unit.
- interviewing staff using the proforma regarding potential difficulties in its use.

Catastrophic health expenditure in an Indian ICU for the management of severe sepsisP. Murthy¹; J. Gopaldas¹¹Critical Care Medicine, Manipal Hospital Old Airport Road, Bengaluru, India**Correspondence:** P. Murthy*Intensive Care Medicine Experimental* 2020, **8(2)**: 001494

Introduction: The rapidly increasing burden of sepsis in India and also the availability of advanced care options have profound impacts on health care costs for patients and their families. High out-of-pocket expenditure, lack of insurance, and low government expenditure create a vicious cycle, leading to household impoverishment.

Objectives: We aim to address the financial implications of sepsis and septic shock management in a tertiary care ICU. We also plan to study the factors influencing financial toxicity and catastrophic health expenditure.

Methods: Prospective data from 23 patients who underwent ICU admission for sepsis and septic shock between January 2019 and July 2019 were collected and analyzed. The time frame for consideration of expenses, including all preoperative investigations, was from the first hospital visit to the day of discharge. Socioeconomic status was assessed using Kuppuswamy Scale [1] and financial burden was assessed using the Comprehensive Score for Financial Toxicity (COST) [2].

Results: Overall mortality in the study was 40% consistent with APACHE II mortality (adjusted for 6 patients who required emergency surgery). The proportion of patients who had partial or full insurance coverage was 50%. The average Kuppuswamy score for the study population is 2.5 (consistent with the middle-income group). Financial toxicity was noted in all irrespective of socioeconomic class. It was significantly higher in lower and middle-income groups than the high-income groups (Table 1).

Table 1: Comparison of socio-economic status and COST Score

Socioeconomic class (Kuppuswamy Score)	Number of patients	COST Score (Mean±SD)	p-Value
Class 1 and 2 (High and upper-middle)	11	20.9±4.79	0.003
Class 3 and 4 (Lower middle and Low)	12	20.9±4.79	

Conclusion: Thus to conclude, a major financial burden was seen in most patients treated for severe sepsis and was highest in low and middle-income groups. Recoverable illness like sepsis needs financial support programs/insurance schemes like the ones seen with cancer care.

Basic Life Support Training amid the COVID-19 pandemic: perspectives from the UK's largest ERC courseA. O'Donnell¹; H. Percival¹; B. Stanley¹; T. Burton¹; N. Coffin²; J. Hulme³; J. Alderman⁴; A. Owen⁴¹Medicine, University of Birmingham, Birmingham, United Kingdom;²Anaesthesia and critical care, Russells Hall Hospital, Birmingham, United Kingdom;³Anaesthesia and critical care, Sandwell and West BirminghamNHS trust, Birmingham, United Kingdom; ⁴Anaesthesia and critical care, Queen Elizabeth Hospital Birmingham, Birmingham, United Kingdom**Correspondence:** A. O'Donnell*Intensive Care Medicine Experimental* 2020, **8(2)**: 001526

Introduction: The Basic Life Support (BLS) course run by Resuscitation for Medical Disciplines (RMD) Birmingham at the University of Birmingham uses a peer to peer teaching model, teaching approximately 1000 healthcare students each year (1). The importance of face-to-face training needs to be balanced with limiting the risk to educators and students and maintaining an environment in which the risk of transmission of SARS-CoV 2 is as low as possible. We therefore describe the modifications that have been introduced to our BLS course; the largest European Resuscitation Council (ERC) certified course in the United Kingdom.

Objectives: This project aimed to investigate the adaptations made to the ongoing academic course (2020-2021) to ensure high quality BLS education is delivered in a safe environment.

Methods: Our course's faculty and student committee produced a COVID-19 strategy using a modified Delphi approach. Amendments to our course's usual running were authored iteratively and shared electronically. Modifications were added at each stage until the group achieved consensus.

Strategic planning utilised guidelines from the ERC and World Health Organisation (WHO) to develop an adapted BLS course for the COVID-19 era (2, 3).

Results: Broadly, our group's strategy was to reduce face-to-face contact where possible, and where impractical, to take steps to minimise risks to trainers and participants.

Data from our prior work (publication under review) suggests that face-to-face teaching outperforms distance learning methods to retrain BLS in healthcare students from their second year of study onwards. Some aspects of our curriculum can be delivered remotely – including all lectures and seminars where no practical training is delivered.

The WHO clearly encourages strict hand hygiene and limited social contact (by reducing group sizes), and the ERC suggests remote training may be effective for professionals requiring BLS training (2,3). Process management and crowd flow through buildings was also analysed and systems were introduced to enable large numbers of people to pass through the educational environment for training and testing without reduction in social distancing and maintaining a low total number of participants in the building at any time.

Conclusion: BLS education at this large-scale ERC BLS course in the UK has been adapted to reduce the risk of COVID-19 transmission, maintaining the use of face to face teaching as the most effective teaching method in our cohort. Such teaching will incorporate additional safety measures with the view to reduce transmission risk of COVID-19, whilst maintaining a high standard of BLS education.

001547**Healthcare stakeholders' perceptions and experiences of factors affecting the implementation of critical care telemedicine (CCT): qualitative evidence synthesis**K. Iliopoulou¹; A. Xyrichis¹¹Florence nightingale faculty of nursing, midwifery and palliative care, King's College London, London, United Kingdom**Correspondence:** K. Iliopoulou*Intensive Care Medicine Experimental* 2020, **8(2)**: 001547

Introduction: Critical care telemedicine (CCT) has long been used to expand the delivery of best care to critically ill patients located in geographically distant areas[1]. During the COVID-19 pandemic, those health systems with CCT appeared better prepared to respond to the pandemic [2]. However, several challenges remain for CCT to be successfully implemented [3].

Objectives: To undertake a qualitative evidence synthesis of healthcare stakeholders' perceptions and experiences of factors affecting the implementation of CCT, with a view hypothesising about factors more likely to foster implementation.

Methods: To undertake a qualitative evidence synthesis of healthcare stakeholders' perceptions and experiences of factors affecting implementation of CCT, with a view hypothesising about factors more likely to foster implementation. Included studies were imported into Nvivo (QSR International Ltd) for coding. Data synthesis followed the Best-Fit framework approach, guided by the Consolidated Framework for Implementation Research (CFIR) [4]. Additional themes not captured by CFIR were classified under a separate theme. The GRADE-CERQual [5] approach was used to summarise confidence in the review findings. Conflicts throughout the process were resolved through team discussion.

Results: Thirteen studies were identified, published between 2008 and 2019, and conducted in North America. Most studies (n=12) included bedside and hub staff, directors and hospital administrators; one study (n=1) included family members. Most studies collected data through interviews and observations (n=10), while three provided qualitative data through open-ended survey questions.

Analysis and synthesis of evidence identified twenty review findings. Most mapped under CFIR's domains of intervention characteristics, inner setting and individual characteristics. The most prominent findings related to networks and communication, knowledge and beliefs about the intervention, and interactions between hub and bedside teams.

ICU stakeholders, including patients and family members, acknowledged CCT's potential for improving patient safety and quality of care regarding standardisation of practice, early recognition of patient deterioration and continuous data collection; and valued the potential of allowing patients to remain in their community. Hospital staff also highlighted the mentoring role of CCT for junior staff at the bedside. Barriers to implementation stemmed from CCT's disruptiveness within the everyday workflow, and additional work imposed on bedside staff, such as relaying patient information to the hub team. The presence of a camera was reported as a risk to patient confidentiality and staff autonomy. The absence of ongoing dialogue and engagement by leadership were perceived as major barriers.

Hospital staff suggested adequate training and rehearsing of the processes relating to the use of CCT prior to its implementation as important facilitators. Both bedside and hub clinicians reported that they wanted their needs to be heard throughout the process, allowing time for them to accept and normalize CCT in their daily workflow.

While bedside clinicians valued prompt access to critical care expertise enabled by the CCT, they were concerned about the hub team interfering with their decisions over patient treatment. The conflict between bedside and hub clinicians was reported, in some instances, raising issues of disrespect and animosity. Effective communication featured by trust, teamness, and a sense of professional community were important enablers to the implementation of CCT.

Conclusion: We concluded with high or moderate confidence in the evidence contributing to several of these review findings. Further research, especially in contexts other than North- America, with

different cultures, norms and practices will strengthen the evidence base for the implementation of CCT internationally.

001606**COVID-19 ICU Daily Review Sheet**T. Baumer¹; E. Godfrey¹; P. Jones²¹Intensive care, Royal Gwent Hospital, Newport, United Kingdom; ²Department of intensive care and anaesthesia, Royal Gwent Hospital, Newport, United Kingdom**Correspondence:** T. Baumer*Intensive Care Medicine Experimental* 2020, **8(2)**: 001606

Introduction: The first patient admitted to our intensive care unit (ICU) with COVID-19 at the Royal Gwent Hospital (RGH), Newport, Wales was on the 9th March 2020. RGH ICU went into surge capacity on the 28th March, remaining well beyond normal occupancy for 40 days. During this time additional doctors were redeployed from the anaesthetic and surgical departments to cover an emergency ICU rota.

Objectives: A quality improvement project was undertaken to introduce a "COVID-19 ICU Daily Review Sheet" that could be completed during daily consultant-led ward-rounds for each patient. The aim was to promote standardisation of care and completion of comprehensive daily assessments, in a time-effective manner, during a chaotic and stressful pandemic environment. A further aim was to assist junior doctors with minimal ICU experience, such as those being redeployed, with structuring reviews of patients.

Methods: Between the 13th and 14th April, pre-intervention measurements were taken of daily ward-rounds (n=32) from the hospital notes regarding junior preparatory review prior to senior review; full systematic patient review; and an "ICU-bundle" review: antibiotics, lines, drug chart, gastroprotection, venous-thromboembolism (VTE). The "COVID-19 ICU Daily Review Sheet" was introduced on the 15th April after emailing staff and making sheets available on the ICU. Post-intervention, between the 25th April and 1st May (7 days), ward-rounds (n=119) were re-assessed.

Results: Following its introduction, the "COVID-19 ICU Daily Review Sheet" was used on 69% (82 of 119) of ward rounds overall between the 25th April and the 1st May. Pre-intervention 31% (10/32) of patients had a pre-emptive junior doctor review and 56% (18/32) received a full systematic review. Post-intervention this had risen to 65% (77/119) and 68% (81/119) respectively. "ICU-bundle" documentation before/after the intervention was as follows: antibiotics (34%/45%), lines (28%/30%), drug chart (0%/28%), gastroprotection (3%/48%), VTE (13%/27%).

Conclusion: The "COVID-19 ICU Daily Review Sheet" had high uptake, appearing to encourage more comprehensive ward-rounds and documentation. The sheets appeared to promote a culture of 'near to normal levels of care' despite being in surge capacity. The wide-spread uptake suggests that the sheets were equally, if not more, time-efficient than free-hand documentation. We would reintroduce the sheet

in the event of a second wave as a useful aid in this complex cohort of patients.

001609

Intensive Care Medicine Experimental 2020, **8(2)**: 001609

Introduction: Antibiotic stewardship programmes (ASPs) aim to improve antibiotic use and patient outcomes and to lower antimicrobial resistance (AMR) rates. Despite growing international commitment and the availability of antibiotic stewardship (AS) implementation guidelines, differences in local practices still may exist.

Objectives: This study aimed to (1) assess current AS practices in intensive care units (ICU) worldwide, and (2) to explore characteristics of AS-focused centers vs. others.

Methods: Data of the DIANA study (Determinants of Antimicrobial use and de-escalation in critical care), a multicentre international prospective observational cohort study, were used. Details of ICU and hospital characteristics, background AMR levels, as well as different aspects of AS practices, including the use of antibiotic de-escalation (ADE), were collected from participating centers. AS-focused centers were defined as centers where (1) local guidelines on antibiotic therapy were available, (2) ASP team members were easily accessible for consultation and/or multidisciplinary AS meetings were held on a regular basis with presence of at least 2 out of 3 of the following team members other than the intensivist: infectious diseases (ID) specialist, medical microbiologist and pharmacist, and (3) microbiology samples were processed daily. Descriptive statistics were used to compare ICUs in AS-focused centers vs. other centers and a 2-proportion two-sided Z-test was used to explore for differences in ADE proportions between both groups.

Results: Data from 144 ICUs were analyzed. Local guidelines on antibiotic treatment were available in 94 ICUs (65%). A scheduled multidisciplinary AS meeting with the intensivist plus at least an ID specialist, a medical microbiologist or a pharmacist, was organized in 28%, 23% and 22% of the ICUs respectively. In 69% of the ICUs, microbiology samples were processed on a daily basis. Consequently, forty-nine ICUs (34%) were categorized as AS-focused centers. AS-focused centers were located more often in the Americas and Oceania, compared to Asia and Europe (64%, 67%, 18% and 38% respectively). Country economy status (high income vs. low and middle income) and hospital status (teaching and non-teaching hospitals) were comparable. Median bed capacity in AS-focused centers and other centers was 17 vs. 11 beds. A closed ICU setting was present in 37% of AS-focused centers, vs. 26% of the other centers. Hospital AMR levels were lower in AS-focused centers compared to other centers. A statistically higher proportion of patients underwent ADE in ICUs located in an AS-focused center, compared to those admitted in other centres ($p < 0.001$).

Conclusion: This study showed that only 1 out of 3 ICUs fulfilled the set criteria of AS-focused center, but these did not have a typical geographical or organisational profile. The observed AMR levels were lower and the ADE rates higher in AS-focused centers.

Surging forward: junior doctors' experiences from the COVID-19 frontline

N. Kelly¹; C. Holt¹; H. Yusuf¹

¹Critical Care, Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom

Correspondence: N. Kelly

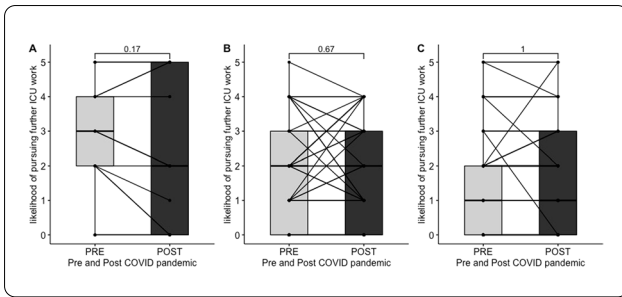

Intensive Care Medicine Experimental 2020, **8(2)**: 001631

Introduction: The COVID-19 pandemic has placed enormous strain on healthcare systems worldwide requiring rapid reorganisation of services. Necessary expansion of Intensive Care (ICU) capacity mandated mass redeployment to support existing ICU staff.

Objectives: The primary end point of this study was the impact of the pandemic on career aspirations, specifically likelihood of pursuing further experience or training in ICM. Other outcomes explored include qualitative data on experiences during the pandemic surge and perceived learning outcomes during this challenging period.

Methods: The study was conducted as a single centre, observational cross-sectional analysis of survey data. Data were collected at Guy's and St Thomas's NHS Foundation Trust, a 1100 bed hospital, regional High Consequences Infectious Diseases (HCID) and ECMO centre. An online questionnaire was offered to all doctors via electronic mailing lists at the end of the 'redeployment' period. Data were analysed using R (version 4.0.0, <http://www.r-project.org>).

Results: 115 doctors completed the survey; 17 already worked on ICU, 41 were redeployed to ICU and 57 worked in other departments during the pandemic. Most respondents (44.8%, 26/58) worked on ICU for 2-3 months. Roughly half of those working on ICU during the pandemic had at least 1 month post-graduate ICU experience (48.3%, 28/58). We found no difference in our primary endpoint of likelihood to pursue further employment in ICU in any of the groups surveyed. That being said as shown in Figure 1, whilst as a cohort there is no consistent shift, on an individual level there is flux in both directions in all groups. Follow up phone calls are ongoing and we hope to present further data on the experiences underlying these individual changes in career aspiration. Our secondary findings showed the majority of trainees deployed to ICU (72.5%) felt they had learnt new skills during their redeployment useful to their parent specialty compared to those not deployed to ICU (29.9%). Canvassing the three words to best describe their experience on ICU the top four words selected were teamwork (67.2%), difficult (44.8%), supportive (44.8%) and camaraderie (36.2%).

Conclusion: The COVID-19 pandemic was an unprecedented national healthcare crisis that rapidly evolved over a short period of time, requiring the mass redeployment of junior doctors under difficult circumstances. However it also presented a unique opportunity for doctors from many specialties to work together towards a collective goal. Despite not resulting in a consistent shift towards or against pursuing further training in ICU, our results support the assertion that those deployed to ICU in particular felt they had learned new skills and become part of a cohesive team rising to the challenges faced.

Burnout experience in the ICU staff of the City Clinical Hospitals in Ukraine

M. Grynovska¹; A. Wong²

¹Anesthesia and intensive care, Ivano-Frankivsk National Medical University and Regional University Teaching Hospital, Ivano-Frankivsk, Ukraine;

²Critical care, Royal Surrey County Hospital, Guildford, United Kingdom

Correspondence: M. Grynovska

Intensive Care Medicine Experimental 2020, **8(2)**: 001642

Introduction Burnout (BO) is reaching epidemic levels in the medical population with prevalence reported around or over 50%¹. Its presence is associated with poor patient safety outcomes². Burnout is a threat to the profession of critical care medicine, with high prevalence rates across critical care provider disciplines³. In Ukraine, specifically, the concept of BO in ICM remains poorly understood and is largely under recognized, or dismissed. We decided to continue investigating the reality of BO experience in our country.

Objectives To assess the BO experience and identify associated risk factors in the ICU of City Clinical Hospitals in Ukraine.

Methods The focus of the study was the frontline ICU staff of two different city clinical hospitals. The final sample size was nurses (n = 99) and doctors (n = 113). Data collection was performed with the help of the Maslach Burnout Inventory (MBI) survey. The BO rate was assessed across various ICU types, seniority, gender and age groups.

Results The response rate was 72%. The overall prevalence of BO in ICUs was 69% (nurses 71.2%, doctors 66.4%). There was no difference on BO subscales between doctors and nurses (95% CI, P > 0.05) We also found no statistically significant difference in the incidence of BO between doctors and nurses (P > 0.05). Our study showed no difference (P > 0.05) in the incidence of BO in doctors across ICU type, seniority level, gender or age group. In contrast, there was a difference in the incidence of BO in nurses across the ICU type (P < 0.05).

Conclusions BO prevalence was notably high in both ICU nurses and doctors. Our findings indicate that doctors and nurses are equally at risk of a BO experience. The study showed no clear association between any of the risks and the incidence of BO in doctors. With regard to nurses, the ICU type proved to be a factor in the incidence of burnout. The nurses of neurosurgery and burn ICUs were most affected possibly due to demanding workload and severity of the

patients in these units. Limitations of our study include a relatively small number of respondents that prevents from drawing conclusions in the context of a country/healthcare system. Further research is warranted in hospitals across the country to determine BO rates and risk factors. We expect our study raise awareness about the reality of BO in Ukraine. We hope obtained data will contribute to better understanding of BO experience and will help us explore the existing opportunities to mitigate its impact and restore fulfillment among ICM professionals.

Intensive Care Medicine Experimental 2020, **8(2)**: 001199

Introduction: In our study we describe the effect of Ventilator Associated Pneumonia (VAP) on the on the length of stay (LOS) in patients with traumatic brain injury (TBI) in the Intensive Care Unit (ICU).

Methods: From December 2016 until January 2020, 156 patients, 96 males and 60 females with TBI requiring mechanical ventilation more than 48 hours GCS ≤ 8 were studied. The mean age was 43 years. On admission to the ICU they had body mass index 27 ± 6 kg/m² and APACHE II score 20 ± 2. Out of 156 patients the 54 had co morbid medical illness.

Results: VAP occurred in 69 out of 156 TBI patients There was no difference in predominance as far as gender was concerned. VAP was significantly associated to patients requiring longer mechanical ventilation 18 days ± 2 and longer sedation 14 days ± 2. Patients with co morbid medical illness and VAP were associated with a significantly greater degree of non neurological organ system dysfunction, though there was no difference in frequency of VAP development compared to the patients without co morbid medical illness. Although VAP was not associated with increased hospital mortality, patients who developed VAP had a longer duration of mechanical ventilation (28 versus 10 days, p < 0.0001) and longer ICU lengths of stay (31 versus 12 days, p < 0.0001).

Conclusion: The effect of VAP in patients with TBI is high; increasing the mechanical ventilation duration and the ICU length of stay; however, does not affect the prognosis and does not seem to be associated with a significantly increased risk of mortality though increases the mechanical ventilation duration.

Seasonal variation and weather changes in admissions to critical care with aneurysmal subarachnoid haemorrhage 2000 - 2019

K. Massie¹; S. Stott²

¹Physiotherapy, Aberdeen Royal Infirmary, Aberdeen, United Kingdom;

²Critical Care, Aberdeen Royal Infirmary, Aberdeen, United Kingdom

Correspondence: S. Stott

Intensive Care Medicine Experimental 2020, **8(2)**: 001211

Introduction: Several reports have suggested that the incidence of aneurysmal subarachnoid haemorrhage (SAH) varies seasonally with peaks in autumn and/or winter (1) and recently have suggested that weather effects may be related (2).

Objectives: To see if admissions to critical care (CC) with SAH were seasonal and if weather factors were related over a twenty year period.

Methods: Our patient record database was searched for patients with an admission diagnosis of SAH between January 2000 and December 2019. Data for age, sex, Glasgow coma score (GCS) at presentation, length of unit and hospital stay, unit and hospital outcome and ultimate discharge destination were retrieved. Weather data for the local health board region were obtained from online weather sources. Variables of monthly maximum, minimum and average monthly temperature and maximum, minimum and average atmospheric pressure were obtained.

Results: 357 patients were identified. 63% were female. Median age 56 years (range 18-86, IQR 17). Median time to CC admission 0 days (range 0-46, IQR 1). Median length of stay 1.8 days (range 0.1-30.5, IQR 3.7). 61% died before hospital discharge, 37.5% died in critical care. 15.9% were discharged to home or normal residence. Median APACHE II score 18 (range 4-40).

There was a seasonal variation of admissions to critical care with a peak occurring in October (figure 1.). There was no correlation with maximum, minimum, average monthly or monthly changes in temperature ($r = -0.10783, -0.07064, -0.11881, -0.02244$ respectively), or with maximum, minimum, average monthly or monthly change in atmospheric pressure ($r = 0.088, 0.449, 0.009, 0.002$ respectively). There was no significance difference in number of deaths according to month of admission ($p = 0.9$)

Figure 1. Total number per month of SAH admitted to critical care 2000-2019

Conclusion: We have shown that there is a seasonal variation in the incidence of SAH being admitted to critical care in the North of Scotland. We have not been able to explain this in relation to changes in temperature or atmospheric pressure.

Intensive Care Medicine Experimental 2020, **8(2)**: 001242

Introduction: To investigate the demographic, clinic and laboratory features of the critically ill patients with gastrointestinal bleeding (GIB) in Intensive Care Unit (ICU).

Methods: This study was performed prospectively in ICU. Patients aged 18 years and older, who had hospitalized for at least 24 hours, with gastrointestinal bleeding, were included the study.

Results: A total of 86 patients were enrolled the study. The mean age was 65 ± 14 years. The APACHE II score was 13 (2-41). Glasgow Coma Scale (GCS) was 13 ± 4 and SOFA score was 3 (0-16). Glasgow-Blatchford risk score was 12 (2-18) and Rockall risk score was 6 (1-10). The most common co-morbid diseases were hypertension (44%), diabetes mellitus (27%), and chronic liver disease (27%). The most frequent predisposing factor for GIB were chronic liver disease (22%) and thrombocytopenia (21%). The anatomic location of bleeding was mostly in the esophagus (35%) and stomach (24%). Endoscopic intervention was performed 42% of patients during ICU follow-up. The length of ICU stay was 5 days (min: 2-max: 28). The ICU mortality rate was 19%. APACHE II, SOFA and Glasgow-Blatchford scores were higher in the patients who died, compared to survivor patients ($p < 0.05$).

Conclusion: As a result of this study, chronic liver disease and thrombocytopenia were found the most common predisposing factor of GIB. The most common localization of bleeding was the stomach and esophagus regions. Approximately half of the patients were treated endoscopically. APACHE II, SOFA and Glasgow-Blatchford scores were higher in patients who died compared to the survivors.

A demographic analysis of admissions to high dependency with COVID-19 at the Queen Elizabeth University Hospital, Glasgow

R. Best¹; R. Hart¹

¹Critical Care, Queen Elizabeth University Hospital, Glasgow, United Kingdom

Correspondence: R. Best

Intensive Care Medicine Experimental 2020, **8(2)**: 001272

Introduction: During the 2020 COVID-19 pandemic, critical care departments across the United Kingdom expanded capacity to care for unprecedented numbers of critically ill patients. The Queen Elizabeth University Hospital in Glasgow (QEUH) is relatively unusual in its separation of high dependency (level 2) and intensive care (level 3) patients within the critical care cohort. Therefore the opportunity was taken to investigate the demographics of the COVID-19 positive patients presenting to high dependency (HDU) during the pandemic and to explore whether these demographics were associated with either HDU or hospital outcome.

Methods: All patients with COVID-19 presenting to HDU at QEUH were identified. Data on age, gender, comorbidities, length of HDU stay, augmented care period (ACP), discharge destination, unit outcome and hospital outcome were collected. Deprivation quintile was calculated using the Scottish Index of Multiple Deprivation (SIMD) according to the patient's home postcode.

The comorbidities that were assessed were diabetes (1,2), cardiovascular disease (excluding hypertension) (1-3), hypertension (1-3), chronic respiratory disease (1,3), renal disease (4) and obesity (5). These comorbidities were chosen as early studies had identified them as comorbidities that might affect infection rate and/or outcome in patients with COVID-19.

Data were analysed to determine whether age, gender, deprivation status or the presence of certain comorbidities were associated with HDU outcome (improved or deteriorated) and hospital outcome (survived to discharge or died in hospital).

Results: Between 24/03/20 and 25/05/20, there were 74 admissions of 69 patients to HDU at the QEUH. Together they amassed 307 patient days in HDU: 13 days at ACP level 3; 230 at level 2; 54 at level 1; and 10 at level 0. Age ranged from 27–76 years (mean 57, IQR 50–65) and 51 patients were male (74%). The majority of patients admitted lived in areas of high deprivation. Length of HDU stay ranged from 1–16 days (median 3, IQR 2–5).

Of the 69 patients, 23 had none of the pre-determined comorbidities (33%); 16 had diabetes mellitus (23%); 8 had cardiovascular disease (12%); 11 had hypertension (16%), 13 had chronic respiratory disease (19%); 4 had renal disease (6%); and 31 were obese (55%). Twenty-four patients were multimorbid (35%), as described as having two or more of the aforementioned diagnoses.

Of the 74 admissions, 42 patients improved and were discharged to the ward (57%); 29 patients deteriorated and were admitted to intensive care (39%); and three patients deteriorated but were not escalated (4%). Of the 69 patients who were admitted to HDU, 51 survived hospital and were discharged home (74%).

In analysis, none of the demographic or comorbidity variables were associated with HDU or hospital outcome.

Conclusion: During the covid pandemic an unusually sick cohort of patients were admitted to HDU at the QEUH, the majority of whom survived to hospital discharge. However, none of the prior identified risk factors for poor outcome were found to be reliable in our cohort. This should be borne in mind in the event of a second wave of the pandemic when making decisions regarding critical care escalation.

Factors predicting mortality in critically ill COVID-19 patients

W. Zarrougui¹; P. Saint Leger¹; M. Alibenali¹; H. Boughanmi¹; N. Elbeki¹; F. Lambiotte¹

¹Intensive care unit, Hospital Jean Bernard, Valenciennes, France

Correspondence: W. Zarrougui

Intensive Care Medicine Experimental 2020, **8(2)**: 001274

Introduction: Since the last week of December, 2019, a massive public health crisis has been rapidly spreading from China to the rest of the world, caused by a newly identified coronavirus named SARS-CoV-2. This rapidly evolving infection affected mainly the respiratory system and can lead to fatal morbidity and mortality.

Objectives: The aim of this study was to describe clinical characteristics and to identify the factors associated with ICU mortality in critically ill COVID-19 patients.

Methods: A retrospective cohort study was performed in the medical ICU of Jean Bernard hospital in Valenciennes, France, including all consecutive critically ill patient with confirmed COVID-19 infection between Mars 11 and Mai 15, 2020. A confirmed case of COVID-19 was defined by a positive RT-PCR (upper or lower respiratory tract specimens). Data were collected by reviewing the electronic medical charts. Were collected: clinical features at admission, severity of illness and ICU course. Univariate and multivariate analysis regression analyses were performed to identify factors independently associated to

mortality. Statistical seizure and analyses were performed using the statistical software package SPSS 24.0.

Results: Among 685 COVID-19 patients hospitalized in Valenciennes regional hospital during the study period, 77(11.2%) were admitted to the ICU. Their general characteristics were: age, 64.67 ± 11 years with ages ranging from 24 to 89 years; male, 52(67.5%); mean BMI, 31.27 ± 9.05 kg/m²; Charlson comorbidity index, 3.03 ± 1.99; duration of symptoms before ICU admission, 9 ± 4.1 days; the mean SAP-SII score, 36.11 ± 10.33; the mean SOFA score, 4.56 ± 2.46; invasive mechanical ventilation (IMV), 57(74%) with median duration, 17[9–26.25] days; the median of peep and compliance during first 3 days were respectively 12[12–16] cmh₂O and 36[30–45] ml/cmH₂O; the most CT- lung opacification percentage at admission [50%–75%], 23(29.9%); Vasopressors, 45(72.7%); hydrocortisone, 23(29.9%); hydroxychloroquine, 29(37.7%); ECMO, 4(5.1%); tracheostomy, 10(13%); thromboembolism complications, 19(24.6%); acute kidney injury (AKI), 34(44.2%); renal replacement therapy, 20(26%); median length of ICU stay, 17[6–26] days; mortality rate, 3.8%.

Univariate analysis showed significant association between mortality and the following factors: age > 65 years (p = 0.03), Charlson index (p = 0.032), IMV at admission (p = 0.032), AKI (p = 0.000), and ventilator free days (p = 0.000).

Multivariate logistic regression analysis has identified only 3 variables as independently associated with ICU mortality: Age(OR, 1.06; 95%CI[1.00–1.13], p 0.048), AKI(OR, 17.74; 95%CI[4.22–74.52], p 0.000), and length of ICU stay(OR, 0.94; 95%CI[0.91–0.98], p 0.011).

Conclusion: In this non selected consecutive COVID-19 population in a medical ICU, the age, acute kidney injury and the length of ICU stay, demonstrated acceptable predictive values for the in-hospital mortality of critically ill patients with COVID-19.

001282

Decline in functional status after ICU discharge of COVID-19 patients

W. Zarrougui¹; N. Bejaoui¹; F. Sedrati¹; N. Elbeki¹; F. Lambiotte¹

¹Intensive care unit, Hospital Jean Bernard, Valenciennes, France

Correspondence: W. Zarrougui

Intensive Care Medicine Experimental 2020, **8(2)**: 001282

Introduction: In December 2019, cases of COVID-19 infection were reported and this novel virus spread rapidly to touch every corner of the world within weeks. COVID-19 affects mainly the respiratory system and would result in acute respiratory distress syndrome, requiring ICU admission and prolonged mechanical ventilation. For ICU survivors, recovery may be characterized by a marked compromise between physical and psychological health after ICU discharge which may decrease quality of life.

Objectives: The objective of our study was to evaluate the incidence and risk factors of post ICU physical impairment of COVID-19 patients.

Methods: A retrospective study was performed in the medical ICU of Jean Bernard hospital in Valenciennes, France, included all consecutive critically ill patients with confirmed COVID-19 infection between Mars 11 and Mai 15, 2020. The study collected clinical features at admission, severity of illness, ICU course, and acute management procedures. Univariate and multivariate regression analyses were performed to identify factors independently associated with physical declines. The statistical analyses were performed using the SPSS 24.0.

Results: A total of 77 patients were included: 52 male (67.5%), mean age, 64.67 ± 11 years; mean BMI, 31.27 ± 9.05 kg/m²; mean Charlson index, 3.03 ± 1.99; mean SAPSII score, 36.11 ± 10.33; mean SOFA score, 4.56 ± 2.46; invasive mechanical ventilation (IMV), 57(74%) with median duration, 17[9–26.25] days; vasopressors, 45(72.7%); hydrocortisone, 23(29.9%); neuromuscular blockers agents, 46 (59.7%); ECMO, 4(5.1%); tracheostomy, 10(13%); median length of ICU stay, 17[6–26] days; mortality rate, 33.8%. Twenty-one (42%) of ICU survivors were transferred to rehabilitation ward with mean length of stay, 19.35 ± 9.45 days. On the day of hospital discharge, 14(28%) patients kept persistent physical impairment.

Univariate analysis identified several factors associated to rehabilitation needs after ICU stay: age, p 0.006; use of corticosteroids and

neuromuscular blockers agents with p value respectively 0.000 and 0.006; duration of IMV, p 0.006 and duration of ICU stay, p 0.000. In multivariate analysis two predictors were independently associated to rehabilitation needs: the age (OR, 1.104; 95%CI[1.00-1.22], p 0.051) and duration of ICU stay (OR, 1.11; 95%CI[1.01-1.22], p 0.023).

Univariate analysis identified the age ($p=0.038$), neuromuscular blockers agents ($p=0.009$) and medical history of diabetes ($p=0.026$) as factors associated with prolonged stay (>14 days) in rehabilitation ward.

Conclusion: Critically ill patients who survive COVID-19 infection frequently experience important and long-lasting physical impairments. In fact, identified factors associated with persistent physical disabilities after ICU discharge may offer physicians the opportunity to facilitate adequate screening and to develop preventive measures to improve health-related quality of life of critical illness survivors.

Descriptive analysis of critically ill patients admitted to a third-level hospital in covid-19 pandemic

P. García Olivares¹; A. Garrido¹; J. Cedeño Mora¹; C. Mata¹; J. Cui¹; P. Oliver¹; G. Castañeda¹; C. Alvarez¹; N. Cangó¹; JM. Gomez¹

¹Intensive Care Unit, H.G.U Gregorio Marañón, Madrid, Spain

Correspondence: P. García Olivares

Intensive Care Medicine Experimental 2020, **8(2)**: 001299

Introduction: COVID-19 is a potentially fatal disease, with high contagiousness, that has become a global public health problem.

Objectives: The aim of this study was to describe the characteristics of patients admitted to the critical care units of a third level hospital during the COVID-19 pandemic.

Methods: Prospective, observational study performed in critically ill Covid-19 patients admitted to H.G.U Gregorio Marañón during March-April 2020. We collected epidemiological data, comorbidities, presentation symptoms, relevant clinical data, organic support measures used, complications during stay, administered treatments and outcome.

Descriptive analysis was expressed as means (SD) for normally distributed quantitative variables, medians (IQR) for non-normally distributed variables, and as percentages for categorical data.

Results: One hundred and fifty patients were included, 70% were male, mean age was 61 years (49-70). Charlson Comorbidity Index 1 pts (0-3) and the most frequent comorbidities observed were: Obesity (MCI ≥ 30) 53%, hypertension 53%, diabetes 18%, dyslipidemia 47%, cardiovascular disease 56%, chronic respiratory disease 26% and immunodeficiency 10%. The elapsed time from the onset of the clinical picture to hospital admission was 6 ± 4 days, being the most common symptoms: fever 90%, cough 70%, shortness of breath 60%, myalgia 46% and headache 7%. The delay until ICU admission was 2 ± 1 days and the main clinical characteristics at admission were: APACHE II 17 ± 5 , SOFA 6 ± 3 , PaO₂/FiO₂ ratio 102 ± 45 , mechanical ventilation 70%, High-flow oxygen therapy 27% and requiring immediate prone-position ventilation 57% of patients. During ICU stay, 88% of patients needed mechanical ventilation, with an average time of 15 days (8-25), 74% prone-position ventilation, with a median of 2 sessions (0-5), 64% neuromuscular blockers and 37% of patients underwent tracheostomy for respiratory support removal. Vasopressor therapy was required by 63% of patients, 30% developed acute renal failure and 10% needed renal replacement therapy. During ICU stay, infectious complications (ventilator-related pneumonia 28% and catheter-related bacteraemia 24%) were the most frequent, followed by delirium 30%, pneumothorax 10% and clinical thromboembolism 7%. Regarding the treatment administered: 99% of patients received antibiotics, 99% Ritonavir/Lopinavir, 97% Hidroxicloroquine, 76% Tocilizumab, 60% Beta-Interferon and 22% Remdesivir. Of all the patients, 76% received corticosteroids at some time during hospital stay.

The ICU mortality was 38%, with mean stay of 24 days (10-32). In-hospital mortality was 40%, with mean stay of 36 days (17-53). The main causes of mortality were multiple organ dysfunction syndrome 47%, and refractory hypoxemia 40%.

Conclusion: There was a significant mortality and a large number of complications in critically ill Covid-19 patients. A high percentage of patients needed respiratory support and prone-position ventilation. Prolonged ICU and hospital stay was required.

Intensive Care Medicine Experimental 2020, **8(2)**: 001309

Introduction: Critically ill patients in intensive care units (ICUs) are exposed to stressful conditions and experience discomfort from multiple sources, such as the environment or related to care provided in the ICU, depending on the care organizations and patient health status. This discomfort may have short-term and long-term consequences for ICU survivors, such as various degrees of anxiety and/or depression or post-traumatic stress disorder (PTSD) (1) which may affect patient's quality of life. Reducing discomfort in the ICU has therefore become a major issue. It has already been demonstrated that the implementation of a tailored multicomponent program for discomfort prevention in adult ICUs (named the IPREA3 program): 1) may decrease the self-perceived discomfort in general adult ICU survivors of at the end of their ICU stay, according to the results of the IPREA3 study, a cluster-randomized controlled study (2); 2) may reduce substantial PTSD symptoms assessed 1 year after ICU discharge, according to the results of the AQUARE study, a prospective cohort study including patients who were exposed and unexposed to the IPREA3 program (3). These promising results justify the need for a confirmatory study using a randomized design, the PTSD-REA study.

Methods: The PTSD-REA study is a stepped wedge cluster-randomized interventional study involving 18 French ICUs. The cluster level comprises the ICUs, which are the units of randomization. Patients hospitalized in the ICUs comprise the individual level.

The intervention is the implementation of the IPREA3 program, a tailored multicomponent program consisting of assessment of ICU-related self-perceived discomforts, immediate and monthly feedback to the healthcare team, and site-specific tailored interventions. The whole duration of the inclusion period will be 15 months and patients will be followed-up 1 year after ICU discharge. During the first month of the inclusion period, no ICU is exposed to the IPREA3 program. Every following month, 2 new ICUs of the 18 participating ICUs are randomized to the application of IPREA3 until the end of the inclusion period, leading to 9 steps. We considered 3 periods, a control period, an unvariable 5-month learning period for each ICU, and an interventional period during which the IPREA3 program will be applied during more than 5 months until the end of the inclusion period. Patients will be included only during the control period and the interventional period. For each participating ICU, the durations of the control period and the interventional period range from 1 to 9 months, according to the randomization date for crossing over to the IPREA3 program.

The eligible patients are patients who survived an ICU stay of at least 3 calendar days with an affiliation to a social security scheme. The exclusion criteria include death prior to the 1-year follow-up after the index ICU hospitalization, patients under trusteeship, patients with cognitive incapacity, and patients who did not understand French sufficiently to complete the questionnaires exploring psychiatric morbidity. All participants provided written informed consent. We planned to include 4500 patients during the study, 2250 patients in each group.

The primary outcome measure is the presence of substantial PTSD symptoms at one year after ICU discharge assessed from the post-traumatic stress-disorder checklist (PCL-5) which is a 20-item self-report measure for PTSD symptoms according to the DSM-5 (Diagnostic and Statistical Manual of Mental Disorders). The secondary outcomes are the following: the ICU stay's duration, the number of days with mechanical ventilation, the overall score of discomfort assessed from the IPREA3 questionnaire, the duration of hospital stay after ICU discharge. The other secondary outcomes will be assessed at 1 year after ICU discharge: the number of symptoms in categories A,B,C, D and E, respectively, assessed from the PCL-5, the scores of the sub-scales A and D, respectively, of the questionnaire HAD-5 (Hospital and Anxiety Depression Scale), the score obtained from the World Health Organization Quality of Life (WHOQOL-BREF), the number of emergency room visits, hospitalizations, and consultations with a psychologist or psychiatrist during the past year since ICU discharge, return to own home, and occupational status.

Results: The inclusion period started on November 1, 2020, but was interrupted on March 19, 2020 due to the consequences of the global COVID-19 pandemic on the functioning of French ICUs, when 1252 patients had already been included. It is planned to resume the inclusions in the ICUs on September 1, 2020. The provisional date for ending the inclusions without further interruption due to the COVID-19 pandemic is now July 31, 2021.

Conclusion: Despite the interruption of the PTSD-REA study due to the COVID-19 pandemic, more than a thousand patients in the control group could be already included. The results of the PTSD-REA study are eagerly expected to confirm that applying the IPREA3 program during the ICU stay may reduce substantial PTSD symptoms at 1 year after ICU discharge in general adult ICU survivors.

Upper gastro-intestinal bleeding in VA ECMO patient: a retrospective cohort study

J. Stern¹; D. Claire²; JF. Timsit³; R. Sonnevill²

¹Intensive care, Bichat-Claude Bernard Hospital, Paris, France; ²Paris, Medical and infectious Intensive Care Unit, Bichat-Claude Bernard Hospital,

Paris, France; ³Intensive care medicine department, Assistance Hopitaux Publique de Paris, Paris, France

Correspondence: J. stern

Intensive Care Medicine Experimental 2020, **8(2)**: 001316

Introduction: Veno-arterial Extracorporeal Membrane Oxygenation (VA ECMO) is used in cases of cardiogenic shock or refractory cardiac arrest. Upper gastrointestinal bleeding (UGIB) is a common complication in intensive care patients. Few data are available for patients on VA ECMO.

Objectives: The objective of our study was to assess the incidence, risk factors and attributable morbidity and mortality of UGIB in this population.

Methods: We conducted a retrospective cohort study in our medical intensive care unit (ICU) at Bichat Hospital (APHP-Paris). All patients admitted between 2014 and 2017 who had a VA ECMO were included. A survival model with death as a competitive risk was used to determine the risk factors for UGIB.

Results: 257 patients were included, 48 patients (18.7%) presented UGIB. These patients had a lower SAPS II score and a lower lactate level at the setting up of ECMO (respectively 51 [41; 67.5] vs 60 [44; 80] $p = 0.05$; 4 mmol/L [2.4; 8.1] vs 5.6 mmol/L [2.7; 10.3], $p = 0.04$) a longer length of stay in ICU and mechanical ventilation duration (respectively 40.5 days [19; 82] vs 15 days [6; 26]; $p < 0.01$ and 32 days [17.5; 45] vs 9 days [5; 18]; $p < 0.01$). UGIB occurred in median at 18 days [7; 43]. The most frequently found lesions on endoscopy were peptic ulcers. In multivariate analysis a BMI (body mass index) > 30 (HR 2.46 [1.22; 4.97], $p = 0.01$), diabetes (HR 2.91 [1.48; 5.72]; $p < 0.01$) and a history of cerebrovascular disease (HR 3.18 [1.19; 8.47]; $p = 0.02$) were associated with a risk of developing UGIB. UGIB was associated with a reduced risk of mortality (HR 0.53 [0.34; 0.83]; $p = 0.01$).

Conclusion: The incidence of UGIB is high in the population of patients on ECMO VA (18.7%). The decrease in the risk of mortality in this population could be explained by a lower severity of patients on admission, allowing survival long enough to develop UGIB. Obesity, diabetes, and a history of cerebrovascular disease appear to be linked to the risk of developing UGIB and could be witnesses to damage to pre-existing splanchnic microcirculation.

Applying RYAN mortality prediction model in patients with severe burns

MK. Belba¹; A. Aleks¹; I. Nezh¹; A. Belba²

¹Anesthesia and intensive care, Mother Teresa Hospital, Tirana, Albania;

²Anesthesia and intensive care, KU Leuven University Hall, Leuven, Belgium

Correspondence: M.K. Belba

Intensive Care Medicine Experimental 2020, **8(2)**: 001331

Introduction: Many prognostic scoring models have been devised to predict mortality risk in burn patients. Ryan mortality prediction model is a system that predicts mortality taking into account three major risk factors: age 60 years or over, the burned surface area (BSA) of at least 40%, and the presence of an inhalation injury. An increasing number of risk factors (0-3) is associated with an increasing mortality rate. This formula predicts 0.3%, 3%, 33%, and approx. 90% mortality when, respectively, zero, one, two, or three risk factors are present [1].

Objectives: The aim of this presentation is to apply this prediction model in two cohort burn patients hospitalized in ICU and to evaluate the observed deaths with the predicted ones.

Methods: The study retrospectively analyzes the data of all burn patients admitted in the ICU of the Service of Burns and Plastic Surgery of the UHC in Tirana, Albania in 1998 to 2008 and 2009 to 2019.

Results: Overall mortality during 2009 to 2019 was improved: 6.89% (116 deaths in 1684 patients) compared with 1998 to 2008 which was 10.5% (255 deaths in 2337 patients). The observed mortality was 0.09%, 5.61%, 35.23% and 81.4% when, respectively, zero, one, two, or three risk factors were present and there is statistical significance for the difference between two decades (table 1). We performed the comparison of the full model (Age, BSA and presence of Inhalation Injury) against a null through Nominal Regression. $\chi^2(3) = 488.808$,

$p < 0.001$). The Goodness of Fit test was used to affirm that the data gathered fit the distribution from the population [$\chi^2(694) = 617.914$, $p = .982$]. The likelihood Ratios confirmed all the predictors of the model to be significant ($p < 0.001$).

Table 1: Analysis of Mortality in two periods

Number of risk factors	1998-2008			2009-2019			p				
	Patients (n=2337) Number %	Deaths (n=255) Number %	Mortality (%) Observed	Patients (n=1684) Number %	Deaths (n=116) Number %	Mortality (%) Observed					
NO RISK FACTOR	1814	77.02	79	30.59	4.30	1144	67.93	7	0.86	0.06	<0.0001
ONE RISK FACTOR											
Age ≥ 60 years	98	4.19	8	3.14		119	7.07	9	2.59		
RSA ≥ 0%burned	136	5.82	37	14.53		134	7.96	11	9.48		
Presence of Inhalation injury	106	4.54	24	9.41		68	4.04	4	3.45		
Σ	340	14.55	69	27.06	20.29	321	19.09	18	15.52	5.61	<0.0001
TWO RISK FACTORS											
Age ≥ 60 years + RSA ≥ 0%burned	9	0.39	4	1.57		27	1.60	6	5.17		
Age ≥ 60 years + Presence of Inhalation injury	34	1.45	21	8.24		34	2.02	15	12.93		
RSA ≥ 0%burned + Presence of Inhalation injury	124	5.31	70	27.45	36.89	115	6.83	41	35.34		<0.0001
Σ	167	7.15	95	37.25	36.89	176	10.45	62	53.45	35.23	<0.0001
THREE RISK FACTORS											
Age ≥ 60 years + RSA ≥ 0%burned + Presence of Inhalation injury	15	0.68	11	5.1	81.25	43	2.55	35	30.17	81.40	0.0001
Σ											0.0001
Overall Mortality %											6.8

Conclusion: Observed mortality in patients with one and two risk factors is improved but when are present the three risk factors mortality is higher. The data derived from this study confirm the strength of the Ryan model.

Evaluate efficacy of tele-yoga on multiple outcomes after a period of critical illness

L. Orwelius¹; T. Jaarsma²; L. Klompstra²; I. Thülen²; A. Strömberg²
¹{street_address}, Linköping, Sweden; ²Department of health, medicine and caring sciences, Linköping University, Linköping, Sweden

Correspondence: L. Orwelius

Intensive Care Medicine Experimental 2020, **8(2)**: 001336

Introduction: Medical yoga, a form of Kundalini Yoga with movements, breathing exercises and meditation has been found to be associated with improved regulation of the sympathetic nervous system and hypothalamic-pituitary-adrenal system. Yoga may improve a number of biological measure (cortisol, systolic blood pressure, resting heart rate, high frequency heart rate variability, fasting blood glucose, cholesterol and low density lipoprotein) (1) as well as patient reported outcome measures e.g. health-related quality of life in various patient populations (e.g. anxiety, depression, stress-related disorders, cardiovascular disease, neurological conditions and cancer). (2-4). This indicates that Medical yoga can be used as an instrument for patients with prolonged disorders after critical illness such as post-intensive care syndrome (PICS) or heart failure. However, for severely ill persons it can be difficult to leave the home and attend regular yoga classes.

Objectives: To develop a feasibility- and pilot tested home-based tele-yoga intervention.

Methods: The tele-yoga includes live yoga sessions twice a week led by a certified instructor and individual daily yoga practice supported by an app. The mHealth tool used is a tablet with Internet connection that contains a video communication ability for the yoga sessions and an app with instructions (text, pictures, and sound files) on how to self-perform medical yoga daily. The video communication app (ZOOM) and yoga app, installed on a tablet with a sim card and 4G surf, were tested for feasibility together with nine persons from a local cardiac patient organization. Further, a pilot study with 10 participants with heart failure (five intervention and five controls) were conducted to test the design of a planned RCT study.

Results: The feasibility testing resulted in minor modifications, and most technical problems were related to sound. Therefore, the yoga instructor changed to a more advanced microphone in the pilot study and a more detailed checklist for using the technology was developed. In the pilot study the design and technology worked sufficiently. The RCT study is now ongoing aiming to recruit 200 participants with post intensive care or heart failure randomized to receive medical yoga remotely at home (teleyoga) for 12 weeks or individualized training

to the same extent. The primary hypothesis is that medical tele-yoga significantly increases physical function, health-related quality of life and mental well-being in people after a period of critical illness compared to a control group receiving individualized exercise advice. The secondary hypothesis is that medical yoga improves sleep, heart rate, blood pressure, biomarkers for stress and inflammation and cognition in people after a period of critical illness compared to a control group receiving individualized exercise advice.

Conclusion: The tele-yoga intervention was feasible after minor adjustments and the RCT design was successfully tested in the pilot study. The ongoing RCT study will evaluate efficacy of tele-yoga on multiple outcomes after critical illness.

Mortality associated with early acute renal failure in critically ill patients

A. Garrido¹; J. Cedeño Mora¹; P. García Olivares¹; B. Moreno¹; G. Castañeda¹; C. Ramirez¹; JC. Barrios Torres¹; M. Sancho¹; A. Jaspel¹; S. Casanova Prieto¹; S. Ramos-Mejía¹

¹Intensive Care Unit, H.G.U Gregorio Marañón, Madrid, Spain

Correspondence: P. García Olivares

Intensive Care Medicine Experimental 2020, **8(2)**: 001341

Introduction: Acute renal failure is very common in the critically ill patients and it is associated with increased mortality.

Objectives: To determine the prognostic impact of the early acute renal failure (ARF) in critically ill patients.

Methods: Prospective, observational study conducted during the months of November and December 2019. Epidemiological data, reason for admission, severity scores, organic support and renal function data, were collected in all patients admitted to ICU. The ARF was defined according to AKIN, RIFLE and KDIGO scores in the first 24 hours of admission.

In descriptive analysis, qualitative variables were expressed in percentages and quantitative variables in means (SD) or medians (IQR). The univariate analysis was performed using Chi-square (RR) for qualitative variables and simple logistic regression (OR) for quantitative variables. The prognostic impact of ARF was determined by means of a multiple logistic regression analysis (OR), adjusted for different confounding factors.

Results: We included 95 patients. **Epidemiological profile:** males 56%, age 60 ± 17 years, some comorbidity 52%. **Reason of admission:** neurological pathology 30%, respiratory 26% and infectious 20%. **Severity scores:** APACHE II 18 (13-25), SOFA 6 (4-8). Mechanical ventilation was required in 52% of patients and 51% needed vasoactive therapy. The three scores used determined ARF in 34% of patients (14% stage I/risk, 8% stage II/damage, 12% stage III/failure), 33% of them required renal replacement therapy. Mortality was 29% and average stay was 11 days (6-29).

In the univariate analysis, the patients with early ARF had higher mortality (50% vs 17.5%, $p = 0.001$). For each stage of ARF there was an increase in mortality (stage I/risk 23%, stage II/damage 50%, stage III/failure 82%, $p = 0.001$).

In the multivariate analysis (adjusted for age, comorbidities, reason of admission, severity scores, mechanical ventilation and vasoactive therapy), early ARF was an independent prognostic factor for mortality (OR 6.28; 95% CI 1.28-30.99). Each stage of ARF increased the risk of death: stage I/risk (OR 1.39; 95% CI 0.33-5.90), stage II/damage (OR 4.64; 95% CI 1.01-21.44), stage III/failure (OR 20.86; 95% CI 3.95-110.27).

Conclusion: Early acute renal failure was an independent prognostic factor for mortality. The risk of death increased with each stage proposed in the scores used.

The Role of FOUR Score in Intensive Care Mortality Prediction

T. Ozturk¹; C. Bor¹; K. Demirag¹; M. Uyar¹

¹Anesthesiology and intensive care, Ege University Hospital, Izmir, Turkey

Correspondence: K. Demirag

Intensive Care Medicine Experimental 2020, **8(2)**: 001356

Introduction: Glasgow Coma Scale which predicts ICU mortality is being criticized due to difficulty in verbal assessment in tracheally intubated patients. FOUR Score (Full Outline of Unresponsiveness Full Outline of Unresponsiveness) includes eye movements, motor response, brainstem reflexes and breathing pattern and it is speculated as a more reliable score. BIS (Bispectral index score) gives numerical data to monitor neurological status. We aimed to compare the FOUR score with GCS and BIS to predict mortality.

Methods: Between August 2015 and April 2016, all unconscious adult patients were monitored by BIS in the first 24-h of admission after hemodynamic and metabolic stabilisation. GCS and FOUR scores were assessed by the same physician. Patients younger than 18, conscious, paralyzed or sedated patients were excluded. Demographics, ICU and hospital stay and mortality were recorded.

Results: 65 patients included (32 males). Mortality was 83% (54/65 patients). Average age, BMI, mean arterial pressure, APACHE II score, duration of ICU and hospital stay differed between the survivors and non-survivors. In predicting mortality, the sensitivity and specificity of GCS, FOUR and BIS scores were 83.3%/63.6%, 83.3%/54.5% and 90.7%/63.6% respectively. The cut-off values of GCS, FOUR and BIS for predicting mortality were 6, 8 and 60, respectively. The correlation between BIS/FOUR and between BIS/GCS score was similar (0.797 vs 0.764).

Conclusion: In this patient population with advanced age and high APACHE II score, GCS ≤ 6 , FOUR score ≤ 8 and BIS value ≤ 60 were related with poor prognosis. When compared with BIS score, the prognostic values of GCS and FOUR score were similar and can be used interchangeably.

Intensive Care Medicine Experimental 2020, **8(2)**: 001359

Introduction: Existing studies have looked at the risk factors for death among COVID-19 patients admitted to the intensive care unit (ICU). However, few is known about the actual process of death such as the precise role of secondary bacterial infections, cardiac or kidney failure.

Objectives: The present study aimed to describe specific causes of death among COVID-19 patients at our ICU to better understand physiopathological pathway of the disease and to guide diagnostic and therapeutic decision.

Methods: Medical charts of all COVID-19 patients died at the ICU of Rimini Hospital between 20/02/2020 and 30/06/2020 were retrieved. Information regarding laboratory test, imaging findings, microbial culture and daily not in the medical records were reviewed to define the final process that lead to death (according to WHO guidelines). Severity of organ failure was estimated by the SOFA score. Finally, we classified patients according to the clinical conditions that contributed to the dying process including the proportionality of care and unexpected deaths.

Results: Among 71 patients admitted to ICU in the study period, 28 (39.4%) died during the ICU admission (median ICU stay: 15 days (range: 0-88)). Respiratory failure was the leading cause of death in 16 (57.1%) patients. Pneumonia-COVID related was identified in 10 (35.7%) deceased patients with a bacterial superinfection present in 4 of those. Six (21.4%) patients developed ventilator associated bacterial pneumonia prior to death and in 3 of those COVID-related pneumonia was not improving while in 1 case severe lung fibrosis had developed leading to impossible weaning from the ventilators (ICU length of stay: 88 days). Bacterial infections were the main cause of death in 7 (25%) patients and in 6 of them COVID-related pneumonia was improving. Finally, 5 (17.9%) patients death was related to other causes: 1 fulminant myocarditis, 1 cerebral hemorrhage, 1 hemorrhagic shock, 1 myocardial infarction, and one disseminated neoplasm. In 3 cases deaths was unexpected while in 5 patients withdrawal of treatment was decided. The median SOFA score increased from 6.5 (3-11) the day of ICU admission to 8 (4-18) 3 days before death, and to 11 (3-18) the day of death.

Conclusion: The course of critically ill COVID-19 patients is heterogeneous. Bacterial infections played an important role in the dying process and a systematic approach to infection vigilance could help to prevent some deaths especially in a contest where inflammatory markers might have been masked by use of steroids or immunosuppressive therapies.

The Impact of Speech and Language Therapy Dysphagia Intervention with COVID-19 patients at a Tertiary Cardiothoracic Centre

S. Stagnell¹; N. Maistry¹

¹Speech and Language Therapy, Royal Brompton Hospital, London, United Kingdom

Correspondence: S. Stagnell

Intensive Care Medicine Experimental 2020, **8(2)**: 001360

Introduction: The increased risk of dysphagia and laryngeal injury in patients following intubation is widely described in the literature [2]. Patients diagnosed with COVID-19 were intubated and ventilated for

prolonged periods and subsequently presented with profound weakness and confusion, all of which contribute to increased risk of post-extubation dysphagia [1, 3]. The presence of Speech and Language Therapy (SLT) within the MDT, to provide early dysphagia assessment [1, 4], is essential.

Objectives: To review the impact on SLT dysphagia intervention using a validated outcome measure with all COVID-19 patients referred to SLT at the Royal Brompton Hospital.

Methods: During the period between March to June 2020 (inclusive), SLT were referred and treated 42 of 136 COVID-19 patients admitted to the Royal Brompton Hospital (RBH). One patient solely received voice intervention and six were repatriated prior to completing their dysphagia treatment; and so these patients were excluded from data analysis.

Impact was measured using 'The Royal Brisbane Hospital Outcome Measures (RBHOM)'. This is a validated numerical scale, which shows progress from Nil-by-Mouth (NBM) to full oral intake [5]. This outcome measure was scored following initial assessment and repeated on discharge.

Results: A total of 35 patients, including 23 with tracheostomy with and without mechanical ventilation, received SLT dysphagia intervention. These are interim findings and data collection is still being collated.

Interim data analysis has shown that an average of eight days of SLT dysphagia intervention resulted in patients having an average five point increase on the RBHOM. Only one patient remained NBM with a gastrostomy on discharge whilst all others returned to full oral intake. From the data collected thus far, 97% of patients went from NBM to safely returning to oral intake.

Conclusion: Whilst this is a small sample of patients and data collection is ongoing, results are strongly showing that SLT dysphagia intervention has a direct impact on improving outcome measures for COVID-19 patients.

Short-term physical and mental health outcome of critically-ill COVID-19 patients after discharge from intensive care unit

A. Topeli¹; B. Halacli¹; E. Ortac Ersoy¹; S. Kilic¹; S. Öcal¹

¹Division of intensive care medicine, department of internal medicine, Hacettepe University Faculty of Medicine, Ankara, Turkey

Correspondence: A. Topeli

Intensive Care Medicine Experimental 2020, **8(2)**: 001381

Introduction: Critically-ill patients with COVID-19 have a prolonged intensive care unit (ICU) course and their short- and long-term health outcome are unknown.

Objectives: To report short-term physical, nutritional, cognitive, psychological impairment, and quality-of-life in ICU survivors with COVID-19, 1 month after ICU discharge.

Methods: Patients who stayed in ICU for > 7 days between March 21, 2020 and May 1, 2020 were included. Patients were evaluated in the follow-up visit within 1st month after ICU discharge, where general

performance, nutritional status, 6-minute-walking test (6MWT), muscle function, cognitive, psychological and quality-of-life assessments were performed. Related samples were compared by Wilcoxon-Signed-Rank test and results are presented as median (IQR).

Results: Out of 30 patients with COVID-19 who were admitted to ICU, 11 patients (7 males, 4 females) with a median age of 60 (52-75) were evaluated. Their admission APACHE II score was 15 (12-18). ICU length of stay was 13 (9-23) and hospital length of stay was 23 (17-33) days. PaO₂/FiO₂ improved at ICU discharge as compared to admission values (260 (217-300) vs 158 (146-227); p=0.03). Five patients received invasive mechanical ventilation. ECOG performance and Clinical Frailty Scale © scores were worse during the follow-up visit than their baseline (0 (0-1) vs 0 (0-0), p=0.03 and 2 (1-3) vs 1 (1-2), p=0.008, respectively). Compared to baseline they lost 7.9% (5.8-11.8) of their weight at ICU discharge and weight loss at follow-up visit was 6.5% (2.4-12.4) kg. Predicted distance walked during 6MWT in 10 patients was 82.2% (72.4-88.8) and 6 patients reported dyspnea at rest. The handgrip strength test was below normal in 4 patients. ICU-acquired weakness according to Medical Research Council was present in 5 patients at ICU discharge, whereas it improved in the follow-up visit compared to baseline (54 (51-58) vs 48 (42-52), p=0.005). The Mini-mental test was abnormal in 2 patients. Three patients had anxiety, 1 had borderline depression and 1 had post-traumatic stress disorder. Six patients had moderate-severe pain and 6 patients reported sleep problems. The physical-component score of Short Form-36 was low in 8, the mental-component score was low in 4 patients.

Conclusion: Short-term outcome of critically-ill COVID-19 patients 1 month after ICU discharge was poor. Long-term outcome should be evaluated in more number of patients.

Meeting the need for Post ICU care of COVID -19 patients- A multi-professional response model for follow up and rehabilitation

A. Ersson¹; P. Ackermærk²

¹Anaesthesia and Intensive Care, Region Sörmland, Nyköping, Sweden;

²Rehabilitation and pain medicine, Region Sörmland, Nyköping, Sweden

Correspondence: A. Ersson

Intensive Care Medicine Experimental 2020, **8(2)**: 001389

Introduction: The Covid-19 pandemic has put the need for ICU rehabilitation in bright light due to extreme strain on ICU capacity. During the pandemic, the Sörmland region became one of the heaviest targeted areas in Sweden with 57 patients/100.000 inhabitants needing intensive care. To meet the anticipated need for ICU rehabilitation, a multi professional taskforce was formed to design and institute a rehabilitation program encompassing all phases of the clinical course from the ICU to hospital discharge and the following time in outpatient care.

ICU patients frequently develop sequel after their ICU stay with longstanding reduction in HRQoL. These impairments, described as PICS (Post Intensive Care Syndrome), involves both cognitive and neuromuscular dysfunction. Early ICU adapted rehabilitation and use of PICS preventive bundles have shown favourable effects on long time outcome and individually tailored aftercare in ICU step down and rehabilitation units has been advocated. Compared to the normal ICU setting, Covid -19 patients are cared for in a most unfavourable ICU milieu which expose them extensively to virtually all known risk factors for PICS including separation from relatives, use of heavy sedation and neuromuscular blockers in addition to the severe respiratory injury and biomedical stress.

In this paper we describe the development of the rehab program. Collection of outcome data are in progress and are not presented at this stage.

Objectives:

- To design and implement a follow up and rehabilitation program for COVID-19 patients.
- Within the program collect data on clinical outcome, PREM and PROM, later to be used to describe longitudinal outcome trajectories.

Methods: During multiple interprofessional workshops, a patient/family centred rehabilitation program was developed and instituted in clinical practice. ICU follow up clinics were used for program coordination and for data collection. The program was organized in in-hospital and outpatient components. A multi professional rehab team was formed and evaluation was done using pre set clinimetrics. A "stepdown unit" was formed where extubated ICU patients could de-escalate respiratory and residual organ support parallel with escalating physio and occupational therapy. At discharge from the stepdown unit, all patients were triaged by a specialist in rehab medicine to individual trajectories.

Results: Between 200311- 200719 a total of 143 patients were treated in the ICU. At the start of the pandemic, an already developed ICU early rehab program was expediently initiated. Thus, an early in-ICU rehab program was available at ICU admission.

The complete Rehab-program was developed during the first three weeks of the pandemic and was operational in April from when all ICU patients were discharged to the stepdown facility. The individual course of the patients is currently monitored by the rehab team at 2, 6 and 12 months scheduled Post ICU clinics. Currently, the 2-month clinics and data collection are in progress.

Conclusion: The urgent demand for post ICU rehabilitation resulting from the COVID-19 pandemic could be rapidly met by the expedient institution of a complete rehab program. This was possible due to the work of an interprofessional response team, endorsed by the hospital board, where ICU and rehab competencies collaborated. This program, catalysed by the pandemic, satisfies a long-experienced need for an organised rehab program for ICU patients.

Post Intensive Care Syndrome: Prevalence 5 years after ICU admission. A partial report

SA. Prieto Garcés¹; LC. García-Medina²; E. Noguera-Alfonso³; Y. Cardenas¹
¹Medicina crítica y cuidado intensivo, Fundación Santa Fe de Bogotá University Hospital, Bogotá, Colombia; ²Facultad de medicina, Universidad de los Andes, Bogotá, Colombia; ³Salud mental, Fundación Santa Fe de Bogotá University Hospital, Bogotá, Colombia

Correspondence: S.A. Prieto Garcés

Intensive Care Medicine Experimental 2020, **8(2)**: 001422

Introduction: Post Intensive Care Syndrome (PICS) is an entity that affects patients cognitively, physically and emotionally after being managed in the Intensive Care Unit (ICU) (1). These sequelae impact the quality of life (QOL) of ICU survivor patients and can persist after 5 years (2). The diagnosis of PICS, same as other pathologies such as Delirium, can be challenging and make it difficult to determine its exact prevalence (Rawal 2017). Given its impact on the QOL of patients, it is necessary to establish its prevalence in order to generate awareness of it and the strategies available to prevent it.

Objectives: The objective is to determine the prevalence of PICS 5 years after admission to the ICU of a Latin American Hospital in Bogotá, Colombia. Also, to characterize the patients that were admitted during that same year.

Methods: A cross-sectional, descriptive study was done. Patients 18 years old or older admitted into the ICU during 2015 were enrolled. Demographics, comorbidities, diagnostics, severity scores, ICU stay,

Hospital stay, days of vasopressor and invasive mechanical ventilation, complications and contact information were gathered. To evaluate PICS, the Post Intensive Care Syndrome Questionnaire (PICSq) was used (3). This tool is a Likert style questionnaire consisting of 18 questions that evaluate the cognitive, physical and emotional spheres (6 questions per sphere). The answers can be graded as "never-0", "sometimes-1", "often-2" and "always-3", thus, giving it a range of 0-54 points. A score of 23 or more is indicative of the development of PICS. Furthermore, A value equal to or superior to 6, 9 and 7 in the cognitive, physical and mental spheres respectively, indicate severe compromise. This tool was previously validated for Spanish language in our institution. Data gathered was analyzed using SPSS ver. 25.

Results: A total of 1434 patients were admitted to the ICU on 2015. At this moment, 119 medical charts have been reviewed. Same event mortality was 21,8%, (26/119), making our available population 93 patients. Most (63,8%) were male and mean age was 64,5 years. Average ICU stay and Hospital stay were 5,7 days and 22,2 days respectively. Vasopressors were used on 38,7% of patients with a mean duration of 2 days. Invasive mechanical ventilation was used on 25,8% of patients with a mean duration of 1,9 days. A total of 23 patients (24,7%) died along the course of the 5 years after ICU admission, 18,2% died the first year, 3,2% on the second year, 1,07% on the third year, 3,2% on the fourth year and none died on the fifth year. This left us with 70 eligible patients for applying the PICSq.

Out of the 70 eligible patients, 47 (67%) had changed contact information or were not available. The PICSq was applied to 23 patients (32,8%) and the results were as following: The average score was 10,2. Only 3 patients had scores above the cut off value of 23, giving PICS a prevalence of 13,04%. The mean score for the cognitive component was 2,56, for the physical component was 5,3 and for the mental component was 2,3. According to the cut off values, out of the 23 patients evaluated, 13,04% had severe cognitive impairment, 26% had severe physical impairment and 8,6% had severe mental compromise. Lastly, for those that did not meet the criteria for PICS, around 20% of patients suffered from severe physical compromise.

Conclusion: The partial results of this study show that PICS affects around 13% of our population, with severe physical compromise being the most common affection for both those diagnosed with PICS and those that did not meet the criteria. The process of gathering information needs to continue in order to establish the real prevalence of PICS in our population. Lastly, a better strategy to follow up patients is needed in the ICU.

Prevalence And Burden Of Hepatobiliar Injury In Pulmonary ICU Patients

E. Macit Aydın¹; Z. Çınar¹; A. Mammadova²; N. Navruzvai²; S. Kodalak²; G. Gurses³

¹Department of anaesthesiology and reanimation, division of critical care, Gazi University Faculty of Medicine, Anaesthesiologist, fellow of critical care, Ankara, Turkey; ²Department of pulmonary critical care medicine, Gazi University Faculty of Medicine, Resident of Pulmonary Diseases, Ankara, Turkey; ³Department of pulmonary critical care medicine, Gazi University Faculty of Medicine, Professor of Respiratory Medicine, Ankara, Turkey

Correspondence: E. Macit Aydın

Intensive Care Medicine Experimental 2020, **8(2)**: 001459

Introduction: Hepatobiliary injury (HBI) is very frequent in ICU patients and associated with poor outcome. Pulmonary ICU patients are vulnerable to HBI reasons like hypoxemia, pulmonary hypertension, right heart failure and frequent ICU infections and antibiotic usage. But there is limited data about HBI's prevalence, type, risk factors and impact on mortality in Pulmonary ICU patients.

Objectives: The aim of this study was to assess frequency, risk factors, types, severity and effect on outcome of HBI in critically ill patients.

Methods: A retrospective observational cohort study was performed in an University hospital pulmonary ICU and all patients who admitted last 5 years were included in the study. All potential risk factors for HBI like sepsis, hypoxia, congestion, medications and nutrition routes, were recorded from the patient files. Hepatobiliary injury and severity are defined according to the classification of the European and American guidelines for 2017 and 2019. The value of R for HBI and the type of damage (hepatocellular, cholestatic and mix) calculated according to RUCAM system. All potential risk factors were compared with univariate analysis (t test, Chi square test, Mann Whitney U test). Risk factors for HBI, mortality, length of stay in ICU were investigated with logistic regression analysis.

Results: 478 patients were included in the study and there were HBI in the 207 (43%) of them. Most frequent ICU admission reasons were, community-acquired pneumonia (21%), respiratory failure (18%) and COPD (18%). The mean age of the patients was 70 ± 15 , 55% of them were male, mean APACHE II score was 20 ± 8 , and mean SOFA score was 4 ± 3 .

HBI developed median 5 days before ICU admission in the 71% of patients and 7 days after ICU admission in the 29% of patients, during the worst period of HBI, 39% of the patients were at stage 1, 33% at stage 2, 15% at stage 3, and 14% at stage 4 HBI was reversible in 77% of the patients. According to R coefficient HBI was considered as cholestatic (54%), mixed (29%) and hepatocellular (16%) patterns. DILI was thought to be present in 42% (86) of the patients with HBI. Mortality was higher in HBI group also (39% vs 6%).

Risk factors for HBI as (OR (95% CI), p) were TPN: 2.3 (1.3-4), p: 0.004, enteral nutrition: 2.3 (1.5-3.7), p: 0.0001, APACHE II score on admission: 1.1 (1.06-1.14), p: 0.001, use of clarithromycin: 2.3 (1.2-4.4), p: 0.01, and immunosuppression: 2.6 (1.1-6.3), p: 0.032. HBI increased mortality risk four-fold in this study population (3.9(2-8), p:0.001). and was not risk factor for the increased length of ICU stay more than ten days. Liver function results of patients with hepatobiliary injuries are given in the table.

Table. Laboratory results of patients with Hepatobiliary injury

AST HBI _{max} *	406±1165
ALT HBI _{max} *	251±747
GGT HBI _{max} *	141±222 (n:179)
ALP HBI _{max} *	208±308 (n:198)
LDH HBI _{max} *	1426±3547 (n:73)
Total bilirubin HBI _{max} *	1.5±2.5 (n:200)
Direct bilirubin HBI _{max} *	0.8±1.7 (n:203)
HBI:Hepatobiliary injury. AST: Aspartate aminotransferase. ALT:Alanine aminotransferase. GGT:Gamma glutamyl transferase. ALP:Alkaline phosphatase. LDH:Lactate dehydrogenase	
*Means±SD	

Conclusion: In this study population, 43% of the patients developed mostly cholestatic type HBI, despite many of them had mild-moderate stage and reversible disease it was an independent risk factor for ICU mortality.

Intensive Care Medicine Experimental 2020, **8**(2): 001500

Introduction: Acute mesenteric ischemia (AMI) is a life-threatening disease. In 2016, the first French national intestinal stroke center was set up (SURVI, Beaujon and Bichat Hospitals, AP-HP, France); it is based on a multidisciplinary and multimodal management of life- and gut-saving strategy, focusing on intestinal viability that is achieved through (1) early AMI recognition, (2) urgent medical protocol, and (3) digestive revascularization and necrotic bowel resection if required.

Objectives: Our objectives were to describe the prognosis in the intensive care unit (ICU) of patients with AMI admitted in the intestinal stroke center, and to analyze factors associated with ICU mortality.

Methods: An observational retrospective analysis of a prospective database was conducted from February 2016 to December 2018, which consecutively included all patients with AMI admitted in ICU in the intestinal stroke center. Collected data were patients' demographic characteristics, past medical history, mechanisms of AMI, intra-operative findings and ICU hospitalization. Data are presented as median [IQR] or number (percentage). Univariate analyses of factors associated with ICU mortality were performed using Chi-squared tests and Mann-Whitney U tests. Multivariate exact logistic regression was performed on clinical relevant factors that were significantly associated with ICU mortality in univariate analyses (p < 0.05). Statistical significance was considered for p-value < 0.05.

Results: Seventy patients (age 65 [54-76] years, 61% of male, SOFA 4 [2-6], SAPS II 42 [30-53]) were admitted to ICU with AMI, mainly due to superior mesenteric artery occlusion (87%). Sixty patients (91%) underwent initial urgent laparotomy. Bowel resection was performed in 32 patients (50%), and 7 patients (10%) had extensive bowel necrosis beyond therapeutic possibilities. Forty-one patients (64%) had endovascular (n = 17) or open (n = 24) initial revascularization of the ischemic gut. Thirty patients (43%) required one or more revision surgeries.

Median ICU length of stay and duration of mechanical ventilation were 6 [2-14] days and 2 [0-5] days respectively. Forty-seven patients (67%) had acute kidney injury. On ICU discharge, 20 patients (29%) had short bowel syndrome and 44 patients (63%) required exclusive parenteral nutrition.

Seventeen patients (24%) died in ICU. Factors associated with ICU mortality in univariate analysis were age ≥ 80 years old, chronic hypertension, signs of hepatic infarction on CT scan, SAPS II on admission, delta SOFA score between admission and day 1 > 0, duration of mechanical ventilation and acute kidney injury.

Delta SOFA score > 0 (OR 9.0, 95%CI [1.8-69.5]) and chronic hypertension (OR 7.7, 95%CI [1.8-42.4]) were independently associated with ICU mortality in multivariate analysis.

Conclusion: We describe for the first time the prognosis of critically ill patients with AMI in an intestinal stroke center in France. The 24% ICU mortality rate suggests that intestinal stroke center might improve the outcomes of ICU patients with AMI.

Intensive Care Medicine Experimental 2020, **8(2)**: 001505

Introduction: Critically-ill patients with COVID-19 have been proposed to have poor prognosis.

Objectives: To evaluate baseline characteristics and outcomes of patients with COVID-19 requiring ICU admission in Turkish ICUs.

Methods: Critically-ill patients admitted to 26 ICUs from 23 Hospitals in Turkey from 10 March to 11 June 2020 were evaluated in this descriptive observational study. Results are presented as median (IQR) and counts (%).

Results: A total of 426 confirmed COVID-19 patients were included. The median age of the population was 67 (57-76) years. There were 254 (59.6%) male and 172 (40.4%) female patients. The most frequent comorbidity was hypertension 217 (50.9%), followed by diabetes mellitus 131 (30.8%), cardiac diseases 107 (25.1%), chronic respiratory diseases 82 (19.2%), cancer 46 (10.8%) and chronic renal failure 16 (3.8%). Duration from start of symptoms till ICU admission was 6 (4-10) days. Admission APACHE II score was 17 (12-25) and SOFA score was 4 (3-7). Admission PaO₂/FiO₂ was 148 (102-206) and SpO₂/FiO₂ 196 (147-240). Admission lymphocyte count was 860 (560-1240) per mm³, CRP was 109.3 (57.7-188.5) mg/L, D-Dimer was 1120 (547-2970) ng/mL and ferritin was 491 (197-958) ng/mL. Invasive mechanical ventilation was applied in 231 (54.2%) patients and vasopressors in 163 (37.3%) patients. Hydroxychloroquine was used in 304 (71.4%), antibacterial treatment in 205 (48.1%), azitromycin in 196 (46.0%), favipiravir in 162 (38.0%), oseltamivir in 158 (37.1%), convalescent plasma in 51 (12.0%), tocilizumab in 41 (9.6%), corticosteroids in 30 (7.0%), intravenous immunoglobulin in 10 (3.3%), lopinavir/ritonavir 9 (2.1%), cytokine/endotoxin removal 9 (2.1%), plasma exchange in 5 (1.2%) patients. ICU length of stay was 7 (3-14) and ICU mortality was 215 (50.5%).

Conclusion: Multi-center study from Turkish ICUs revealed that more than half of critically-ill COVID-19 patients were older than 65 years of age, invasive mechanical ventilation was applied in more than half of patients and ICU mortality rate was high.

Intensive care support in cancer patients: a retrospective study in an oncological center

M. Leitão¹; T. Vieira²; B. Pereira³; F. Faria⁴

¹Oncologia Médica, Instituto Português de Oncologia do Porto, Porto, Portugal; ²Intensive care, São João University Hospital Center, Porto, Portugal; ³Intensive care, Ipo, Porto, Portugal; ⁴Intensive care, Instituto Português de Oncologia do Porto Francisco Gentil, Porto, Portugal

Intensive Care Medicine Experimental 2020, **8(2)**: 001540

Introduction: Cancer is the second global cause of death and incidence is increasing. Mortality of ICU cancer patients has dropped, yet prognostication and patient selection remain to be adjusted. The severity of acute illness could be more important to predict short-term survival than the underlying type or stage of cancer.

Objectives: To determine the outcome of patients with solid tumors in ICU, the usefulness of SAPS 2 and APACHE II as prognostic tools and identify poor outcome factors in the oncologic population.

Methods: We enrolled patients with solid malignancies in active systemic treatment admitted in an oncologic intensive care unit due to medical complications in a 3-year period. Clinical data were collected retrospectively.

Results: In our sample (n=57), gastrointestinal cancers were the most frequent (14, 25%) followed by lung and breast (9 each, 16%). The cancer was stage IV in 36 patients (64%), 78% received chemotherapy in the 30 days prior and half was of palliative intent; 6 patients had received immunotherapy. Infection, acute respiratory failure and hematological disturbances were the most common problems at admission (75%, 77% and 82%), 39% of cases were classified as multi-organic dysfunction. Major ICU interventions included invasive mechanical ventilation (53%) and vasopressor support (40%). ICU and hospital mortality were 25% and 44%. Six month mortality was 60%. Stage IV cancer, ECOG performance status, hematologic disturbances and infection were not independently related to higher mortality. APACHE II and SAPS2 scores showed a positive correlation with mortality in the ICU. APACHE II and SAPS2 score distributions showed statistically significant relation to mortality (p=0.017).

Conclusion: Stage IV cancer was not an independent risk factor for acute mortality, confirming the results of other published works. Most of the patients that survived the hospital stay were alive in 6 months. APACHE II and SAPS2 are often used in cancer patients, although they were never validated in this population. In our work, these scores reasonably predict ICU mortality, but were far from perfect tests.

Conclusion: Patients receiving systemic treatment for cancer should be considered for ICU admission like other severely ill patients without cancer. Larger prospective studies are needed to understand prognostic factors and refine predictive scores in this special population. Individual evaluation of patient characteristics, oncological disease and treatment response are essential. Dialogue between oncologists and intensive care specialists is paramount in the decision making process of this population.

Brachial plexopathy secondary to prone positioning, an aetiology to consider during the COVID-19 pandemic

A. Truelove¹; A. Baldwin²; R. Shirley³; T. Ali⁴

¹Critical Care Medicine, Stoke Mandeville Hospital, Aylesbury, United Kingdom; ²Intensive care, Stoke Mandeville Hospital, Aylesbury, United Kingdom; ³Plastic surgery, Stoke Mandeville Hospital, Aylesbury, United Kingdom; ⁴Intensive care department, Stoke Mandeville Hospital, Aylesbury, United Kingdom

Correspondence: A. Truelove

Intensive Care Medicine Experimental 2020, **8(2)**: 001544

Introduction: With the ongoing Coronavirus disease 2019 (COVID-19) pandemic, increased numbers of patients are being admitted to intensive care units (ICU) worldwide. Many guidelines recommend early utilisation of the prone position ('proning') following intubation in this patient population, owing to the evidence that this position improves

lung mechanics and gas exchange.¹ The increased utilisation of proning in patients where sedation and muscle relaxants have been used creates the hypothetical risk of precipitating brachial plexus injuries, for which the terms 'Prone Position Plexopathy' has been coined.² The objective of this paper is to report a case and a review of the relevant literature.

A 36 year old gentleman presented to the emergency department with an 8 day history of progressive shortness of breath. His past medical history was limited to a high body mass index (BMI) and a previous traumatic brain injury (TBI) in 2002. He was found to be significantly hypoxic despite maximal oxygen therapy, and was brought to the critical care unit for ventilation and proning directly. He initially improved with airway pressure release ventilation (APRV) and frequent proning; however, he developed a ventilator-associated pneumonia (VAP) and deteriorated, and was transferred for veno-venous ECMO (VV-ECMO). On his return, he was noted to have new right upper limb weakness despite a computed tomography (CT) scan of his head showing no new signs; on examination he was unable to abduct his right shoulder and he had MRC grade 2 of the right Bicep, with generalised bilateral weakness. On nerve conduction studies and electromyography of his right upper limb several weeks after a successful discharge, he was found to have an underlying moderately severe lesion of the upper trunk of the right brachial plexus from which the large majority of nerve fibres to the right suprascapular, musculocutaneous and axillary nerves are derived, with relative sparing of the right middle and lower trunks, and posterior and medial cords, confirming the neurological findings.

Methods: A systematic literature search was conducted on PubMed using the search strategy: ("prone position*") AND ("brachial plexus injur*" OR "brachial plexopathy" OR "nerve injury"), which identified 34 articles that were subsequently screened. The resulting seven full-text articles were assessed for eligibility. Five studies, of which three were case reports and two were case series, were included.³⁻⁷

Results: Twenty-one cases of brachial plexopathy, or impending brachial plexopathy, secondary to proning were identified. The most common reason for proning was for spinal surgery (n = 18). This was followed by thoracoscopic oesophagectomy (n = 1), debridement of necrotising fasciitis (n = 1) and, indeed, the use of prone positioning in a patient with ARDS in an intensive care unit setting (n = 1). Only one case within the dataset underwent proning as it is described in the use for patients with ARDS secondary to COVID-19, and this was the patient who was prone for up to 12 hours a day in ICU as part of the management of ARDS. All of the plexopathies identified had almost entirely resolved within ten months, with two patients experiencing residual sensory deficits.³⁻⁷

Conclusion: injury secondary to proning during the COVID-19 pandemic, and the second case in an ICU patient prone for the management of ARDS. Brachial plexopathy is a pathology to consider in patients who have undergone proning in an ICU environment as part of their treatment of ARDS secondary to COVID-19 who show signs of focal neurological deficits of the upper limb upon removal of paralysis and sedation; and as the COVID-19 pandemic continues, adaptations such as modifying SSKIN (a five step model for pressure ulcer prevention) during proning and using scoring systems in critical care follow up will be needed to improve outcomes.

Intensive Care Medicine Experimental 2020, **8(2)**: 001645

Introduction: Novel Coronavirus (SARS-Coronavirus-2: SARS-CoV-2) or Coronavirus Disease 19 (COVID-19) emerged in Wuhan, China in December 2019 and it was declared a global pandemic in March 2020.

Objectives: To describe the epidemiological characteristics and clinical manifestations of patients with COVID-19 in South-East London Region.

Methods: A single centre retrospective observational study was completed comprising patients with laboratory confirmed diagnosis of Covid-19 in a period between 12th March and 3rd April. Data was collected on patient characteristics, clinical manifestations, laboratory results, radiology findings and management in Intensive Care Unit (ICU). Moreover, described some of the complications that were noted in the COVID-19 cohort.

Results: 57 patients (68% male) were followed up for 23 days. The most common co-morbidities were hypertension (54%), obesity (53%) and type 2 diabetes (32%). The most common clinical manifestations were shortness of breath (88%), fever (88%) and cough (84%), which was initially noted 8 days prior to ICU admission. The typical radiology findings seen in COVID-19 patients were bilateral infiltrates on chest X-ray. Laboratory findings that were common in majority of patients were lymphopenia with raised white cell count, raised C-reactive protein and raised ferritin. 21% of the patients required renal replacement therapy due to acute kidney injury. Invasive mechanical ventilation (IMV) was required by 93% of the cohort; however, initially the unit did not try non-invasive ventilation for COVID-19 patients. PaO₂/FiO₂ ratio illustrated appropriately the biochemical picture of acute respiratory distress syndrome. At the end of the follow-up period for this study, 35% had died, 28% had been discharged from hospital, 9% was stepped down to the ward from ICU and 28% remained in ICU. The average ICU stays in this cohort was 15 days. Mortality was correlated with age, PaO₂/FiO₂ ratio, ventilator settings, peak ferritin and neutrophil count over the first 72 hours of IMV.

Some of the complications that were seen in this cohort: eight patients developed pneumomediastinum, surgical emphysema and pneumothoraces, one patient had a ST-elevation myocardial infarction requiring PCI and one had a micro-haemorrhage/subarachnoid haemorrhage (8 mm) and one patient developed posterior reversible encephalopathy syndrome (PRES).

Conclusion: This retrospective observational study described the clinical characteristics and outcomes of a South-East London cohort. It described few of the complications that were seen in this cohort, which could be co-related to COVID-19. Moreover, it reports factors that are correlated with mortality for patients with COVID-19.

001293**Fluid management in acute burn injuries**

Intensive Care Medicine Experimental 2020, **8(2)**: 001293

Introduction: In severely burnt patients, it is important to focus on fluid resuscitation, not just pain relief, because a burnt patient loses a big amount of fluid.

Objectives: Our study's purpose is to find out how much fluid did these patients get during the prehospital care.

Methods: We included those patients who suffered an at least 20% second, third degree burn, and their fluid resuscitation started in the prehospital phase. We did our study with document analysis. We checked the documents from 2008.01.01. to 2018.12.31. With the help of including and excluding criteria we could include 104 people (n=104). For data analysis we used Microsoft Word and Excel 2016 and SPSS version 25.0. For statistical tests, we used correlation, Chi-square test and independent T-test.

Results: In this study there were 70 male (67,3%) and 34 female (32,7%) patients. The average age was 56,59 years. Patients suffered an average 31,90% burn. In the prehospital care these people got averagely 1315,84 ml fluid. The 32,7% of the patients died during hospital care. We found that TBSA (total burn surface area) correlate significantly with surviving (p < 0,01). Surviving also correlate with almost every complications significantly (p < 0,001). We also found that Evans formula is more sensitive than Parkland formula, and there is a significant difference between real fluid resuscitation and recommended fluid resuscitation by the formulas (p < 0,001). We confirmed that Parkland formula decreases occurrence of complications. It was also clear that patients got more than twice as many fluid prehospitally than Parkland formula would provided.

Conclusion: Evans formula is more sensitive and it would drive patients fluid management better, but in prehospital care it is impracticable due to lack of equipment. There is more chance of complications if the patients got not the right amount fluid what they're needed. Finally patients got more than twice as many fluid as it was recommended by Parkland formula in the guideline, so it is clear the prehospital medical providers didn't work as the guideline would recommend.

001407**Validity of APACHE II and SAPS II scores as predictors of early global mortality at 3 months from sepsis**

M.J. Palavras¹; C. Faria¹; M. Cabral²; F. Santos¹; J. Gonçalves¹; A. Araújo³; L. Pereira³

¹Department of internal medicine, Centro Hospitalar de Leiria (CHL), Hospital de Santo André (HSA), Leiria, Portugal; ²Department of cardiology, Centro Hospitalar de Leiria (CHL), Hospital de Santo André (HSA), Leiria, Portugal; ³Intensive care unit, Centro Hospitalar de Leiria (CHL), Hospital de Santo André (HSA), Leiria, Portugal

Correspondence: M.J. Palavras

Intensive Care Medicine Experimental 2020, **8(2)**: 001407

Introduction: APACHE (Acute Physiology and Chronic Health Evaluation) II and SAPS (Simplified Acute Physiology Score) II have become a necessary tool to describe ICU (intensive care unit) populations and to predict differences in mortality. Both are calculated in the first 24 hours of hospitalization, in which higher levels correspond to more serious diseases and a higher risk of death. Sepsis is a major cause of morbidity in ICU, it is estimated that about half of the patients have a nosocomial infection and are, therefore, at a higher risk of death.

Objectives: The aim of this study was to determine the comparative efficacy of different scoring system (APACHE II and SAPS II scores) in assessing the prognosis of critically ill patients that were admitted to the ICU by sepsis in a tertiary hospital and compare them for

prediction of the outcome in these patients in early mortality (up to 3 months).

Methods: We performed a retrospective review of five hundred and thirty three patients that were admitted to the ICU from January 2018 to December 2019. We included all patients (medical or surgical patients) over the age 16 years old, and we selected those with the first diagnosis of "sepsis". Patient selection and information collection were obtained through medical records. It was calculated the predictive mortality by APACHE II and SAPS II and also the early mortality.

Group comparisons between survivors and non-survivors from sepsis were performed using the Student-T test for continuous variables and Pearson chi-square test for categorical variables. A p-value less than 0.05 was considered significant. Statistical analysis was performed using SPSS software version 25.0 (IBM, Armonk, NY, USA).

Results: Out of 533 patients, 71 had sepsis (13%). Of these 71 patients, 36 (50,7%) died up to 3 months. Average APACHE II and SAPS II scores in all patients were 23,5 ± 8,1 (p=0,02) and 52,9 ± 17,7 (p<0,01) respectively, and they were significantly different between survivors and non-survivors. A statistically significant positive correlation was established between the values of SAPS II and APACHE II (r=0.76; p<0.01). By the examination of validity and classification accuracy by ROC curve, we conclude that: SAPS II had AUC > 0,662 and APACHE II had AUC > 0,639. Both can predict the risk of mortality in these patients, but SAPS II seems to be slightly more accurate. We also observed that elderly patients were expected to have a worse prognosis. The average age of survivors was 64,5 ± 13,8 years and for non-survivors 75,2 ± 8,8 years (p < 0,01).

Conclusion: Both APACHE and SAPS II were accurate tools to describe and predicted mortality caused by sepsis. There was no significant difference in the clinical values of SAPS II and APACHE II and taking in consideration the high correlation between both, only one, could be enough to make a mortality prediction.

001463**Validity of APACHE II or SAPS II as predictors of the hospital length of stay in multi-trauma patients: the analysis of a Portuguese ICU in a tertiary hospital**

C. Faria¹; M.J. Palavras¹; M. Cabral²; F. Santos¹; J. Gonçalves¹; A. Araújo³; L. Pereira³

¹Department of internal medicine, Centro Hospitalar de Leiria (CHL), Hospital Santo André (HSA), Leiria, Portugal; ²Department of cardiology, Centro Hospitalar de Leiria (CHL), Hospital Santo André (HSA), Leiria, Portugal; ³Intensive care unit, Centro Hospitalar de Leiria (CHL), Hospital de Santo André (HSA), Leiria, Portugal

Correspondence: C. Faria

Intensive Care Medicine Experimental 2020, **8(2)**: 001463

Introduction: APACHE (Acute Physiology and Chronic Health Evaluation) II and SAPS (Simplified Acute Physiology Score) II are the two

main tools to evaluate patients in an intensive care unit (ICU), 24 hours after admission, regarding the predictable intrahospital rate of death. In multi-trauma patients, previous reviews showed that SAPS II was valid to predict intrahospital death in these patients when compared to APACHE II. However, the correlation of these scores with the hospital length of stay was not demonstrated.

Objectives: The aim of this study was to verify if there is a correlation between the main score systems used in a Portuguese tertiary hospital ICU and the hospital length of stay (LOS) in multi-trauma patients.

Methods: This retrospective review evaluated the admitted patients in an ICU during two years, from January 2018 to December 2019, through the consultation of clinical records, calculated predictive mortality by APACHE II and SAPS II, as well as the hospital length of stay, including the time spent in ICU. We obtained a population of 533 patients from which we selected the ones admitted with "multi-trauma" as first diagnosis.

Group comparisons between both scores and LOS were performed using the Pearson correlation. A linear regression model was applied. A p-value less than 0.05 was considered statistically significant. Statistical analysis was performed using SPSS software version 25.0 (IBM, Armonk, NY, USA).

Results: Out of 533 patients, 27 had multi-trauma (5.06%). These 27 patients were 53.6 ± 18.1 years old, from which 6 (22.2%) were female and 21 (77.8%) were male. The hospital LOS was 47.2 ± 24.3 days. Average APACHE II and SAPS II scores were 13.9 ± 6.0 and 33.0 ± 12.7 , respectively. Pearson correlation showed us that there is a correlation between SAPS II and LOS ($p=0.021$) that was not verified to APACHE II ($p=0.188$). Therefore, it was possible to apply a simple linear regression model correlating the SAPS II and the hospital LOS which concluded that each unity added to SAPS II represented an increase of 0.42 days to the LOS. This linear regression model explains the LOS variation by 6% ($p=0.028$).

Conclusion: A correlation between SAPS II and the hospital length of stay was verified with a statistic significance that was not verified with APACHE II. It is possible to assume that the calculation of SAPS II in multi-trauma patients could predict the approximated hospital length of stay, which is a remarkable predictor to clinicians to established the plan for these patients. Further studies on this topic are needed to confirm the association between SAPS II and the hospital length of stay.

The value of APACHE II and SAPS II as predictors of intrahospital mortality in critical patients with Acute Kidney Injury

J. Gonçalves¹; S. Flavia¹; M. Cabral²; C. Faria¹; MJ. Palavras¹; O. Gomes³; L. Pereira³

¹Department of internal medicine, Centro Hospitalar de Leiria (CHL), Hospital Santo André (HSA), Leiria, Portugal; ²Cardiologia, Hospital Santo André - Hospital Distrital De Leiria, Leiria, Portugal; ³Serviço de medicina intensiva, Centro Hospitalar de Leiria, Leiria, Portugal

Correspondence: J. Gonçalves

Intensive Care Medicine Experimental 2020, **8(2)**: 001522

Introduction: APACHE (Acute Physiology and Chronic Health Evaluation) II and SAPS (Simplified Acute Physiology Score) II are commonly used scoring systems to calculate the severity of illness in intensive

care patients. Both are calculated in the first 24 hours of hospitalization and can predict the risk of intrahospital mortality. Acute Kidney Injury (AKI) is frequent and has high morbidity and mortality rates, which determines an enormous importance in the context of ICU (Intensive Care Unit).

Objectives: The aim of this study is to investigate the capacity of main score systems to predict intrahospital mortality of patients with AKI, in a Portuguese tertiary hospital ICU.

Methods: We performed a retrospective review that evaluated the admitted patients in an ICU during two years, from January 2018 to December 2019, through the consultation of clinical records and calculated predictive mortality by APACHE II and SAPS II. From the 535 patients included, those with AKI at admission were selected, regardless of the main diagnosis, according to Acute Kidney Injury classification (AKIN).

Group comparisons between survivors and non-survivors from AKI were performed using the Student-T test for continuous variables and Pearson chi-square test for categorical variables. A p-value less than 0.05 was considered significant. Statistical analysis was performed using SPSS software version 25.0 (IBM, Armonk, NY, USA).

Results: Out of 535 patients, 272 patients (50.8%) had AKI and 263 patients (49.4%) had not. The mortality rate was 37.9% and 21.7%, respectively, with significant difference between them ($p<0.01$). Patients with AKI were mainly males (57%). There is no difference between the mortality rate and gender ($p=0.06$). Out of 272 patients with AKI, 169 survived (62.1%) and 103 died (37.9%). The average age of survivors was 68.93 ± 14.59 years and of non-survivors group was 74.14 ± 11.82 years. The mean SAPS II score in the survivors group was 53.60 ± 19.24 while in the non-survivors group was 68.08 ± 19.83 ($p<0.01$). The mean APACHE II score was 25.11 ± 9.36 and 30.98 ± 8.84 , respectively ($p<0.01$). Concerning creatinine and urea levels in both groups of patients, there was no difference neither in mean creatinine levels ($p=0.72$) neither in mean urea levels ($p=0.34$). APACHE II and SAPS II are valid predictors of intrahospital mortality in critical patients with Acute Kidney Injury at admission. Furthermore, non-survivor patients showed a higher age mean than survivors, as expected. Despite our assumptions, the main renal function analytical parameters showed no influence in the outcome of the patients with Acute Renal Injury.

Conclusion: APACHE II and SAPS II are valid predictors of intrahospital mortality in critical patients with Acute Kidney Injury at admission. Furthermore, non-survivor patients showed a higher age mean than survivors, as expected. Despite our assumptions, the main renal function analytical parameters showed no influence in the outcome of the patients with Acute Renal Injury.

01524 Comparison of 3 risk prediction scores for Covid-19 in a UK hospital

A. Garg¹; F. Wyn-Griffiths¹; S. Hiou¹; F. Hossain²

¹Anaesthetics, Walsall Manor Hospital, Birmingham, United Kingdom; ²R&D, Walsall Manor Hospital, Birmingham, United Kingdom

Correspondence: A. Garg

Intensive Care Medicine Experimental 2020, **8(2)**: 001524

Introduction: As the Covid-19 pandemic has spread around the world, several new scores have been released to predict risk of critical illness or mortality among Covid-19 patients. None of these scores have been validated in the UK population.

Objectives: We attempted to compare 3 scores – COVID-GRAM [1], HNC-LL [2] and CURB-65 scoring systems in assessing accuracy for predicting critical illness or in-patient mortality among Covid-19 patients at our institution.

Methods: We collected data on 429 patients with RT-PCR confirmed Covid-19 infection identified from the local ISARIC CCP and hospital databases, admitted during March and April 2020. Our endpoints were 1). Critical illness defined as Deaths and/or ICU admission 2). In-patient mortality.

Results: The incidence of inpatient mortality and progression to critical illness in our cohort was 32.1% and 38.7% respectively. COVID-GRAM tool showed the highest accuracy in predicting critical illness (AUC 0.647; 95% CI 0.600 to 0.692) and inpatient mortality (AUC 0.695; 95% CI 0.649 to 0.739). There was no significant difference in accuracy of AUC between CURB-65 and COVID-GRAM ($p=0.9074$) for inpatient mortality but both were better than HNCLL. ($p=0.0415$ and 0.0112). HNCLL showed lowest accuracy in predicting both the endpoints of interest.

Conclusion: While COVID-GRAM was most accurate in predicting critical illness and inpatient mortality from COVID 19, it was only marginally higher than CURB65. We recommend the continued use of CURB 65 as convenient and easy to use tool in predicting complications and mortality from COVID 19.

Acceptability of Non-Invasive Eye Tracking in Intensive Care Unit: A Cross MDT Questionnaire

A. Al-Hindawi¹; F. El-Hibri¹; M. Vizcaychipi¹

¹Intensive care unit, Chelsea and Westminster Hospital, London, United Kingdom

Correspondence: A. Al-Hindawi

Intensive Care Medicine Experimental 2020, **8(2)**: 001239

Introduction: Eye tracking has a long history in diagnosis of neuropsychiatric and neurodevelopmental disorders, specifically in schizophrenia and autism [1]–[4]. It has recently been advocated for as a method for inferring attention as a surrogate marker of delirium but has been hampered due to lack of technological solutions available for the Intensive Care Unit (ICU) environment [5]. To that extent, we have developed a non-invasive, end of the bed, eye tracker that automatically tracks the eye movements and the gaze of a patient without instrumentation or calibration. We sought to understand the acceptability of this new monitoring method from the multidisciplinary team across a single centre prior to deployment in a clinical feasibility trial.

Objectives: To ascertain the:

1. Practical issue with current delirium assessment methods.
2. Acceptability of automating delirium detection.
3. Acceptability of non-invasive eye tracking in intensive care.

Methods: A Google Form of qualitative and quantitative questions was made ascertaining the views of delirium assessment and the views on the automation of delirium detection. A picture of the system as setup in an ICU bed-space was then shown with an explanation of its function (Figure 1). Open questions were asked about their opinion prior to closed questions of specific interest.

R version 4.0.1 was used for analysis.

Results: A wide range of MDT roles were gathered ($n=29$, 65% nurses, 21% doctor, 3% dietician, 3% pharmacist, 3% critical care technologist, 3% patient care coordinator). Nurses found that current delirium assessment methods were laborious, often confusing to perform and are only formalising their intuition but welcomed automation (82%). The majority (92%) of responders welcomed the use of eye tracking as a method of delirium detection. The majority thought that the setup would not interfere with their day to day clinical activities with the patient (75%), their families (80%), and other members of the MDT (98%). Qualitatively, a theme of avoiding “clutter” around the bed-space was highlighted. The end of the bed camera marker (a 10x10cm plastic code) was highlighted as a potential point of delirium ‘generation’. Of interest, the theme of privacy and was not highlighted.

Conclusion: Non-invasive eye tracking as a method of delirium assessment is generally well accepted in AICU across the MDT. Specific care is to be taken to avoid adding further clutter around an already busy AICU bed-space.

APACHE II and SAPS II as death predictors in intensive care surgical patients

F. Santos¹; M. Cabral²; J. Gonçalves³; C. Faria³; M.J. Palavras¹; N. Ferreira⁴; L. Pereira⁴

¹Department of internal medicine, Centro Hospitalar de Leiria (CHL), Hospital Santo André (HSA), Leiria, Portugal; ²Department of cardiology, Centro Hospitalar de Leiria (CHL), Hospital Santo André (HSA), Leiria, Portugal; ³Department of internal medicine, Centro Hospitalar de Leiria (CHL), Hospital de Santo André (HSA), Leiria, Portugal; ⁴Department of intensive care, Centro Hospitalar de Leiria (CHL), Hospital Santo André (HSA), Leiria, Portugal

Correspondence: F. Santos

Intensive Care Medicine Experimental 2020, **8(2)**: 001515

Introduction: Intensive Care Unit (ICU) delivers care through a multidisciplinary approach. In order to predict the probability of death we have some severity indices to use, such as Acute Physiology and Chronic Health Evaluation II (APACHE II) and Simplified Acute Physiology Score (SAPS II). They were initially designed for sepsis patients, but nowadays they are used as mortality predictors in ICU patients of all etiologies.

Objectives: The aim of the study was to analyze if APACHE II and SAPS II are feasible scores to predict mortality in surgical patients admitted to ICU, given that both were not originally designed for these kind of patients.

Methods: The authors designed a retrospective study, considering all the patients admitted to the ICU during a two year period (from January 2018 until December 2019). The APACHE II and SAPS II scores were analyzed in order to understand in which cases these scores are more accurate. All the patients over 16 years old were included. The patients admitted for a period inferior to 24 hours were excluded.

The statistical analysis was made using SPSS software version 205.0. T-student test was used to compare survivals and non survivals patients in different time-lines and ROC curve to understand the validity of the scores in surgical patients.

Results: We analyzed 533 patients, 155 of them admitted in ICU as surgical patients. 74 women and 81 men, with median age of 68.6 (± 17.1). With an APACHE II mean of 18.9 (± 9.3) and SAPS II mean 45.6 (± 20.1). 113 were survivors and 42 were non-survivors, (mortality rate of 27%). The survivors presented APACHE II score mean of 16 and a SAPS II mean score of 40 ($p < 0.01$). The non-survivors presented a mean APACHE II score of 25 and a mean SAPS II score of 61 ($p < 0.01$). ROC curves showed that both scores were good predictors of mortality in ICU, showing a AUC 0.782 for APACHE II ($p < 0.01$) and 0.782 ($p < 0.01$) for SAPS II. Between the non-survivors ($n = 42$), 69% ($n = 29$) died at the ICU admission and 12% ($n = 5$) during hospital admission after ICU discharge. 19% ($n = 8$) died at home before 3 months after ICU discharge.

For predicting mortality during hospital admission after ICU discharge, mean APACHE II score of 21.4 (± 12) ($p = 0.14$) and mean SAPS II of 57.6 (± 17.5) ($p > 0.01$) for APACHE II and SAPS II did not show feasible results to predict mortality at home during 3 months after ICU discharge ($p = 0.64$ for APACHE II and $p = 0.16$ for SAPS II).

The patients were divided on scheduled surgical ones ($n = 40$) and non-scheduled surgical patients ($n = 115$). In scheduled surgical patients the mortality rate was 12.5% ($n = 5$), with APACHE II and SAPS II scores predicting death in these patients showing no accuracy at all ($p = 0.07$ and $p = 0.54$, respectively). In the non-scheduled surgical patients the mortality rate was 32% ($n = 37$); in this patients both scores showed to be good mortality predictors in this group (APACHE II with $p < 0.01$, SAPS II with $p < 0.01$).

Conclusion: The results showed that APACHE II and SAPS II are both good mortality predictors scores in surgical patients admitted in ICU. SAPS II was better in predicting mortality during hospital admission after ICU discharge than APACHE II.

Both showed valid results to predict death during ICU admission and early death (< 3 months).

Both showed accurate results to predict mortality in non-scheduled surgical patients but not on scheduled surgical ones.

Intensive Care Medicine Experimental 2020, **8(2)**: 001186

Introduction: Young trauma patients undergo repeat radiologic imaging during initial trauma evaluation and ICU stay through high radiation exposure of these patients is suspected studies are scarce. In this regard we retrospectively calculated ionizing radiation exposure of young ICU trauma patients due to medical imaging.

Methods: We reviewed records of < 40 year old ICU trauma patients with lengths of stay (LOS) > 20 days treated within the past 18 months. All imaging studies involving ionizing radiation were recorded. A Typical Effective Dose (TED) per type of study was assumed based on the literature. TED's incurred by plain radiographs (XR), computed tomographic (CT) scans and fluoroscopic studies (FL) were added to calculate a Cumulative Effective Dose (CED) per patient. CED's were compared to established limits of annual radiation exposure. The total medical radiation detriment was calculated using the formula $0.073 \times \text{CED} / \text{Sv}$. Numbers given represent mean \pm sem.

Results: 36 patients (male:34 mean age 26.8 ± 1.1 years; mean LOS 48.6 ± 7.7 days; mean Injury Severity Score ISS: 32.7 ± 1.7) underwent 1311 XRs (36.4 ± 2.7 /patient), 248 CT-scans (6.9 ± 0.5 /patient), and 25 FL's (0.8 ± 0.2 /patient; 1 limb angiography, 23 fluoroscopy guided bone fixation procedures, 1 diaphragm fluoroscopy). The mean CED/patient was 40.5 ± 2.8 mSv. Partial CED's attributable to XR, CT and FL were 2.5 ± 0.3 , 37.3 ± 2.8 and 0.81 ± 0.15 mSv/patient or $8 \pm 2\%$, $89 \pm 3\%$ and 3% of total CED respectively. The mean detriment due to medical exposure to ionizing radiation in our study was 0.00296 ± 0.0002 .

Conclusion: The mean CED exceeded international and national (environmental: 1 mSv occupational: 20 mSv) annual radiation exposure limits. CT scans accounted for the bulk of CED. Studies designed to investigate the short-term benefits vs long-term sequelae of X-ray

imaging studies performed in ICU patient are needed especially individuals at child-bearing ages with long life-expectancies.

Current views and understanding in an anaesthetic department surrounding power injection of intravenous contrast via central venous catheters for CT

E. Caine¹; D. Horner¹

¹Anaesthetics, Charing Cross Hospital, London, United Kingdom

Correspondence: E. Caine

Intensive Care Medicine Experimental 2020, **8(2)**: 001288

Introduction: During the COVID 19 pandemic, the anaesthetic team was often involved in the transfer of patients from intensive care (ICU) to computerized tomography (CT). With the associated thromboembolic events in COVID patients, often these scans were CT pulmonary angiograms (CTPAs) and therefore required higher intravenous (IV) contrast flows. Often these patients had been on ICU for a long period of time, had no peripheral access and only a central venous catheter (CVC) line in situ. We came across a huge variation in clinical practice with CVC lines being used for power injecting contrast. Some radiographers would not allow the CVC line to be used and asked for a peripheral cannula to be inserted. Others were happy for the CVC line to be used, as long as the accompanying doctor connected the power injector to the CVC line took responsibility for it. This variety in practice led us to research current understanding and experience with injecting IV contrast down a CVC line via a power injector and to review the literature and guidance surrounding it. We then ran a teaching session for the anaesthetic department and reassessed these views after this session.

Objectives: 1. To find out current understanding and experience in the radiology and anaesthetic department surrounding power injecting IV contrast down a CVC line.

2. If required, to run a teaching session to help develop an understanding of the issues and guidance surrounding administering IV contrast in patients with CVC lines but no peripheral access.

3. To find out whether further education has changed understanding or practice.

Methods: We sent out a short questionnaire via SurveyMonkey to both the anaesthetists (n = 28) and to the radiographers (n = 27). This was to find out the current understanding, experiences and practices of both anaesthetists and radiographers. We then offered a teaching session to the anaesthetic department on the equipment used in CT, the CVC lines used at the hospital, the flows of IV contrast required for certain CT scans and how Poiseuille's Law links pressure in the lines to its length, gauge, and viscosity of the contrast. We also reviewed the current literature looking at CVC lines used with power injectors. We then did a second questionnaire for the anaesthetists (n = 11) which looked at whether their views and practice had changed.

Results: Results showed that 85% of radiographers were not comfortable with IV contrast being given via the CVC line. Despite this, around half anaesthetists who answered the questionnaire have been asked by the radiographer to connect the power injector to the CVC line. 100% anaesthetists found the teaching useful with 91% anaesthetists feeling informed about the issues surrounding giving IV contrast via a CVC line compared to 9% prior to teaching.

100% anaesthetists said that this teaching would change their practice, with 36% anaesthetists likely to give IV contrast via through a CVC line compared to 64% prior to teaching.

Conclusion: There is currently no UK national guidance on injection of IV contrast via a CVC line. In the United States, the American Committee or Radiology has recently released guidance suggesting that for power injection of IV contrast via CVC lines the radiologist should consult the manufacturers guidance (American College of Radiology, 2020). Some hospitals have local policies (UCSF, 2020; Royal Marsden NHS Foundation Trust Policy, 2017) but this is not something that we currently have implemented at our hospital.

Seeing as there is no formal guidance nationally, and few hospitals have formal policies implemented, often it comes down to individual risk analysis as to whether IV contrast can be injected via a CVC line.

Our data showed that few anaesthetists were well informed on these issues prior to teaching.

Anaesthetists and intensivists are often involved in the transfer of unwell patients. As a result, they are often involved in decision making such as whether or not IV contrast can be injected down a central line. Interestingly, following teaching, the number of anaesthetists who would power inject IV contrast via a CVC line nearly halved. This quality improvement project shows that with education on this subject, anaesthetists may change their practice. 100% of anaesthetists said that they would like a formal policy in place in order to help with the decision-making process. This is something we hope to create and implement in the future in concordance with the radiology department.

Intensive Care Medicine Experimental 2020, **8(2)**: 001328

Introduction: Point-of-care ultrasound (POCUS) has a major role in the management of patients with acute hypoxic respiratory and circulatory failure and guides hemodynamic management. There is scarce literature on POCUS assessment characteristics in COVID-19 pneumonia with hypoxic respiratory failure.

Methods: The study is an observational, prospective, single-center study conducted in the intensive care unit of Adan General Hospital from May 1st, 2020, to June 25, 2020. The study included adults suspected to have COVID-19 transferred to the intensive care unit (ICU) with fever or suspected respiratory infection. Patients were transferred to the ICU after reverse transcriptase-polymerase chain reaction (RT-PCR) testing. A certified intensivist in critical care ultrasound who was blinded to the RT-PCR results, performed the lung ultrasound and echocardiography within 12 hours of the patient's admission to the ICU. We calculated the E/e', E/A ratio, left ventricular ejection fraction EF, IVC diameter, RV size and systolic function. We performed ultrasound in 12 chest areas.

Results: Of 92 patients with suspected COVID-19 pneumonia, 77 (84%) cases were confirmed.

In the group of patients with confirmed COVID-19 pneumonia, echocardiographic findings showed normal E/e', deceleration time (DT), and transmittal E/A ratio in comparison to the non-COVID19 patients (P .001 for both). The IVC diameter was <2 cm with > 50% collapsibility in 62 (81%) patients with COVID-19 pneumonia; a diameter of > 2 cm and < 50% collapsibility in all patients, with a P value of 0.001, was detected among those with non-COVID-19 pneumonia. There were 3 cases of myocarditis with poor EF (5.5%), severe RV dysfunction was seen in 9 cases (11.6%), and 3 cases showed RV thrombus.

	Confirmed COVID-19 77 cases (84.4%)	Non-COVID-19 15 cases (15.5%)	Total 92 cases (%)	P value
Median age (IQR, years)	53 (82-36)	68 (25-80)	71 (77%)	0.005

Diagnostic performance of transthoracic and transesophageal echocardiography to predict cardiac tamponade after cardiac surgery

AJ. De Bie¹; B. Van Straten¹; L. Van Kessel¹; L. Otterspoor¹

¹Intensive care, Catharina Ziekenhuis, Eindhoven, Netherlands

Correspondence: L. Otterspoor

Intensive Care Medicine Experimental 2020, **8(2)**: 001393

Introduction: Cardiac tamponade is a severe complication after cardiac surgery. Echocardiography, both transthoracic (TTE) and transesophageal (TEE), may help to identify cardiac tamponade in postoperative period, but its diagnostic value is still questioned and has not been studied in large cohorts.

Methods: From January 2011 to March 2017, 8,974 adult patients underwent cardiac surgery in the Catharina hospital Eindhoven, a tertiary referral cardiothoracic center. A retrospective study was conducted in which patients with suspected cardiac tamponade were included. Sensitivity and specificity were calculated by comparing echocardiographic findings with surgical confirmation of tamponade. Patients in whom a re-exploration was not performed and recovered without intervention were considered not having tamponade.

Results: 511 patients (male = 65%, median age 66 years) were included in whom 427 echocardiograms were performed. The following patient characteristics differed between patients who underwent a TTE or TEE: percentage of emergency surgery (13 vs 35%), EuroSCORE (mean (SD) 9 (11) vs 18 (22)), and duration extracorporeal circulation (mean (SD) 115 (69) vs 171 (101) minutes). Cardiac tamponade was confirmed at re-exploration in 189 patients, while 278 patients were considered to be negative. In-hospital mortality of the re-intervention group was 14%. The diagnostic value for TTE comprises a sensitivity of 64% (95% CI 53 - 75), a specificity of 96% (95% CI 92-98), a positive predictive value (PPV) of 81% (95% CI 69 - 89), and a negative predictive value (NPV) of 90% (95% CI 86 - 93). Regarding TEE, the diagnostic value a sensitivity of 50% (30 - 70), a specificity of 79% (59 - 91), a PPV of 68% (44 - 86), and a NPV of 63% (45 - 78). The area under the ROC curve for TTE was 0,80 (p < 0.001), and for TEE 0.64 (p = 0.072).

Conclusion: In patients within 4 weeks after cardiac surgery, TTE has a high specificity and negative predicting value to detect cardiac tamponade. These diagnostic values were lower for TEE, which might be caused by a selection bias based on severity of disease.

Intensive Care Medicine Experimental 2020, **8(2)**: 001491

Introduction: The long-term sequelae after Covid-19 severe disease are largely unknown. In particular, late radiological and clinical evolution have not investigated yet.

Objectives: The aims of this study is to describe morphological abnormalities of "late" lung CT scan in relationship to disease severity and clinical evolution in a small cohort of Covid-19 critically ill patients with severe interstitial pneumonia.

Methods: We retrospectively analyzed the data of 24 Sars-Cov-2 positive patients with severe interstitial pneumonia admitted to the intensive Care Unit in a large regional hospital in Northern Italy, in March-April 2020, with a "late" lung CT scan performed for clinical reason not earlier than 2 weeks after hospital admission. CT scans were analyzed by two experienced radiologists and classified according to morphological abnormalities previously described in ARDS subjects based on the Fleischner Society Glossary, including 1) ground glass opacities 2) consolidation 3) fibrotic pattern with interlobular and intralobular thickening or cyst walls and 4) decreased attenuation, which includes emphysema and small airways disease. Six patients had two CT scan (i.e. admission and follow up CT scan) for longitudinal analysis. Clinical data were electronically recorded and retrospectively collected in an electronic data base.

Results: Patients were 22 M and 2 F, the median age was 66 (min 39, max 79). The median time from symptom onset to ICU admission was 5 days (range 4-8). 9 patients (37.5%) underwent immediate intubation and mechanical ventilation (MV) and were directly admitted to ICU, whereas the majority (62.5%) received prior non invasive ventilation (NIV). The median duration of MV was 24 days (range 18-34). One patient was treated with NIV and never MV. Patients were ventilated according to protective strategies with TV of 6-8 ml/kg, plateau < 20 mmHg. Hypoxemia was extremely severe as indicated by median PaO₂/FiO₂ (PF) before intubation of 99 (range 81-143), which ameliorated by day 1 (134; range 101-178), to day 5 (146; range 137-180), day 10 (183; range 147-211) and day 15 (191; 147-251); Kruskal-Wallis test, p = 0.015. PEEP levels decreased significantly over time, from day 1 (mean PEEP = 12, range 12-14), to day 5 (mean PEEP = 12; range 10-14) day 10 (mean PEEP = 10, range 9-12) and day 15 (mean 9.5, range 7-10); Kruskal-Wallis test, p < 0.001. Rescue therapies were frequently used: prone position in 16 (66%) and NO in 3 (12%). 7 patients (25%) died in

ICU. The median length of ICU stay was 27 days (range 19-34). Surviving patients were discharged home (n = 13) or to a rehabilitation facility (n = 4). Length of hospital stay (LOS) was 51 days (range 34-68). CT scan were performed at a median time of 36 days (range 19-55) after hospital admission. Ground glass opacities (n = 20), classical morphological abnormalities of the early phase, and reticular pattern (22), a typical late abnormality, were both the most frequent pattern. Parenchymal consolidation (n = 19), bronchiectasis (n = 17) and emphysema (n = 13) were also frequent. Longitudinal analysis (n = 6) shows reticular pattern in all subjects, both in early and late scans (resembling early fibrosis in these latter). Notably, decrease attenuation pattern could only be observed in late scans, except in one patient with few bronchiectasis on admission.

Conclusion: In a selected cohort of patients with severe Covid-19 disease requiring prolonged ventilation and hospital stay, follow up CT scans show severe lung damage with predominant reticular pattern, resembling early fibrosis, emphysema and small airways disease (i.e. bronchiectasis). These abnormalities are likely the consequences of the disease and not related to previous lung pathology. Long-term follow up studies will be necessary to determine the clinical and morphological evolution of critically pulmonary Covid-19 disease, to provide new preventive and therapeutic strategies.

A prospective observational trial study comparing diaphragmatic ultrasound for prediction of weaning failure in critically ill patients

J.P. Lasso-Perdomo¹; A. Vargas-Villanueva¹; C. Santacruz Herrera¹

¹Departament of critical and intensive care medicine, Fundacion Santa Fe de Bogota University Hospital, Bogotá, Colombia

Correspondence: A. Vargas-Villanueva

Intensive Care Medicine Experimental 2020, **8(2)**: 001492

Introduction: Weaning failure from mechanical ventilation is associated with an increased risk of morbidity and mortality. Different diaphragmatic ultrasound parameters have been studied. However, there are many gaps in our understanding of the discriminatory capacity to predict weaning failure.

Methods: A prospective study in a heterogeneous cohort of patients in intensive care units. The diaphragmatic ultrasound was used to determine the diaphragmatic inspiratory excursion (DE), time to peak inspiratory amplitude of the diaphragm (TPIAdia), diaphragmatic excursion velocity (DE/TPIAdia, cm/sec), and diaphragm thickening fraction (Δtdi %). The measures were performed at the end of a spontaneous breathing trial (SBT) and compared with the extubation outcome. Also, the rapid shallow breathing index (RSBI) was calculated. Weaning failure was defined as the inability to maintain spontaneous breathing for at least 72 h, without any form of ventilatory support.

Results: The study included 43 patients. Median age was 72 years [58.0-77.5], APACHE II score was 18.0 [9.0-23.0], and RSBI previous to the SBT was 37 [24.0-48.5]. Patients who failed the SBT (30%) had a lower median vital capacity (12.4 [11.5-14.1(mL/Kg)] vs. 21.3 [15.6-23.6]; p=0.05), DE (cm)(1.8 [1.6-2.1] vs. 1.50 [1.3-1.8];p=0.03), and Δtdi % (29.0% [21.0%-35.0%] vs. 39.0% [28.2% - 47.5%];p=0.02). [E1] RSBI had the highest discriminatory capability (AUC-ROC 0.76). Among DUS measures, Δtdi % had the highest AUC-ROC (0.71), followed by DE (0.70), and DE/TPIAdia (0.54). Using both, the DE/TPIAdia and RSCI the discriminatory capacity was improved and associated with a successful weaning trial (AUC-ROC 0.77). DE/TPIAdia (cm/sec) alone was not able to discriminate patients who failed the SBT (1.40 [1.10-1.80] vs. 1.55 [1.22- 1.80]; p=0.69).

Conclusion: Combining the used of DE/TPIAdia and RSBI leads to a discriminatory capability improventfor detecting patients at high risk of extubation. This combined measure was similar to RSBI alone.

Intensive Care Medicine Experimental 2020, **8(2)**: 001577

Introduction: Patients with severe respiratory diseases usually use accessory respiratory muscles. In that specific patients sternocleidomastoid and trapezius muscle may be hypertrophic than in control intensive care unit (ICU) population. That specific muscles may have different ratio as compared to the quadriceps femoris muscle, which is usually an indicator of nutritional status and overall skeletal muscle status.

Objectives: The aim of this study is to compare the diameter of accessory respiratory muscles in patients with respiratory diseases and patients without such diseases and compare these muscles with the quadriceps femoris muscle in the patients with and without chronic respiratory diseases. We aimed to determine whether there is a correlation between the ultrasound-measured thickness of accessory respiratory muscles and patients age, hemoglobin, body mass index (BMI), duration of mechanical ventilation (MV) in the ICU, and patients' outcome in the ICU.

Methods: Ethics committee approval was obtained for this study and patients or their legal representatives gave written informed consent. A total of 50 subsequent patients admitted into the ICU were examined. Patients of both genders were included, with and without chronic respiratory diseases, including patients using mechanical ventilation. The study was performed using a Mindray TE7 ultrasound machine with the depth of the linear probe at 70 – mm and gain of 90 – dB; settings remained unchanged during the study. The probe was set at the musculoskeletal ultrasound mode. Measurements of the right m. sternocleidomastoideus (SCM), the right trapezius muscle, and the right quadriceps femoris muscle (vastus lateralis, vastus intermedius, vastus medialis, and rectus femoris; MQF) were taken at the admission into ICU, three times in each patient. The final value was the average of three measurements. Laboratory measurements, a duration of MV, and survival were registered.

Results: Out of 50 patients examined, there were 15 patients with previously recognized chronic pulmonary diseases, and 48 patients were mechanically ventilated. Patients with chronic pulmonary diseases have a significantly thinner SCM than patients without chronic pulmonary diseases (79 ± 13 vs. 92 ± 17 mm; Student's t test P = 0.007), and it was thinner in relation to SCM than in patients without chronic lung disease(SCM/MQF 16,9 ± 3.5% vs. 19.8 ± 5.3%; P=0.03). No differences in other muscles was observed. A significant negative correlation was observed between patients age and MQF (r=-0.359, P=0.01), BMI and MQF (r=0.338; P=0.02) and MQF and patients' hemoglobin (r=0.458, P=0.001). Treatment outcomes were not affected by the thickness of accessory respiratory muscles.

Conclusion: The thickness of the SCM was lower in the patients with chronic pulmonary diseases than in patients without such diseases. The importance of accessory respiratory muscle thickness for the respiratory function in the ICU may be better evaluated after subsequent measurements and whether elasticity of the muscles was evaluated.

Failure of focused echocardiography to differentiate pulmonary embolism in COVID-19 offers potential role for lung ultrasoundL. Tong¹; J. Powys-Lybbe¹; C. Moxey¹; O. Valencia²; HD. Aya¹; J. Aron¹¹General intensive care unit, St George's Hospital, London, United Kingdom; ²Cardiovascular sciences research centre, St George's, University of London, London, United Kingdom**Correspondence:** L. Tong*Intensive Care Medicine Experimental* 2020, **8(2)**: 001594

Introduction: A high incidence of pulmonary embolus (PE) has been reported in patients infected with Covid-19 [1]. When computed tomography (CT) is not available, transthoracic echocardiography (TTE) has a high specificity for the diagnosis of PE [2]. However, raised pulmonary pressures associated with Covid-19 can create similar echocardiographic changes to a PE [3]. Lung ultrasound (LUS) can identify PE associated wedge infarcts and may have a place in diagnosis when other investigations fail [4].

Objectives: To evaluate the role of focused echocardiography and lung ultrasound in the diagnosis of PE in patients with COVID-19 pneumonitis.

Methods: We performed a prospective observational study of Covid-19 patients admitted into intensive care during a 3-week period. Patients received focused echocardiography (looking at RV dilatation, TRVMax, TAPSE and RVS') and 6-point lung ultrasound (giving each region a score of 0 to 3 [5]). On day 1 and 5 of admission, cumulative lung score was also calculated using ROC curve analysis for the best cut-off threshold for PE. Individual lung regions were reviewed to determine if a score 3 (wedge infarct) was associated with PE. Covid-19 was confirmed by viral PCR swabs. Fisher exact test or odds ratio (OR) were used to determine association between variables. *P* values less than 0.05 is considered statistically significant.

Results: 49 Covid-19 positive patients were admitted to our intensive care units during the study period. 16/49 (32.7%) patients had confirmed PE. We did not find any statistical difference in focused echocardiography between the two groups. RV dilatation was seen in 15/38 (60.5%) patients with PE and absent in 9/11 (81.8%) non-PE patients (*p* = .19). TAPSE of 26 mm or more was seen in 5/20 (25%) PE patients and < 26 mm in 15/26 (57.7%) non-PE patients (*p* = .22). RVS' > 16 mm was seen in 10/30 (33.3%) patients with PE and absent in 8/14 (57.1%) patients without PE (*p* = .54). TRV Max of 30 mmHg or more was seen in 12/28 (42.9%) patients with a PE and < 30 mmHg in 10/13 (76.9%) patients without PE (*p* = .22).

43/49 had complete 6-point lung ultrasound scores. At day 1 of admission, average cumulative lung scores did not differ significantly between patients with or without PE (9.3 (SD 2.8) vs 8.7 (SD 3.4); *p* = .6). At day 5 of admission, a cumulative lung score of ≥ 7 was shown to be significantly associated with presence of PE (*p* = .03, OR 5.83, 95%CI 1.06-32.02). Individually, left upper lobe score of 3 (*p* = .012) and left lateral and score of 3 (*p* = .038) were significantly associated with presence of PE.

Conclusion: Focused echocardiography is not useful in the diagnosis of PE in COVID-19. Under these circumstances lung ultrasound has diagnostic value.

Diagnostic value of quantitative computed tomography in patients with COVID-19 pneumoniaS. Tsarenko¹; L. Davydova²; D. Dolotova³; Y. Andreev⁴; A. Andreev¹; E.Filimonova¹; M. Lysenko¹; A. Gavrilov³¹Intensive care, Moscow City Clinical Hospital № 52, Moscow, Russia;²Intensive care, Moscow city clinical hospital №52, Moscow, Russia;³Skobel'syn institute of nuclear physics, Moscow State University, Moscow, Russia;⁴Faculty of fundamental medicine, Moscow State University, Moscow, Russia**Correspondence:** A. Andreev*Intensive Care Medicine Experimental* 2020, **8(2)**: 001599

Introduction: In March, 2020 – June 2020 Central and East Europe had a period of the response to COVID-19 pandemic. Disease severity of pneumonia on admission can be assessed by various scales, including PORT, PSI, CURB-65, CRB-65 and SMRT-CO. Some of them include laboratory findings but none of them include the amount of lung lesion on CT, which is important to assess COVID-19 pneumonia. The most frequent types of lesions on CT for COVID-19 pneumonia are ground-glass opacity (GGO) and consolidation. Lesion volumes can be determined by quantitative CT. Therefore, it is important to analyze the relationship between quantitative CT parameters and clinical and laboratory findings.

Objectives: To evaluate the sensitivity of COVID-Multivox program in estimation of severity of lung injury in COVID-19 patients and to assess the correlation between quantity of involved lung parenchyma, types of CT-findings and laboratory findings.

Methods: 76 patients with COVID-19 were retrospectively reviewed from March 15, 2020 to March 31, 2020. Laboratory data and CT findings on admission were analyzed. CT quantitative parameters, including GGO volume, consolidation volume, total lesion volume, percentage of GGO, and consolidation) were calculated. Relationships between the CT findings and laboratory data were statistically estimated (Spearman rank correlation coefficient was used).

Results: There were 56.6% men of the 76 people examined. The most common laboratory markers of COVID-19 were an increase in the level of C-reactive protein, observed in 72 (94.7%) patients, an increase in LDH, noted in 62 (81.6%) patients, and lymphopenia, which was noted in 40 patients (52.6%). CT-findings revealed total lesion volume 11,2%-54,2% (mean 29,4%), with a GGO volume 9,4%-49,2% (mean 28,5%) and a consolidation volume 0,3-1,8% (mean 0,7%).

A correlation was revealed between LDH and the total volume of the affected lung tissue, the total percentage of lesions by the type of ground glass, the percentage of consolidation (*r* = 0.610, *r* = 0.628, *r* = 0.316; *p* < 0.01, respectively), slightly less correlation of the level of C-reactive protein with similar volumes (*r* = 0.497, *r* = 0.468, *r* = 0.410; *p* < 0.01), as well as an inverse correlation between the total volume of the lesion and the level of lymphocytes (*r* = -0.251, *p* < 0.05).

Conclusion: There is a strong correlation of the percentage of lung tissue lesion, detected by quantitative computed tomography, with

the level of LDH and C-reactive protein. Quantitative lungs CT may be used not only to estimate the degree of the lung damage, but also to assess the severity of the systemic inflammatory response for patients with COVID-19.

The current state of critical care ultrasound training in Ukraine

M. Grynovska¹; A. Wong²

¹Anesthesia and intensive care, Ivano-Frankivsk National Medical University and Regional University Teaching Hospital, Ivano-Frankivsk, Ukraine; ²Critical care, Royal Surrey County Hospital, Guildford, United Kingdom

Intensive Care Medicine Experimental 2020, **8(2)**: 001635

Introduction Ultrasound (US) is increasingly recognized as an essential tool in the ICU setting. The safety and utility of bedside ultrasonography by an appropriately trained ICU physician has now been well demonstrated¹. Despite the worldwide routine use of ultrasound in ICUs, a large number of ICU physicians remain unacquainted with US techniques. Following the 2011 international expert statement, the training of every ICU physician should incorporate basic level of critical care ultrasonography (CCUS)². We decided to continue investigating the evolving CCUS paradigm of ICU physician skills and competencies in our country.

Objectives To summarize knowledge on the current use of CCUS and attitudes towards its utilization in the ICUs of two city hospitals.

Methods Our study focused on the ICU physicians (n=113) of two city hospitals. Data collection was performed with the help of an electronic survey.

Results The response rate of the survey was 78%. 64% of the respondents were young specialists. The majority (56%) had no previous experience in CCUS and only 45.5% were aware of the locally organized training programs. The most useful CCUS modalities reported were TTE and TEE, pleural/ lung US, vascular US for access, nerve block, FAST and vascular US-DVT. All of the respondents recognized the existence of barriers to CCUS training, citing lack of formal training and financial costs as the most significant ones. Although In Ukraine CCUS still remains the prerogative of the on-call radiologists, it was not perceived as a training barrier.

Conclusions While Ukraine is lacking a formal CCUS training program, there is an unmet demand for it in the ICU. Our survey has demonstrated a prevailing lack of US skills among the young ICU physicians. At the same time there was a general consensus on list of core US modalities that should be incorporated in such training as well as on the barriers that prevent ICU physicians from mastering them. The young demographics of the study has also highlighted the potential for international training programs and initiatives. Due to the limited number of respondents in our survey, further study across hospitals is required to fill in the knowledge gap on the country-specific state of CCUS training. We expect our ongoing study to be the call for action among the ICU physicians to stimulate the activity of the locally organized training programs. In future we hope to start a cross-country conversation on the challenges of CCUS standards implementation and the possible ways forward.

Intensive Care Medicine Experimental 2020, **8(2)**: 001637

Introduction: SARS-CoV-2 has spread rapidly from first recognition in December 2019. Radiological findings on chest radiograph (CXR) and computerised tomography (CT) are often non-specific, most commonly consistent with atypical pneumonia, with predominant bilateral, peripheral and basal involvement [1,2]. Current recommendations advise that CT imaging should be reserved for the evaluation of complications and should not be employed as a diagnostic tool for Covid-19 [3,4]. As an alternative, CXRs are often the first-line imaging modality employed, and there is paucity in the literature regarding how this correlates with definitive reverse transcriptase polymerase chain reaction (RT-PCR) testing.

Objectives: To describe radiological findings on CXR and CT imaging in patients with acute respiratory failure caused by SARS-Cov-2 infection and to investigate whether classical radiological features of SARS-Cov-2 infection on CXR are reliable as a diagnostic tool.

Methods: This was a single centre retrospective observational study. Patients admitted to Intensive Care Units (ICUs) in a tertiary teaching hospital from March to May 2020 with a CXR and a RT-PCR test were included. Baseline and serial CXRs and, where available, CT scans were reviewed and findings categorised under pre-specified headings. Reports of radiological features as classic Covid-19 were noted, according to the British Society of Thoracic Imaging (BSTI) grading templates[5]. These CXRs were deemed to fulfil the criteria of lower lobe and peripheral predominant multiple opacities that are bilateral, and given the BSTI code CVCX1. A chi-square statistic was used for the univariate analysis, and estimation of predictive values. A p-value less than 0.05 was considered statistically significant.

Results: 134 patients were included in the study. 109 (79%) had a positive PCR for Covid-19. On review of the CXRs[sL1] of the Covid-19 positive cohort, 42.4% (45) of patients had alveolar consolidation (26.6% lobar, 73.3% bilateral), and 89.6% (95) had hazy increased opacity (90.5% bilateral, 9.5% Lobar) which was associated with a positive PCR ($p = 0.02$). Of the 44 patients who had a CT scan, 35 had a positive PCR. Within these 35 CT reports, 10 had ground-glass opacity (2 central, 8 peripheral), 4 had enlarged lymph nodes, 3 had pulmonary embolisms or pleural effusions, 2 had architectural distortion and there was 1 example each of air bronchogram, vascular thickening and fibrous stripes (figure 1). Classic radiological features of Covid-19 were associated with a positive PCR ($c2(1) 7.9, p = 0.005$), with a sensitivity of 65.1%, specificity of 64.3%, positive predictive value of 87.3% and negative predictive value of 32.7%.

Conclusion: Covid-19 infection typically presents with bilateral hazy increased opacity on CXR, and less frequently bilateral alveolar consolidation. Classic radiological features of Covid-19 infection can be useful as a screening tool.

Intensive Care Medicine Experimental 2020, **8(2)**: 001640

Introduction: Point of care ultrasound (POCUS) is an important diagnostic and monitoring tool in ICU. The ICU at Addenbrooke's Hospital in Cambridge, UK is running a successful educational POCUS program for the last 6 years. Focused ultrasound is widely used also by the emergency medicine and acute medicine physicians in our institution with a separate certification body and educational program.

Objectives: In 2019 an innovative collaborative project for training in POCUS was established by the ICU, emergency medicine and acute medicine focused ultrasound leads. The aim of the project was to provide equal quality of training and governance of the POCUS amongst the acute specialities.

Methods: A two day course Point of care ultrasound for acute specialities (POCAS) was launched covering the requirements for certification of the three acute specialities. The certification bodies were approached for course approval and CPD points. The course was aimed for acute specialty physicians ST3 to consultant level. The administration of the course and the venue were provided by the Postgraduate Medical Centre. The course consisted of lectures and practical sessions covering focused lung, heart, abdominal, and vascular ultrasound. The faculty was represented by the POCUS mentors in the acute specialities and consultant cardiologist, respiratory physician and radiologist experts in the ultrasound field. The learners were offered POCUS educational mentorship program run by the same faculty at Addenbrooke's Hospital.

Results: Two courses were run in 2019- April and December edition. The April edition was attended by 23 learners and the December one by 24. The spring edition had more equal attendance spread amongst the three specialities while the winter one had minimal attendance from the emergency medicine. It can be explained by deanery required parallel course running for this speciality just before our course. Most of the attendees were doctors in training. The consultant attendance was 2 for the first edition and 3 for the second one. The courses received detailed feedback evaluating the course as a valid method to acquire theoretical knowledge and basic practical skills in POCUS. Interestingly the lectures run by the acute specialities ultrasound leads were valued more than the ones delivered by the experts appraising the simplicity of explanation and focused approach. The acute medicine attendees rated the vascular access practical session very high which can represent less experience in their field in placement of lines under US guidance. The most valued session was the one with video cases of ultrasound imaging of real patients, their interpretation and application to the clinical management of the patients. The mentorship educational program was established and we are training 12 learners of which 5 got already certified in POCUS.

Conclusion: Point of care ultrasound is a powerful tool in the diagnosis and management of the acutely unwell patients. We have established a training system in POCUS amongst the acute specialities that guarantee high quality of training offered to all the learners regardless of their primary speciality and adequate governance of the educational process.

001221**FACTORS ASSOCIATED WITH MORTALITY IN PATIENTS ADMITTED AS SARS-CoV-2 PNEUMONIA**

Intensive Care Medicine Experimental 2020, **8(2)**: 001221

Introduction: COVID related severe respiratory syndrome (SARS-CoV-2) is associated to a high mortality. Several risk factors have been identified, such as hypertension, obesity, advanced age or male gender.

Objectives: We wanted to study the presence of such factors in our population, and assess if there existed a relation with the mortality in patients admitted in our Intensive Care Unit as pneumonia caused by SARS-CoV-2.

Methods: Retrospective, observational and analytical study, on patients diagnosed with SARS-CoV-2 pneumonia admitted to the ICU of a tertiary hospital, between March and June 2020.

We collected demographic, clinical and therapeutical variables including: age, gender, ethnicity, previous medical conditions and treatment, presenting symptoms, need of mechanical ventilation, treatment received, complications (neurological, musculoskeletal, cardiac, abdominal, renal, nosocomial infection, haemorrhagic thrombotic) and mortality.

We used χ^2 test and Fisher's exact test, regression study, considering statistical significance when $p < 0.05$.

Results: A total of 101 patients were included in the analysis, with a global mortality of 26.7%. 69 were men, with a mortality of 24.6% among them, and 32 were women, with a mortality of 31.2%.

Subgroup analysis identified female gender and Hispanic ethnicity as risk factor for increased mortality. 13 women were Hispanic (40.6%), mortality within that subgroup 53.8%, $p = 0.049$.

In studied cohort most of the previously identified risk factors weren't associated to an increased mortality, not even obesity, in 36.6% of our patients, regression study: OR -2.4, $p = 0.017$, CI [(-5.4)-(-0.5)].

Presenting symptoms were dyspnoea and hypoxemia in 82.2% and 83.2%, respectively. Within the first 24 hours, 69 patients (68.3%) needed invasive mechanical ventilation, and 29 (28.7%) non-invasive, without relation with their mortality. Of those 29 patients, during admission 7 (24.1%) required intubation.

Regarding treatment received, prolonged neuromuscular blockade (43 patients, 42.6%, $p = 0.03$) was the only therapeutical intervention related to mortality. A persistently positive PCR test on 30th day occurred in 7 patients (6.9%) and was significantly related to mortality ($p = 0.01$).

Regarding complications, only renal failure (23 patients (22.8%) presented impaired renal function, with or without needing renal replacement therapy) had a significative relation with mortality ($p = 0.04$).

In the regression study, there was also a relation with mortality in use of kidney replacement therapy (4% of cohort), $p = 0.03$, OR 2.17, CI [0.04-0.9], and prolonged neuromuscular blockade (42.6%), $p = 0.02$, OR 2.29, CI [0.06-0.8].

Conclusion: In our cohort, Hispanic female patients were more prone to die. The extended use of neuromuscular blockade, possibly due to the presence of a more severe respiratory failure, and the persistence of Coronavirus detection on the 30th day of admission, indicating continued viremia, were related with mortality. Among complications, the one most associated with mortality and worse prognosis was renal failure.

Introduction: Although Brazil is the second country in the world in number of cases and deaths by COVID-19 there are limited information describing clinical characteristics and outcomes of the patients requiring treatment in Brazilian intensive care units.

Objectives: To describe the clinical characteristics and outcomes of patients with COVID-19 requiring treatment in an intensive care unit in northeastern Brazil.

Methods: Retrospective observational study of 187 consecutive patients with confirmed diagnosis of COVID-19 admitted to a 35-bed ICU at a tertiary hospital in the state of Maranhão, Brazil, from March 27 to June 15, 2020. We collected demographic and clinical-laboratory data, therapeutic interventions including management of respiratory failure, complications and mortality.

Results: Of the 187 patients included in the study, the median age was 64 years (IQR 51–75), 122 (65.2%) were male and 163 patients (87.1%) had at least one chronic disease, the most common being arterial hypertension (100 patients, 53.4%) and diabetes melitus (86 patients, 45.9%). Upon arrival to the ICU, patients had a median PaO₂/FIO₂ of 195 (IQR 136-300). Thirty-seven patients (19.8%) were treated with non-invasive respiratory support while 150 (80.2%) underwent invasive mechanical ventilation. Seventy-four patients (39.6%) underwent

hemodialysis and one patient was treated with ECMO. Seventy-nine patients (42.2%) died during the ICU stay. Mortality among the 150 patients undergoing invasive mechanical ventilation (77 patients, 51.3%) was significantly higher than that of the 37 patients undergoing non-invasive respiratory support (5.4%), $p < 0.0001$. Among the 74 patients (39.6%) who had a bacterial infectious complication, mortality (38 patients, 51.3%) was significantly higher compared to the 110 patients who did not have a secondary infection (38 patients, 34.5%); $p = 0.001$.

Conclusion: This case series describes the clinical characteristics and outcomes of 187 critically ill patients with COVID-19 treated in a tertiary hospital in northeastern Brazil.

Mechanisms of antibiotic resistance of microorganisms in patients with severe respiratory infections in intensive care unit

V. Ziamko¹

¹Viciebsk State Order of Peoples' Friendship Medical University, Viciebsk, Belarus

Correspondence: V. Ziamko

Intensive Care Medicine Experimental 2020, **8(2)**: 001255

Introduction: It has been known about possibility of microorganisms to create specific multi-layered structures called biofilms. Non-cellular deoxyribonucleic acid actively participates in regulation of properties of biofilms. Thus, in biofilms transfer of genetic information including genes responsible for sensitivity to antibacterial drugs occurs much more often than in single-living bacterial cells. However, despite the involvement of extracellular deoxyribonucleic acid in adhesive processes and intercellular interactions, its role has not been fully understood.

Methods: 238 isolates isolated from sputum and pharynx of 175 patients during 2016-2019 were studied. Patients were divided into two groups: the 1st group of 139 people (79.4%) had severe respiratory infections, the 2nd of 36 people (20.6%) - respiratory infections of moderate severity.

Results: A method was developed for determining percentage of deoxyribonucleic acid in microbial community using 4'-diamidino-2-phenylindole dihydrochloride. Average age of the 1st group was higher than the second ($p < 0.05$). *Pseudomonas aeruginosa* had the largest mass of biofilm and percentage of deoxyribonucleic acid in group 1, 48,25 [30,5-70,1] mcg/ml and 5,21 [2,17-7,67] %, $p = 0,04$. A strong relationship was found between percentage of deoxyribonucleic acid in *Pseudomonas aeruginosa* and severity of disease, $r = 0,73$, $p < 0,05$. The incidence of adverse outcomes in isolating antibiotic resistant isolates was higher than in antibiotic sensitive ($p < 0,05$). Analysis of results made it possible to propose fatal outcome when mass of microbial biofilm is $> 47,5$ mcg/well and percentage of deoxyribonucleic acid is $> 2,33\%$ ($p < 0,01$).

Conclusion: Method for determining percentage of deoxyribonucleic acid in biofilm has been proposed. With age there is a decrease in immune system which contributes to adherence of more pathogenic, antibiotic resistant microflora which has high biofilm weight and deoxyribonucleic acid percentage leading to disease progression and death.

Lysozyme activity in serum of patients with severe bacterial pneumonia

V. Ziamko¹

¹Viciebsk State Order of Peoples' Friendship Medical University, Viciebsk, Belarus

Correspondence: V. Ziamko

Intensive Care Medicine Experimental 2020, **8(2)**: 001266

Introduction: In modern concepts of pathogenesis of inflammatory diseases, much attention is paid to nonspecific humoral factors of immune system, including lysozyme.

Objectives: To create a simpler and a cheaper way of evaluating lysozyme activity in biological fluids and analyse its level in patients with severe bacterial pneumonia.

Methods: A complex examination of 56 patients with severe bacterial pneumonia and 50 practically healthy people was performed. Blood was taken from the ulnar vein before meals into sterile test tubes.

Results: We have created a simpler and a cheaper way of evaluating lysozyme activity in biological fluids, which demands little time and has clear evaluation criteria. The invention relates to medicine, namely to laboratory diagnosis. From cell walls of *Micrococcus lysodeikticus* culture ATCC 4698 peptidoglycan substrate was prepared, and the activity of lysozyme was calculated by the formula obtained after constructing calibration curve for lysozyme, which showed the dependence of the concentration of lysozyme and the optical density of the solution of Congo red. The positive effect of the proposed method was that the substrate for the production of reaction was prepared once and could be used for a long time. The way was easy and simple in play. The sensitivity of this method to lysozyme was 0.06 mg/ml. This is enough to determine immunodeficiency states, because the content of lysozyme in biological fluids varies according to various data in a wide range from 0.2 to 28 mg/ml in normal.

It was found that the lysozyme activity in the serum was lower in patients with severe bacterial pneumonia (116.0; 56.5-160.1 mcg/ml) in comparison with practically healthy people (246.0; 183.6-305.7 mcg/ml).

Conclusion: There was a statistically significant decrease of nonspecific humoral resistance in patients with severe bacterial pneumonia.

Antimicrobial resistance in the critically ill: new perspectives for the future?

S. Branco Ribeiro¹; A. Krystopchuk¹; S. Castro²; J. Moreno³; D. Nuñez⁴

¹Emergency and intensive care medicine department, Algarve University Hospital Centre, Faro, Portugal; ²Serviço de medicina intensiva 1, Centro Hospitalar Universitário do Algarve, Faro, Portugal; ³Intensive care department, Centro Hospitalar e Universitário do Algarve, Faro, Portugal, Portugal; ⁴Intensive care unit, Centro Hospitalar Universitário do Algarve - Faro, Faro, Portugal

Correspondence: S. Branco Ribeiro

Intensive Care Medicine Experimental 2020, **8(2)**: 001294

Introduction: The ongoing emergence of antimicrobial resistance is considered a major threat for public health. Mainly due to its extremely vulnerable population of critically ill patients, the unique nature of the intensive care unit (ICU) environment makes this a focus for the emergence and spread of many antimicrobial resistant pathogens. However, and despite the total burden of multi-drug resistant (MDR) bacteria in the broader community remains a blind spot, it now seems that a growing number of patients are already colonised or infected with MDR microorganisms on arrival in the ICU.

Objectives: To investigate the relationship between MDR bacterial infections, patient provenience and mean hospital stay before ICU admission.

Methods: This was a retrospective study performed in a mixed medical and surgical ICU at Faro Hospital, Portugal, between January and December 2019. During the study period, 464 patients were admitted to the ICU. Data from a total of 104 patients were collected after applying exclusion criteria. Patient demographics, clinical details and microbiological data were recorded and analysed.

Results: One hundred and four patients were included in this study. They were predominantly male ($n=67$, 64.4%), with a mean age of 61.4 years, a mean APACHE II of 21, and mainly admitted due to urgent surgical causes ($n=50$, 48.1%). Overall, 171 organisms were isolated from these patients. The most frequent infection sites were urinary (26.7%), respiratory (25.3%), bloodstream (18.8%) and intra-abdominal (16.3%). Most bacterial isolates were Gram-negative (59.1%). *Escherichia coli* was the main genus identified, of which 27.3% were MDR. *Staphylococcus aureus* represented 40.4% of all Gram-positive isolates, with 33.3% methicillin-resistance. Prevalence of MDR bacteria was 24.2%, of which the most frequent were *Escherichia coli* (16.2%), *Staphylococcus aureus* (13.5%), *Pseudomonas aeruginosa* (13.5%), *Enterobacter aerogenes* (13.5%) and *Klebsiella pneumoniae* (10.8%). Interestingly, MDR bacteria were isolated in patients coming predominantly from the Emergency Department (ED) ($n=62$, 59.6%), with a mean hospital stay before ICU admission of 3,3 days. Infections by MDR bacteria were also associated with an increased hospital length of stay.

Conclusion: In this study we noted that critically ill patients infected with MDR bacteria were admitted predominantly from the ED, with a mean hospital stay before ICU admission of 3,3 days. These findings suggest they could be already colonised or infected with MDR pathogens on arrival to the ICU, and make us think about having to reconsider the usual empiric coverage strategies used in several patients. Future studies are required to prove this changing pattern of antimicrobial resistance and its growing tendency of occurrence in the community. Additional efforts to increase the effectiveness of infection control programs, knowledge of local epidemiologies of resistance and antimicrobial stewardship strategies are essential to make progress in this problematic matter.

Intensive Care Medicine Experimental 2020, **8(2)**: 001298

Introduction: Since the start of the COVID-19 pandemic, age and chronic diseases have been described as important risk factors related to patient prognosis.

Objectives: To assess whether the age and comorbidity of COVID-19 critical patients are independent risk factors related to mortality.

Methods: Prospective, observational study carried out in patients admitted to HGU Gregorio Marañón critical care units during the COVID-19 pandemic. Demographic and clinical data, comorbidities, severity risk scores, complications during stay, administered treatments and outcome, were collected.

Descriptive analysis was expressed as mean (SD) or median (RIC) for quantitative variables and as percentages for qualitative variables. Univariate analysis was performed using Chi-square (RR) for qualitative variables and a simple logistic regression analysis (OR) for quantitative variables. Multiple logistic regression analysis, adjusted for severity, was carried out to determine if the age and comorbidity were independently factors related to mortality.

Results: We included 150 patients, 71% were male, mean age was 58 ± 14 years. Charlson comorbidity Index was 1(0-3), 53% presenting obesity and 53% hypertension (comorbidities not included in that index). Severity risk scores: APACHE II 16 (12-20), SOFA 6 (4-8). 88% of patients required mechanical ventilation and 74% prone-position. 63% of patient required vasoactive drugs, 30% developed renal failure and 10% required continuous renal replacement therapy. Mortality in ICU was 38%, with the following age distribution: < 40 years 10%, 41-50 years 30%, 51-60 years 32%, 61-70 years 52% and 71-80 years 48%. The univariate analysis showed that **age (range)** OR 1.54; 95% CI 1.17-2.02, **Charlson index** 1.44; 95% CI 1.17-1.78 and **hypertension** RR 2.07; 95% CI 1.05-4.05, were related to an unfavourable prognosis, but not obesity (BMI >30) RR 1.17; 95% CI 0.60-2.25. When the age was analysed by ranges, after the sixth decade the risk of death increased significantly: 61-70 years RR 9.44; 95% CI 1.91-46.66 and 71-80 years RR 8.05; 95% CI 1.62-39.91.

In the multivariate analysis, adjusted for severity (APACHE II, SOFA and mechanical ventilation), obesity and hypertension, both **age OR 1.46; 95% CI 1.04-2.04** and **Charlson Comorbidity Index OR 1.24; 95% CI 1.02-1.56** remained as independent risk factors for mortality.

Conclusion: In our experience, both age and comorbidity, expressed as the Charlson index, were independent risk factors associated with mortality in critically ill COVID-19 patients.

001321**A Retrospective Analysis of Unit Acquired Infections in a West London Adult Intensive Care Unit During the COVID-19 Pandemic**

H. Wilson¹; R. Snooks¹; H. Said¹; M. Popescu¹

¹Intensive Care Unit, West Middlesex University Hospital, Isleworth, United Kingdom

Correspondence: H. Wilson

Intensive Care Medicine Experimental 2020, **8(2)**: 001321

Introduction: Unit acquired blood infections are commonly used as a quality indicator. Intensive care units report such data quarterly and this is collected by ICNARC(1).

West Middlesex University Hospital (WMUH) has a high turnover AICU, with 199 and 167 admissions for quarters 1 and 2 respectively in 2019. From April to December 2019, WMUH had reported 0 unit acquired infections. Nationally, an increase in secondary bacterial infections in COVID ICU patients has been reported(2). Studies have reported 50% of COVID patients who died had secondary bacterial infections(3).

Objectives: To compare the incidence of unit acquired infections during the COVID-19 pandemic with a typical pre-pandemic period.

Methods: We included 74 patients over a 55-day period. Patients were confirmed COVID positive from throat or tracheal aspirate swab PCR. Data was extracted from the ICE reporting system. Unit acquired infections were deemed to be positive blood cultures greater than 48 hours after admission.

Results: Thirteen patients had a unit acquired infection. There were 16 positive blood cultures in total, as some had more than one positive culture during admission. Cases are broken down by organism, see Figure 1. Average length of time from admission to positive blood culture was 14.4 days. The length of stay for all 74 COVID positive ICU patients was 12.6 days compared to 25.8 days for those who developed unit acquired infection. 32 out of 74 COVID patients died (43.2%). 7 of the 13 patients with a positive blood culture died (53.8%).

Conclusion: We have demonstrated an unexpected increase in unit acquired infections during the COVID pandemic. 17.5% of patients developed a unit acquired infection, compared to 0% over a similar time period in 2019.

This is almost certainly multifactorial, with the average length of stay and exposure to invasive procedures a significant risk factor in developing infection (1). During the height of the pandemic, WMUH AICU

was expanded from an 11-bed unit with a maximum of 6 level 3 beds to 35 level 3 beds.

We can speculate that increasing the nursing ratio from standard 1:1 to 1:4.5 patients, as seen on an international level (3), along with multiple-proned patients, made it challenging to maintain usual strict infection control measures.

In particular, proned patients with CVCs sited in the internal jugular vein may have been at a greater risk of contamination from organism containing oro-pharyngeal secretions.

Additionally, lines were inserted in closed spaces whilst wearing heavy PPE, making sterility challenging. Once in situ lines could be contaminated when disconnecting during patient turning, as reported at other ICUs (2). These patients were also physiologically unstable, receiving multiple courses of antibiotics and iatrogenic immunosuppression with steroids. It is therefore not unreasonable that this group of patients developed secondary infection.

Intensive Care Medicine Experimental 2020, **8(2)**: 001339

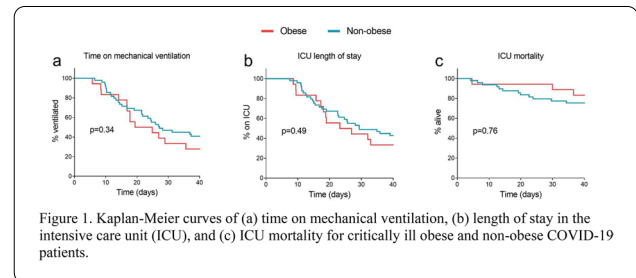

Introduction: Obesity appears to be an independent risk factor for ICU admission and a severe disease course in COVID-19 patients (1). An aberrant inflammatory response and impaired respiratory function have been suggested as underlying mechanisms (2, 3). Today, it is not known whether obesity is only a risk factor for COVID-19 susceptibility and for the need of intensive care, or whether it also influences the outcome of the patients once admitted on intensive care units.

Objectives: We investigated whether obesity is associated with differences in inflammatory, respiratory, and clinical outcome parameters in critically ill COVID-19 patients.

Methods: Sixty-seven COVID-19 ICU patients were divided into obese (BMI ≥ 30 kg/m², n=18) and non-obese (BMI <30 kg/m², n=49) groups. Plasma concentrations of interleukin (IL)-6, interferon gamma-induced protein (IP)-10, monocyte chemoattractant protein (MCP)-1, and granulocyte colony-stimulating factor (G-CSF) were determined from ICU admission until 10 days afterwards, and routine laboratory and clinical parameters were collected.

Results: BMI was 32.6 [31.2-34.5] and 26.0 [24.4-27.7] kg/m² in the obese and non-obese group, respectively. Apart from temperature,

which was significantly lower in obese patients (38.1 [36.9-38.9] vs. 38.7 [38.0 -39.5] °C, p=0.02), there were no between-group differences on ICU admission. Plasma cytokine concentrations declined over time (p<0.001 for all), but no differences between obese and non-obese patients were observed. The kinetics of clinical inflammatory parameters and respiratory mechanics were also similar in both groups. Finally, no differences in time on ventilator [22 [16-40] vs. 27 [14-40] days, p=0.34], ICU length of stay [25 [17-40] vs. 29 [15-40] days, p=0.49], or 40-day mortality (17% vs. 24%, p=0.76) between obese and non-obese patients were apparent (Fig. 1).

Conclusion: In COVID-19 patients requiring mechanical ventilation in the ICU, obesity is not related to a different immunological response, unfavourable respiratory mechanics, or impaired outcome.

Introduction: The clinical spectrum of SARS-CoV-2 infection ranges from asymptomatic cases to severe pneumonia and viral sepsis leading to organ dysfunction and high mortality (1). A subset of critically ill COVID-19 patients develop a hyperinflammatory state. Anakinra, a recombinant interleukin-1 receptor antagonist, is known to be effective in several hyperinflammatory diseases. Recently, small studies suggest that anakinra improve respiratory function and clinical outcome in COVID-19 patients (2-4).

Objectives: We investigated the effects of anakinra on inflammatory parameters and clinical outcomes in critically ill, mechanically ventilated COVID-19 patients with clinical features of hyperinflammation.

Methods: In this prospective cohort study, 21 critically ill COVID-19 patients treated with anakinra were compared to a group of 39

critically ill COVID-19 patients receiving standard care. Serial data of clinical inflammatory parameters and concentrations of several circulating cytokines were aligned on start day of anakinra in the treatment group, and median start day of anakinra in the control group. Analysis were performed from day -10 to +10 relative to alignment day. Clinical outcomes were analyzed during 28 days. Additionally, a sensitivity analysis was performed in propensity score matched groups.

Results: Patient characteristics and clinical parameters on ICU admission were similar between groups. Due to bias by indication, plasma levels of ASAT ($p=0.0002$), ferritin ($p=0.009$), and temperature ($p=0.001$) were significantly higher in the anakinra group on alignment day. Following treatment, no differences in the kinetics of circulating cytokines were observed between both groups. Decrease of temperature ($p=0.03$), white blood cell counts ($p=0.02$), and plasma levels of ferritin ($p=0.003$), procalcitonin ($p=0.001$), creatinine ($p=0.01$), and bilirubin ($p=0.007$) was more pronounced in the anakinra group (Fig. 1 a-f respectively). No differences in clinical outcomes were observed between groups. The propensity-matched analysis confirmed these results.

Conclusion: Anakinra is effective in treating clinical signs of hyperinflammation that may promote organ dysfunction in critically ill COVID-19 patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 001349

Introduction: Procalcitonin (PCT) is a biochemical marker that can increase in hours in the presence of bacterial infection, which may assist in the early recognition of bacteremia and sepsis with a high specificity and sensitivity. Studies conducted in recent years reveal that the PCT level in plasma varies according to the type of pathogen causing the infection and the gram staining feature. In our study, the relationship between the type of causative pathogen and PCT level in patients diagnosed with bloodstream infection was investigated with a retrospective observational study design.

Methods: 208 infection episode from 137 ICU patients who were diagnosed as bloodstream infection between January 2016 and February 2018 were included in the study. The highest fever, leukocyte, CRP and procalcitonin values in 24-h before and 24-h after the blood culture, infectious agent, APACHE II score, use of antibiotic when blood culture was taken, duration of ICU stay and 30-day survival was recorded using the data in the electronic patient file.

Results: Patients were divided into four groups as gram positive, gram negative, fungus and multiple agents according to the culture results. No significant difference was observed between the groups for fever, leukocyte and CRP levels, while procalcitonin level was found higher in gram negative infections ($p < 0.0001$). Procalcitonin cut-off value for gram negative infection was 5.95 ng/ml (sensitivity 54%, specificity 81%). It has been shown that procalcitonin and CRP levels correlate with APACHE II score, but the correlation coefficient of procalcitonin value is higher. The relationship between PCT and CRP levels with 30-d mortality was found significant, with a procalcitonin cut-off value was 4.99 ng/ml (sensitivity 66.7% specificity 75%), while CRP cut-off value 19.01 mg/L (sensitivity 62.4% and specificity 67%). No significant difference in PCT levels was found between the patients who used antibiotics and those who did not when culture was taken. There was also no significant relationship between the duration of ICU stay and the PCT level.

Conclusion: In conclusion, we think that procalcitonin is a marker to help predict the causative agent of infection and determine the probability of mortality in patients with bloodstream infection.

Introduction: Despite most common SARS-CoV-2 infection clinical findings are related to respiratory apparatus, Covid-19 may affect other organs than lungs such as liver, bowel and kidneys [1]. Commonly, in fact, patients suffer for abdominal and gastro-enteric symptoms[2]. We report the first case, to our knowledge, of a Covid-19 patient affected by ascending colon perforation due to a Pseudomembranous Colitis (PC) in absence of Clostridium Difficile (CD) toxins, but with SARS-CoV-2 identification in gastric fluid.

Methods: In April 2020, a 73-years-old man came in our ED with fever and dyspnea for 24 h. His remote medical history revealed ischemic heart disease, hypertension and NIDDM. Chest X-ray showed right basal consolidation and bilateral congestion. A RT-PCR test for Covid-19 was negative. The patient was admitted with the diagnosis of CAP and heart failure and treated with antibiotics and diuretics. Ten days later, respiratory symptoms and radiological findings worsening led to perform a new nasopharyngeal swab for Covid-19 that resulted positive. The patient needed CPAP ventilation and hydroxy-chloroquine, azithromycin and LMWH administration were started. Five days later, he developed fever and diarrhea: on physical examination abdomen is quite manageable. Piperacillin/tazobactam was started empirically. An abdominal CT scan showed a parietal ascending colon thickening and intra-peritoneal air collection. Right hemicolectomy with ileostomy for perforation has been performed. After surgery, he was admitted to our ICU. The anatomopathological examination revealed a PC. Diffuse tissue edema, acute inflammation and necrotizing vasculitis with fibrin thrombi and intravascular neutrophils infiltration were identified (Fig.1). Samples from ileostomy and stool in rectal ampoule were negative for CD toxins. A PCR test for SARS-CoV-2 performed on gastric fluid was positive. After improvement, the patient was discharged from ICU to a low intensity ward.

Results: Necrotizing vasculitis is commonly found in Covid-19 patients in several organs [3]. Some authors suggest enteric involvement in up to 50% of Covid-19 patients, but it's not yet completely understood. ACE-2 receptor is expressed by intestinal epithelium: mouse models suggested that ACE-2 receptor modification due to infection can cause bowel inflammation and colitis [4]. In this case, clinical findings were typical and patient had several predisposing factors for CD colitis. Since CD tests were always negative and the patient improved without CD specific therapies, we supposed viral infection related necrotizing vasculitis as pseudomembranous colitis and perforation cause. Anatomopathological findings and viral RNA detection in gastric fluid support our hypothesis.

Conclusion: Many COVID 19 patients present GI symptoms together with respiratory ones. Gastro-enteric involvement may be due to enteric viral replication. CD negative PC due to a necrotizing vasculitis, in our case, may be a SARS-CoV-2 infection complication too.

A cross-sectional study of personal protective equipment use in a UK intensive care unit during the COVID-19 pandemicM. Chotalia¹; JE. Alderman¹; K. Hook²; I. Ewington²; AM. Johnston²; D. Balthazor²; J. Patel¹¹Birmingham acute care research group, University of Birmingham, Birmingham, United Kingdom; ²Critical care, Queen Elizabeth Hospital Birmingham, Birmingham, United Kingdom**Correspondence:** M. Chotalia*Intensive Care Medicine Experimental* 2020, **8(2)**: 001361

Introduction: Healthcare workers are at high risk of contracting Severe Acute Respiratory Syndrome Coronavirus-2 (SARS-CoV-2) pneumonia from either infected patients or staff [1]. Whilst effective use of personal protective equipment (PPE) is essential, sourcing adequate supplies has been a global challenge. [2].

Objectives: To perform a cross-sectional study at two time points during the COVID-19 pandemic to estimate the type and quantity of PPE being used in the intensive care unit.

Methods: This was a single-centre, prospective study at the Queen Elizabeth Hospital Birmingham. PPE use was in line with Public Health England guidance for ICUs [3] and all staff entering the COVID-19 ICU wore Level-3 PPE. Redeployed non-clinical military and outpatient hospital staff were trained as donning and doffing officers to ensure staff followed the PPE protocols. Donning officers recorded the type of PPE used every time a staff member entered the ICU. This was documented for each day, over two sampling periods (19th-30th March and 18th-28th April) on one of our three dedicated COVID-19 ICUs. Continuous data is presented as mean (\pm SEM) and compared using a Student's t-test. Categorical data is presented as % and analysed using a chi squared test. A p value of < 0.05 determined statistical significance.

Results: Over the total period of data collection, 5,066 donning episodes were recorded. The daily mean number of patients was 22 (\pm 2) and staff working on the area was 101 (\pm 6). The daily mean number of donning episodes was 300 (\pm 26), equating to approximately 3 episodes per healthcare worker or 14 episodes per patient each day.

Fig.1

Colic mucosa showing a "focal explosive" lesion typical of pseudomembranous colitis characterized by a mushroom-like mass of mucus and neutrophils

The colic wall presents oedema and acute inflammation with foci of necrotizing vasculitis and intravascular neutrophils

86% of donning episodes were with an FFP3 face mask and 14% used a powered respirator.

In the second study period, the number of staff and patients increased, as did the number of donning episodes (see Table 1). A greater frequency of donning episodes relative to the number of staff on the unit was also observed (3.4 vs 2.4 episodes per staff member per day) and a higher proportion of staff wore FFP3 masks rather than powered respirators (FFP3 mask use: 89.3% in 2nd period vs 77.4% in 1st period; $p < 0.0001$).

Eleven percent of nursing staff were on leave due to illness each week. Staff sickness rates were equivalent between the two periods of data collection (10.6% vs 10.5%). Non-clinical nursing staff (working in administrative roles) had a sickness rate of 5.4% over the same study period.

	Daily average (all)	Daily average (1st)	Daily average (2nd)	pvalue
Patients (n)	22 (±2)	16 (±2)	27 (±1)	<0.0001
Healthcare Worker (n)	101 (±6)	84 (±4)	116 (±8)	0.004
Donning episodes	300 (±26)	199 (±6)	390 (±21)	<0.0001
Donning episodes per HCW	3	2.4	3.4	N/A
FFP masks (n)	257 (±27)	154 (±9)	348 (±22)	<0.0001
Powered respirators (n)	43 (±3)	45 (±5)	42 (±5)	0.80
Gloves (n)	321 (±25)	244 (±12)	398 (±22)	<0.0001
Surgical gowns (n)	300 (±26)	199 (±6)	390 (±21)	<0.0001
Visors / goggles (n)	257 (±27)	154 (±9)	348 (±22)	<0.0001

Conclusion: Vast quantities of PPE were used on a daily basis during the UK-peak of the COVID-19 pandemic to maintain the safety of staff and patients. Whilst the number of healthcare workers increased between the two periods, PPE use relative to the number of staff was also greater. This may be explained by the introduction of additional support teams to deliver interventions as patient numbers grew (proning, line insertion et cetera). FFP3 masks were more frequently used compared to powered respirators.

Compared to prior reports [1] a lower rate of illness in healthcare workers was observed in our study, and sickness rates in clinical nursing staff were only slightly higher than their non-clinical colleagues. This indicates a lower rate of healthcare worker infection - which could in part be explained by the PPE strategy used in our ICU.

In conclusion, PPE use and preference changed over two time periods in one area of a single ICU during the COVID-19 pandemic. As equipment is scarce but in high demand, healthcare departments should be encouraged to regularly audit PPE use to better estimate clinical need.

Intensive Care Medicine Experimental 2020, **8(2)**: 001368

Introduction: SARS-CoV-2 infection, originating from Wuhan, China is the underlying cause of COVID-19 disease [1]. The first known patient with COVID-19 disease was admitted to our intensive care unit (ICU) at the Royal Gwent Hospital (RGH), Newport, Wales on the 9th March.

Objectives: In this case-series analysis we describe the epidemiology of the first wave of COVID-19, focusing on the interplay between ethnicity and social deprivation, by using data from the first 60 days at the RGH ICU.

Methods: Our prospective service evaluation recorded anonymised data on patient age; sex; BMI; postcode; ethnicity; Welsh Index of Multiple Deprivation (WIMD) score [2]; need for any assistance with daily activities; APACHE II score; time from hospital admission to ICU, and ICU mortality. Background data on ethnicity for the hospital catchment area was obtained from the UK Census data 2011 (Office for National Statistics).

Results: The Black, Asian and Minority Ethnic (BAME) population, while being only 5% of the background population, represented 35% of ICU COVID-19 admissions (18 of 52) and 35% of deaths (6 of 17). Within the BAME group, 72% (13 of 18) of patients were from geographical areas representing the 20% most deprived (lowest quintile) in Wales, versus 27% of Caucasians (9 of 33). When looking at deaths by ethnicity, more occurred within the lowest deprivation quintile in the BAME group (4 of 6 deaths) compared to the Caucasian group (3 of 11).

Conclusion: We found that patients from the BAME group are at significantly higher risk of ICU admission and death from COVID-19, despite an overwhelming Caucasian background population (95%). We observed a striking interaction between deprivation and ethnicity, which may be multifactorial, including greater prevalence of comorbidities; increased community spread; genetic polymorphisms; or other unidentified factors [3-5]. These factors need further investigation and evaluation.

Intensive Care Medicine Experimental 2020, **8(2)**: 001378

Introduction: Convalescent plasma containing virus specific antibodies has been used before and was associated with reduced mortality during Spanish flu, SARS, and H1N1 influenza A pandemics.

Therapeutic plasma exchange (TPE) has shown some benefits for cytokine clearance in sepsis with multiorgan failure in the past and in 2009 H1N1 influenza A pandemic. We combined both therapies together for COVID-19 treatment.

Objectives: To evaluate safety and efficacy of therapeutic plasma exchange followed by convalescent plasma therapy in critically ill patients with severe acute respiratory syndrome corona virus 2 (SARS-COV-2) infections.

Methods: 6 patients with laboratory-confirmed COVID-19 and acute respiratory distress syndrome (ARDS) were treated with one session TPE followed by 500 ml convalescent plasma transfusion in addition to standard treatment who met the following criteria: severe pneumonia with rapid progression and life threatening illness (PAO₂/FIO₂ <300 and mechanical ventilation, shock, organ failure). The study was conducted at Mediclinic City Hospital, Dubai, UAE from April 20, 2020 to June 20, 2020. Outcomes measured were death from any cause, time to negative SARS-COV-2 PCR, time to removal of mechanical ventilation after intervention, clinical (body temperature, Sequential Organ Failure Assessment (SOFA) score, PAO₂/FIO₂), biochemical (ferritin, D-dimer, CRP, LDH, procalcitonin) and radiological parameters before and after therapy. Mechanical ventilation days, ICU length of stay, hospital length of stay were also measured.

Results: Patients were in the age range of 36-65 years, 4 males and two females. All patients were receiving mechanical ventilation, Methylprednisone and therapeutic anticoagulation. All the patients survived and were discharged home. Time to negative SARS-COV-2 RT-PCR was 1-18 days and time to removal of mechanical ventilation was 2-41 days after intervention. Out of six, 4 patients were off mechanical ventilation within 7 days of therapy. 3 out of 6 patients had normal body temperature, 5 had improved PAO₂/FIO₂ within 48hrs. SOFA score improved by 2 points within 48 hrs in 3 patients and within 5 days in another 2 patients. All the biochemical parameters improved within 48 hrs except D-dimer which worsened in 3 patients after therapy. Chest X ray showed improvement in pulmonary lesions within 48 hrs and significant improvement by day 7. Mechanical ventilation days, ICU and hospital length of stay was 8-42, 10-42 and 20-60 days respectively.

Conclusion: Critically ill Covid-19 patients with ARDS treated with therapeutic plasma exchange followed by convalescent plasma in addition to standard therapy showed improvements in clinical, laboratory, and virological parameters. Although this uncontrolled limited case series had very good success rate, further evaluation in clinical trials is necessary in order to corroborate the findings.

Intensive Care Medicine Experimental 2020, **8(2)**: 001387

Introduction: On March 2020, World Health Organization (WHO) declared COVID-19, a disease caused by the SARS-COV2 virus, as a pandemic. Some studies have highlighted advanced age, male sex, and other comorbidities as cardiovascular diseases, diabetes, and pulmonary diseases, increase the risk and severity of the COVID-19. There have been few molecular level hypotheses raised for the variable susceptibility to disease and vulnerability to severe disease. Landsteiner's ABO carbohydrate moieties are genetically inherited. Some reports suggest a correlation between ABO blood group, cardiovascular diseases, and cancers, as well as typing and susceptibility to certain infections, including COVID-19 infection.

Only few clinical studies demonstrated that there exists a relationship between infection risk and the blood groups, and how blood group O had a negative predictive effect, associated with a lower risk of infection and mortality, and the blood group A was correlated with a severe pulmonary damage.

Objectives: Main: To analyze a group of COVID-19 patients admitted to our Intensive Care Unit (ICU) between March-2020 and June-2020 by their blood group and Rh factor.

Secondary: To determine the frequency of main comorbidities, analytical results, ICU evolution, treatment needed, ventilation characteristics, and score on risk scales.

Methods: Observational, descriptive, retrospective study in COVID-19 patients admitted to our ICU in 3 months, using a database of 14 patients, with previous defined blood group and Rh factor, and medical history, analytical results (at the admission, 2 days, 4 days, 6 days and 8 days later), ICU evolution, treatment needed (vasoactive drugs and COVID-19 drugs), ventilation characteristics and scores on the risk scales (APACHE, SOFA and SAPS II).

Results: The clinical characteristics of 14 patients included according to their blood group, were: main age of patients 63 (44–78) and the percentage of female patients was 57%. The most frequently detected blood group was type O with 57% amongst the COVID-19 patients. This was followed by group type A with 43%. Rh factor more detected was positive with 93%, being statistically significant the relation between female gender and positive Rh factor 54% ($p = 0.011$).

An important history of cardiovascular diseases was determined among these patients, highlighting high blood pressure 50% type O and 50% type A; obesity 50% type O and 37,5% type A, dyslipidemia 66% type O and 12,5% type, without statistically significant.

No important difference was found in the analytical results at the admission, 2 days, 4 days, 6 days and 8 days later; just highlight the main D-Dimer levels at the admission in ICU was substantially more elevated in type A (4342 ng/ml) than O (1429 ng/ml).

Group type A had highest needs of vasoactive drugs: Noradrenaline 100% (62% Group type O), Dobutamine 50% and Adrenaline 16% (both 0% in Group type O), and also a 100% needed glucocorticoid treatment (62% Group type O).

The use of renal replacement therapy was prescribed for 50% of patients in Group type A, compared to 12,5% in Group type O, as well as the need of percutaneous tracheostomy (same percentages).

The ICU evolution was fateful in Group type A, with 50% of death, compared to 37,5% in Group type O, without statistically significant differences. Likewise, the ICU evolution was worse in negative Rh factor patient.

Fibrinolytic therapies such as rtPA, or bronchodilator therapies with nitric oxide, were used for the treatment of refractory cases, in 33% of Group typ A, and in the negative Rh factor patient, unlike 7% positive Rh factor patients, being statistically significant ($p = 0,017$).

No differences in mechanical ventilation was found between both groups.

Finally, in relation to the score on risk scales, SAPS- II after the admission of patients with positive Rh factor, had a mean of 34,63, statistically significant ($p = 0,012$); we did not detect differences in SOFA or APACHE scales after the admission.

Conclusion: Group type O and positive Rh factor were the most frequent in our COVID-19 patients, being statistically significant the relation between female gender and SAPS-II score after admission with positive Rh factor. Although Group type A patients were less numerous, they needed more vasoactive drugs, refractory treatments and had worse ICU evolution.

Intensive Care Medicine Experimental 2020, **8(2)**: 001391

Introduction: Providing an efficient care to the patients of the most severely affected category – ICU patients – has become one of the serious problems appearing in the COVID-19 pandemics [1]. A typical patient's clinical portrait in ICUs of COVID centers is very similar in different countries, however, the key to improve the treatment results for critically ill patients has not yet been found [2].

Objectives: The aim of the study is to identify predictors of the severe pneumonia caused by the SARS-CoV-2 virus in patients admitted to an intensive care unit (ICU) of the COVID-center of the Federal Research Clinical Center.

Methods: In this report, we describe the clinical, laboratory and instrumental data of 70 patients admitted to the ICU, and discuss the found predictors of the severe COVID-19 pneumonia course.

Results: The mortality in the ICU was 48.9%, the mortality among the patients required mechanical ventilation was 57.9%. The following factors have been determined which contribute to the development of the severe course of the disease and to the risk of the mortality: male gender ($p = 0.021$), age older than 70.5 years ($p = 0.014$), initial lymphocytopenia of lower than $0.98 \times 10^9/l$ ($p = 0.014$), neutrophil to lymphocyte ratio of higher than 7.75 ($p = 0.004$), D-dimer level of higher than $0.85 \mu g/ml$ ($p = 0.001$), IL-6 of higher than 184.7 pg/ml ($p = 0.011$), procalcitonin of higher than 0.22 ng/ml ($p = 0.009$), hyperglycemia of higher than 9 mmol/l , signs of myocardial damage (high-sensitive troponin T of higher than 22 pg/ml ($p = 0.005$), echocardiography data), and a severe vitamin D deficiency (lower than 9.9 ng/ml , $p = 0.044$).

Conclusion: Clinical features of the patients change in course of pandemic. These are influenced by changes in treatment approaches and new discoveries in disease pathophysiology. Above mentioned predictors of severe course of disease is partly modifiable and we are able to influence them and perhaps achieve better results in treatment of severe patients with COVID-19.

Intensive Care Medicine Experimental 2020, **8(2)**: 001394

Introduction: The COVID-19 is considered as the major pandemic that we have experienced in the last century. Therefore, the management of the critically ill patients with COVID-19 is extremely important. The need for intensive care might differ according to institutions or even countries, depending on the demand and supply ranging from 5% to 32%. ICU mortality due to COVID-19 varies from 16% to 78% according to different studies. As of July 28th, 2020, a total of over 270000 COVID-19 cases and 2800 deaths have been reported in Saudi Arabia. No data available concerning the characteristics and outcomes of severe COVID-19 patients in the Kingdom.

Objectives: To describe the demographic and clinical characteristics and report our management and the outcomes of patients admitted for severe COVID-19.

Methods: Retrospective descriptive observational cohort study was conducted, from Mars 25, 2020, to July 28, 2020, in King Fahad armed forces hospital, Kingdom of Saudi Arabia. We included all adult patients with confirmed severe COVID-19 and required ICU admission or ICU management outside ICU. We collected baseline data on demographics, clinical presentation, laboratory, arterial blood gas, ventilation setting, the management, and the outcomes.

Results: Of the 110 patients included in the study, 52 (47.3%) were admitted in ICU and the remaining patients were followed by ICU team in the ward. The median (IQR) age was 62 (54-70) years and 74 (67.3%) were male. 97 patients (88.2%) had at least one comorbidity, mainly diabetes mellitus (70%) and hypertension (65.5%). The median (IQR) of SOFA score and APACHE II score were 4 (3-5) and 9 (7-13) respectively. The median time from first symptom to ICU team management was 7.0 days. All patients had acute respiratory failure and 34 patients (30.9%) had combined others organ damage. The lymphopenia less than $1.0 \times 10^9/L$, D-dimer more than 1 mcg/mL and high ferritin occurred in 49%, 54.5% and 85.5% respectively. The respiratory support was needed for 90 patients (81.8%), among them 86 patients (78.2%) received continuous positive airway pressure (CPAP). Invasive mechanical ventilation within the first 24 hours of admission occurred for 8 patients (7.3%). Moderate to severe acute respiratory distress syndrome (ARDS) was observed in 71.8% of the patients and the median (IQR) PaO₂/FIO₂ was 152 (123-191). The median FIO₂ was 45% (IQR, 35%-60%). Awake proning with CPAP was performed for 31 patients (28.2%). All patients had negative fluid balance during at least the first 3 days of ICU team management. Methylprednisolone was administered to 78 patients (71%) and empiric antibiotics to 106 patients (96.4%). During hospital stay, 20 patients (18.2%) required tracheal intubation and the median (IQR) length of stay was 8 (5-11) days. Among the 110 patients, three were still in the ICU, and 8 (7.5%) had died.

Conclusion: In this single center case series of severe COVID-19, all patients had acute respiratory failure and the majority needed respiratory support mainly by CPAP and the rate of mortality was low, less than 8%.

Intensive Care Medicine Experimental 2020, **8(2)**: 001397

Introduction: Catheter-related bloodstream infection (CRBSI) and other infections have been frequent in patients admitted in ICU for

Covid -19. However, many cultures collected with suspected infection have been negative or contaminated.

Objectives: We aim to analyze the microbiological isolates from blood cultures in patients admitted for Covid-19 and Catheter-related bloodstream infection (CRBSI) in our Unit during the months of the Covid-19 pandemic.

Methods: Retrospective, descriptive, observational study of the microbiological isolates in blood cultures and catheter tips in patients admitted for Covid-19 from March to May 2020 in the ICU of a third-level hospital. The data we used was obtained from the ENVIN-HELICS registry. The following were analyzed: demographic data, number of blood cultures extracted, number of positive blood cultures, percentage of Gram positive, Gram negative and fungal organisms, number and incidence density of CRBSI, hospital mortality and ICU mortality.

Results: 60 patients were included, 48 (80%) were men and 12 women (20%), median APACHE II score 14.1 points, median age 60.47 years. Some blood culture was extracted from 51 patients (90%), 31 of them (53.4%) had the blood culture positive. In total, 163 blood cultures were performed: 73 were positive (45%) and 90 negative (55%). Of the positive results, 80% correspond to Gram positive microorganisms, 9% to Gram negative and 9% to fungi. The most frequent microorganism was coagulase-negative Staphylococcus (34%).

69 catheter tips were removed. In 21 (30.4%) microorganisms were isolated: gram positive 60%, gram negative 17% and fungi 23%. The remaining 69.6% were negative. There were 12 CRBSI in a total of 1285 days of central venous catheter (9.34 bacteremia/1000 days of central venous catheter). Utilization ratio = 1.02.

ICU mortality was 33% and hospital mortality 38.98%.

Conclusion: Our study reported a high number of blood cultures sent and catheters removed with suspected infection. Although most blood cultures were negative, there is a high rate of Gram-positive isolated and catheter-related infections, probably due to the high number of devices used and the severity of the disease. Despite these data, mortality in our ICU is similar to that described in the literature.

This study makes us think that in an unknown Scenario and with exceptional protection measures, we cannot forget "zero projects" as a measure to lower infection rates and to establish improvement points in ICUs.

Intensive Care Medicine Experimental 2020, **8(2)**: 001424

Introduction: SARS-CoV 2 (COVID-19) critical ill patients with pneumonia requiring mechanical ventilation (MV) frequently present endotracheal tube (ET) obstruction episodes. ET obstruction and ET emergent change procedure may increase the risk of Intensive Care Unit (ICU) complications with prognostic implications.

Methods: Retrospective observational trial. Patients with confirmed SARS-CoV-2 (COVID-19) pneumonia requiring mechanical ventilation longer than 48 hours between March 6th and May 6th 2020 were included. In patients with ET obstruction and ET emergent change, the following events were recorded: new onset ventilator associated pneumonia (VAP), pneumothorax and mortality related to ET change. Intubation days, ICU-stay and mortality were compared between both groups (patients with ET obstruction vs patients without ET obstruction).

Results: 49 COVID-19 patients with pneumonia required MV. Two patients died in the next 48 hours and were excluded. 47 patients were included. Mean age was 61,7 (+/- 1,6) years old, 35 (74,4%) male. Mean APACHE 2 was 14,4 (+/- 0,8), mean SAPS 2 34,1 (+/- 1,3). Global mortality was 29,7%. Mean ICU-stay was 29 (+/- 2,6) days and mean intubation days 24 (+/- 2,4). In 28 patients (59,5%) ET was changed at least once. Mean ET change day was 11,1 (+/- 1,3) . Among ET change

group, 14,3% had pneumothorax; 60,7% developed VAP in the follow 72 hours, 58,8% of which had new germ isolation. After comparing both groups, patients who needed ET change stayed longer intubated (28,4 vs 17,7, $p < 0,05$) and admitted in ICU (34,5 vs 21 days, $p < 0,05$). There were not significant differences in mortality. One patient died (3,6%) secondary to a ET change.

Conclusion: More than half SARS-CoV 2 intubated critical ill patients presented ET obstructions. These episodes may increase the risk of developing complications such as VAP and pneumothorax, which determine longer intubation period and ICU-stay. Strategies headed for limiting and preventing ET obstruction episodes may decrease morbidity during MV, having an impact in ICU-stay.

Intensive Care Medicine Experimental 2020, **8(2)**: 001439

Introduction: The recent SARS-CoV-2 pandemic has motivated the evaluation of several therapeutic agents as treatment for the coronavirus disease 19 (Covid-19). Remdesivir has been shown to be superior to placebo in shortening the time to recovery in adults hospitalized with Covid-19(1).

Objectives: After the early access program implementation in Portugal, we began to treat Covid-19 patients with remdesivir according to the published criteria. We aimed to determine the impact of remdesivir in the outcomes (ICU length of stay, SOFA score improvement and adapted clinical eight-category ordinary WHO scale (ACECOWS) improvement, at ICU discharge date) of patients admitted to ICU with SARS-CoV-2 pneumonia, as compared to supportive care (SC) (with no use of off-label drugs). Secondary objective was to determine the impact of remdesivir in the duration of mechanical ventilation of Covid-19 patients and ICU-mortality and hospital mortality of both groups.

Methods: We performed a single center retrospective cohort study. All adult patients admitted in ICU with SARS-CoV-2 pneumonia were eligible for the study. SARS-CoV-2 pneumonia was diagnosed using clinical and radiologic and microbiological criteria. Statistical assessment of the outcomes was made between remdesivir-treated group vs SC group.

Results: 43 patients (mean age 61 years, 65% males) were included in the analysis (36 in SC group and 7 in the remdesivir group). The ICU length of stay (8.8 days vs 12.1 days, $p = 0.408$) and duration of mechanical ventilation (4.9 days vs 8.1 days, $p = 0.41$) were lower in the remdesivir-treated group. In addition, remdesivir-treated group was associated with greater SOFA score improvement ($p = 0.036$) and greater ACECOWS improvement ($p = 0.030$) at ICU discharge. Till now, no deaths were registered in the remdesivir-treated group, either during ICU or hospital stay in our cohort.

Conclusion: Despite our small cohort, remdesivir seems to be superior to SC in the treatment of Covid-19 patients, with a faster and more marked clinical improvement at ICU discharge.

Intensive Care Medicine Experimental 2020, **8(2)**: 001471

Introduction: During the UK peak of the COVID-19 pandemic, many intensive care units expanded bed capacity rapidly. In our own unit, our bed capacity peaked at 258%, with 37 days spent above 100% capacity. Combined with this; redeployment of staff from other areas and use of personal protective equipment understandably leads to concerns about increased rates of hospital acquired infection, or cross-contamination between patients. We sought to examine our own experience through analysis of blood stream infections.

Methods: We identified all patients admitted to our intensive care between March and May 2020 with COVID-19 pneumonia. Data was collected on demographics and outcome from our local critical care database Wardwatcher, and positive microbiology from blood cultures obtained peripherally or from invasive lines.

We categorised positive results into pathogenic organisms, likely contaminants, and low pathogenicity organisms associated with nosocomial infection. To review results over time, we categorised into first 48 hours, 3 to 7 days, 7 to 21 days, and after 22 days of ICU stay. Analysis was performed in Excel.

Results: From March to May 2020, we admitted 52 patients with COVID-19 pneumonia of whom 96% were invasively ventilated. 71% of patients were male, median age 57, median length of stay 16 days and overall ICU mortality was 27%. All ventilated patients had arterial and central venous catheters (CVC) placed, with those experiencing longer stays having lines replaced if concerns about possible line infection.

Overall we documented 61 positive blood culture results of which 16% were pathogenic (*Klebsiella pneumoniae*, and *Candida albicans*), the majority of these grew from samples from CVCs and represent 3 separate patient episodes (6%). 31% were nosocomial associated organisms (*Enterobacter* species, one vancomycin resistant enterococcus faecium), again the majority from CVC samples.

Over time, we saw the majority of positive blood cultures occurring after 7 days, with both pathogenic and nosocomial organisms peaking between 7 to 22 days (see Fig 1).

Conclusion: Our results demonstrate similar rates of pathogenic blood stream infections compared to published literature of 8%(1), the majority of which occurred after 7 days in ICU, similar to a recently published cohort from UK(2). This concurs with other published evidence on the need for focus on infection control measures to reduce morbidity in this patient cohort when faced with the unique challenges associated with a pandemic.

Intensive Care Medicine Experimental 2020, **8(2)**: 001474

Introduction: Respiratory infection is a frequent reason for ICU admissions or complications. It is a condition associated with substantial morbidity and mortality. Multiple organ failure is often observed in this setting. Timely management and appropriate antibiotic selection are of paramount importance in order to achieve favorable outcomes. Biofire® FilmArray® Pneumonia Panel Plus is a multiplex PCR platform that may rapidly identify the pathogen. It may detect 18 bacterial and 8 viral pathogens commonly associated with CAP, as well as 7 antibiotic resistance genes.

Objectives: We examine the impact of the use of Biofire® FilmArray® in the management of ICU patients with severe respiratory infections requiring mechanical ventilation in a six bed general ICU of a provincial hospital in Northern Greece.

Methods: It is a retrospective observational study of the impact of the use of Biofire® FilmArray® in the treatment of patients with severe respiratory infections and respiratory insufficiency requiring mechanical ventilation during one year. The parameters analyzed included: demographics, microbiological and routine laboratory data, use of antibiotics, clinical outcome. Also, we defined two groups, depending on whether Biofire® FilmArray® was tested within 48 hours from admission or not.

Results: A total of 19 patients were included in the study. In 13 of them, Biofire® FilmArray® was positive. Ten tests revealed the presence of multiple pathogens; in 5 tests, 9 “fastidious” (i.e. difficult to grow without specific conditions) microbes were detected, (Haemophilus inf, Streptococcus pne), 6 were positive for viruses (Influenza A, Rhinovirus, Parainfluenza), 8 tests identified 12 common ICU pathogens (Acinetobacter, Klebsiella, Pseudomonas), in two cases Legionella was diagnosed and in one case Moraxella. Routine cultures yielded negative results in most of these cases (84,6% bronchial secretions, 76,9% pharyngeal). The test results led to antibiotic treatment modification in 76,9%. In 4 samples the presence of antibiotic resistance genes was noted and appropriate antibiotics were selected.

Conclusion: The introduction and integration of Biofire® FilmArray® in the clinical practice, had a decisive impact in the treatment of the patients. This was demonstrated not only in minimizing the time to obtain the results, but also when considering that the routine cultures collected on admission to the ICU often yielded negative results. Thus, Biofire® FilmArray® provided a valid identification of the pathogen and, at the same time, allowed for a prompt de-escalation of the broad-spectrum antibiotics initially administered. In conjunction with the economic implications of this practice, sparing unnecessary antibiotic usage may be beneficial for both the patients and the antibiotic resistance patterns of the nosocomial flora.

001487**Do common CONTACT ISOLATION CRITERIA PREDICT THE CARRIER STATE OF MULTIDRUG-RESISTANT MICROORGANISMS IN CRITICALLY ILL PATIENTS?**

L. López-Rodríguez¹; D. Vasco²; D. Manzano²; F. Palacios²; JA. Lorente³

¹Intensive Care, University Hospital of Getafe, Madrid, Spain; ²Intensive care, University Hospital of Getafe, Madrid, Spain; ³Intensive care., University Hospital of Getafe. CIBER of Respiratory Diseases. European University, Madrid, Spain

Correspondence: L. López-Rodríguez

Intensive Care Medicine Experimental 2020, **8(2)**: 001487

Introduction: Despite the widespread use of contact isolation criteria (CIC) in critically ill patients, their ability to predict the carrier state of multidrug-resistant microorganisms (MDRO) has not been well defined.

Objectives: To determine the ability of commonly used CIC to predict the carrier state of MDRO in critically ill patients.

Methods: Patients admitted consecutively to the Intensive Care Unit (ICU) were studied. Inclusion criteria were all patients admitted from July 2018 to December 2019. Exclusion criterion was previous ICU admission.

Pharyngeal and rectal swabs were collected at admission and weekly for epidemiological surveillance cultures. The presence of any of the following CIC was registered: (1) hospital admission for longer than 6 days over the previous 3 months; (2) admission in a chronic health care facility; (3) known MDRO carrier; (4) antibiotic treatment for more than 6 days in the previous month; (5) receiving hemodialysis or peritoneal dialysis; (6) diagnosis of a chronic condition associated with colonization by MDRO; (7) transferred from another institution.

Sensitivity (Sn), specificity (Sp), positive predictive value (PPV) and negative predictive value (NPV) to predict the carrier state by MDRO were calculated for each of the criteria. Values are percentage and median (p25, p75). WASSPSS (Wise Antimicrobial Stewardship Support System) and SPSS V25.0 were used for the analysis. The local Ethics Committee approved the study.

Results: We studied 1,156 patients (age 70 [61-78] years, SAPS III 55.5 [47-66] points, ICU non survivors 42 [26.6%], women 50 [31.6%]) of whom 158 (13.7%) were isolated for having at least one of the CIC. Carrier state was confirmed by culture of the first surveillance sample in 40 patients. The 7 criteria were present, respectively, in 123 (12%), 11 (1%), 21 (2%), 76 (7%), 6 (1%), 15 (1%) and 24 (2%). For each criteria considered individually, Sn was <50% (except for criterion 1: Sn 67%) and PPV <30% (except criterion 3, PPV 52%). Each criteria considered individually had Es and NPV >90%. At least one of the CIC was found in 158 (15%) patients (Sn 80%, Es 88%, PPV 20%, NPV 99%).

Conclusion: Individual CIC, in general, have a very low Sn and a high Sp for the detection of MDRO carrier state. None of the CIC is useful enough to determine the carrier state, since Se and PPV (which should be interpreted with caution as it depends on the prevalence) are low. The use of a set of 7 CIC presents a moderate Se for the detection of MDRO carrier state.

Intensive Care Medicine Experimental 2020, **8(2)**: 001493

Introduction: De-escalation consists in the reappraisal of anti-microbial therapy as soon as antimicrobial susceptibility testing results are available, and may be achieved through replacing broad-spectrum antibiotics by narrow-spectrum drugs, or stopping components of an antibiotic combination. No study has been performed so far to explore this strategy on animal models, and its effect on microbial diversity and resistance genes in the microbiota and on the immune system remains unknown.

Objectives: Here, we aimed to study the effect of antibiotic de-escalation versus non de-escalation on a microbiota exposed to environmental anti-microbial resistance pressure, both on microbial diversity and resistance genes in the microbiota, but also on the immune system.

Methods: Mice were divided in three groups, whether they received amoxicillin, imipenem, or imipenem followed by amoxicillin. The ICU environment was recreated by co-housing antibiotic-treated mice with mice previously contaminated with carbapenemase-carrying *E.coli*. Stools were cultured in selective media supplemented with cefotaxime, ertapenem and colistin, and the stool DNA was extracted for PCR and whole metagenomics analysis. Blood cytokines were measured by ELISA.

Results: Stool culture revealed the carriage of carbapenemase-positive *E.coli*, confirmed by PCR in 7/8 mice in the imipenem group, 5/10 mice in the de-escalation group and 7/9 mice in the amoxicillin group ($p > 0.05$). Metagenomics analysis showed no difference in diversity and in antimicrobial resistance genes between groups. ELISA tests are still ongoing.

Conclusion: There were no difference between groups in terms of antimicrobial resistance emergence, as confirmed by culture, PCR and metagenomics techniques. Antibiotic de-escalation does not prevent the acquisition of resistance genes compared to narrow or broad-spectrum antibiotic regimen.

Serum ACE "1" levels in critically ill patients with COVID-19 disease

DJ. Kirkin¹; A. Gardner¹; S. Rodriguez-Villar²

¹Anaesthetics, King's College Hospital, London, United Kingdom; ²Intensive care medicine, King's College Hospital, London, United Kingdom

Correspondence: DJ. Kirkin

Intensive Care Medicine Experimental 2020, **8(2)**: 001509

Introduction: Genetic similarities with SARS-CoV-1, and subsequent biophysical data, suggested a role for Angiotensin Converting Enzyme 2 (ACE2) in the SARS-CoV-2 invasion of pneumonocytes^{1,2,3}. Subsequently, other proteins constituting the Renin-Angiotensin-Aldosterone System (RAAS) have been scrutinised for their relevance to the COVID-19 pathology. Such proteins may be pharmacological targets benefiting outcomes, or biomarkers of disease severity.

Angiotensin Converting Enzyme (ACE) performs a key role within the RAAS, cleaving angiotensin 1 to angiotensin 2 (ANG-2). ACE is prevalent in the pulmonary epithelium, and thus equally ANG-2. ANG-2 is a potent vasoconstrictor, and associated with inflammation, fibrosis and oxidative stress⁴. It has been implicated in COVID-19 disease severity, raised ANG-2 has been reported in cases of COVID-19⁵ and in mice studies of ARDS is associated with severe lung injury⁶.

While much literature focusses on the regulatory functions of ACE2 on ANG-2, we considered a potential role for measuring serum ACE to monitor disease severity. We hypothesised that unknown pathological mechanisms would modify serum ACE levels, given an increase in ANG-2. We were unclear whether this may be through a negative or positive feedback mechanism.

Objectives: To perform opportunistic isolated serum ACE levels on COVID-19 patients admitted to our Intensive Care Unit (ICU), during a 1-month period, to determine whether it was objectively altered during the disease state. This pilot study would justify future, systematic investigation.

Methods: Within the analysis period we tested 28 patients admitted to our District General Hospital ICU, London. Severe Acute Respiratory Syndrome Coronavirus 2 infection had been diagnosed by reverse-transcriptase polymerase-chain-reaction for 26 patients and 2 with compelling radiographic evidence. Data on ACE-inhibitor use was not available, though it is likely no patient used them within 7 days of testing.

Results: Of the patients tested, 26 had a normal serum ACE level (8-52 IU/L) representing 93% of the sample. One patient's level was objectively low (<5 IU/L), and another high (78 IU/L). The overall cohort mortality was 32%. Of note, both objectively abnormal patients died.

Conclusion: ANG-2 is regulated in its production by ACE, and removal by ACE-2. Any increase in ANG-2 activity may be resultant from an excess of the former, and/or a deficiency in the latter. Given the largely normal serum ACE amongst the population, it further implicates a downregulation of ACE-2 in the pathophysiology of severe COVID-19. Murine and *in vitro* studies of SARS-CoV-1 observed decreased ACE-2 expression following its interaction with the viral spike protein^{7, 8}.

ACE does not appear to be reliably modified during the COVID-19 disease process for use as a biomarker, or to justify future biochemical analysis; an important negative finding for ongoing investigations into the relevance of the RAAS pathway to COVID-19. Robust investigation of the changes to ANG-2 regulation, particularly relating to ACE-2, is required.

Is there A RELATIONSHIP BETWEEN THE CARRIER STATE OF MULTIDRUG-RESISTANT MICROORGANISMS AND MORTALITY IN CRITICALLY ILL PATIENTS?

L. López-Rodríguez¹; D. Manzano¹; D. Vasco¹; F. Palacios¹; JA. Lorente²

¹Intensive Care, University Hospital of Getafe, Madrid, Spain; ²Intensive care, University Hospital of Getafe. CIBER of Respiratory Diseases. European University, Madrid, Spain

Intensive Care Medicine Experimental 2020, **8(2)**: 001511

Introduction: The implementation of isolation measures in critically ill patients with multidrug-resistant microorganisms (MDRO) is resource consuming. However, whether patients who are carriers of MDRO have a higher mortality is not well established.

Objectives: To determine whether the carrier state (CS) of MDRO in critically ill patients is associated with mortality.

Methods: Patients admitted consecutively to Intensive Care Unit (ICU) from July 2018 to December 2019 were studied. Inclusion criteria were patients who met any of the following contact isolation criteria: (1) hospital admission for longer than 6 days over the previous 3 months; (2) admission in a chronic health care facility; (3) known MDRO carrier; (4) antibiotic treatment for more than 6 days in the previous month; (5) receiving hemodialysis or peritoneal dialysis; (6) diagnosis of a chronic condition associated colonization by MDRO; (7) transferred from another institution. Exclusion criterion was previous ICU admission. Demographic variables and SAPS III were recorded. Survivors (SUR) and non survivors (NONSUR) were compared using a univariate analysis (Chi-square test) and a multivariate logistic regression analysis, adjusting for SAPS III score. Values are percentage and median (p25, p75). The strength of the association was measured by the odds ratio (OR) and its 95% confidence interval (CI). The WASPSS (Wise Antimicrobial Stewardship Support System) and SPSS V25.0 were used. The local Ethics Committee approved the study.

Results: We studied 192 patients, NONSUR 52 (27.1%), CS 66 (34.4%). NONSUR, as compared to SUR were older (75.5 [65.0-79.0] vs. 69.0 [58.3-77.8] years, $p = 0.074$), had a higher SAPS III score (64, 5 [51.5-75.8] vs. 54.0 [45.0-62.0], $p = 0.001$), had a lower proportion of women

(17.5% vs. 82.5%, $p = 0.037$), and a similar proportion of patients with CS (18 [34.6%] vs. 48 [34.3%], $p = 0.548$). In univariate analysis, the mortality of CS versus non CS was not different (18 of 66 [27.3%] vs. 34 of 126 [27.0%], $p = 0.548$). In multivariate analysis, after adjusting for SAPS III score, CS was not significantly associated with mortality (OR 1,171; 95% CI 0.574-2.388, $p = 0.665$).

Conclusion: MDRO carrier state is not associated with increased mortality in critically ill patients.

INFECTIONS IN PATIENTS WITH COVID-19 AND ACUTE RESPIRATORY FAILURE requiring MECHANICAL VENTILATION

L. López-Rodríguez¹; F. Palacios¹; D. Vasco¹; D. Manzano¹; JA. Lorente²

¹Intensive care, University Hospital of Getafe, Madrid, Spain; ²Intensive care, University Hospital of Getafe. CIBER of Respiratory Diseases. European University, Madrid, Spain

Correspondence: L. López-Rodríguez

Intensive Care Medicine Experimental 2020, **8(2)**: 001516

Introduction: A more detailed knowledge of infectious complications in critically ill patients with COVID-19 may help the implementation of preventive measures and improve survival.

Objectives: To determine the prevalence of infections and the most frequent pathogens involved, and its impact on mortality, in patients with COVID-19 and acute respiratory failure requiring invasive mechanical ventilation.

Methods: We studied all patients admitted to our Intensive Care Unit (ICU) with the diagnosis of viral pneumonia due to SARS-CoV-2 and requiring invasive mechanical ventilation from March 8 to May 1, 2020. Patients transferred to another facility were excluded. The end point was survival status on day 60 after ICU admission. All patients were treated with selective digestive decontamination (oral and enteral neomycin, tobramycin and nystatin). Data are median (p25-p75) or n and percentage. Data were compared by the Chi square test or the Fisher exact test, as appropriate, or by the Mann-Whitney U test. Association between independent variables and survival status was analyzed by multivariate regression analysis adjusted by the SPAS III score, and measured by the odds ratio (OR) and its 95% confidence interval (CI). A p value < 0.05 was considered statistically significant. The local Ethics Committee approved the study.

Results: We admitted 118 patients during the study period, of whom 6 were transferred to another facility. Of 112 patients, age was 67 (59-62) years, 79 (70.5%) were male, SAPS III score was 50 (46-55), 53 (47%) had had at least one infection, and 41 (37%) had died by day 60. The prevalence of any infection was (48%, 46%), primary bacteremia (11%, 10%), secondary bacteremia (8%, 7%), catheter-related bacteremia (18%, 27%), urinary tract infection (UTI) (21%, 12%), for survivors and non survivors, respectively ($p > 0.3$ for all comparisons). Only ventilator associated pneumonia (VAP) differed in survivors and non survivors (4 of 71 [6%] versus 8 of 41 [20%], respectively, $p = 0.029$; adjusted odds ratio 4.47, 95% CI 1.11;18.02).

The most common pathogens in all isolates were: for primary bacteremia ($n = 12$ isolates), *S. faecalis* 6 (50%), other grampositive cocci 6 (50%); for secondary bacteremia ($n = 8$ isolates), gramnegative bacilli 4 (50%), *S. faecalis* 3 (38%); for catheter-related bacteremia ($n = 24$ isolates), *S. epidermidis* 12 (50%), *S. faecalis* 7 (29%); for VAP ($n = 21$ isolates), *S. aureus* 5 (24%), gramnegative bacilli 5 (24%), *S. faecalis* 2 (10%); for UTI (23 isolates), *S. faecalis* 9 (39%), gramnegative bacilli 8 (25%).

Conclusion: Infections are very prevalent in patients with COVID-19 and acute respiratory failure. VAP is strongly associated with survival.

S. faecalis and a variety gramnegative bacilli, along with *S. aureus* in the case of VAP, are the most prevalent microorganisms isolated in these patients. Measures aimed at pneumonia prevention could improve survival of critically ill patients with COVID-19.

SARS-Cov2 pneumonia: Highlights from our experience

I. Guzmán Adum¹; A. López Fernández¹; J. Machado Casas¹; J. Castaño Pérez¹

¹Intensive care unit, Hospital Universitario Virgen de las Nieves, Granada, Spain

Correspondence: I. Guzman

Intensive Care Medicine Experimental 2020, **8(2)**: 001517

Introduction: Since Covid19 was first described, almost 17 million cases and more than 665,000 deaths have been reported; therefore it is considered an emergency situation in public health of international interest. It is postulated that many characteristics of the most affected population have direct relationship with mortality.

Objectives: - To describe the main aspects related to the increased mortality of patients admitted with Covid19 in the ICU of the Virgen de las Nieves Hospital.

- Describe the differences between the characteristics and evolution of the patients admitted in our ICU and those published by other centers.

Methods: Observational, retrospective and analytical study that includes the patients admitted to the ICU with Covid19 between March and July 2020. A database was created in SPSS with the demographic characteristics of the patients, comorbidities, APACHE II in the first 24 h, laboratory tests related to inflammation and coagulation and type of respiratory support. Data was evaluated in terms of descriptive statistics with frequencies, means and standard deviation for variables with normal distribution and median with interquartile range for non-parametric distributions; Comparisons between groups according to mortality were made using the Student's T test for quantitative variables and chi-square for qualitative variables.

Results: Of the 58 patients included, 79% were men and 21% women. Their mean age was 60 years (+/- 11), their main comorbidities were: hypertension (54%), diabetes mellitus (35%), obesity (56%), COPD (28%), kidney failure (9%). ICU mortality 33%, hospital mortality 39%. SCID score mean was 1.94 (+/- 1.3). Analytically, the difference between the ferritin on the first and seventh day (delta ferritin) stands out with an average of 306 (+/- 2190), the comparison of delta ferritin between the living and the dead had a p 0.029. Patients exclusively with IMV were 32 (54%) and combination of HFNO+IMV 17 (29%), average hours of HFNO prior to IMV was 6 (2-23), days of IMV 19 (10-26), APACHE II in patients with combined MV 12 (+/- 4) and exclusive IMV 15 (+/- 4) with a p = 0.007, pO2/FiO2 in patients with combined VM 148 (+/- 54), exclusive IMV 120 (+/- 45) p = 0.04, mortality of patients with combined VM 25% and exclusive VM 30% (p = 0.16).

Conclusion: -Delta ferritin and not the ferritin peak is independently associated with mortality. The lower the ferritin clearance capacity is, the higher the mortality.

-Patients who received HFNO prior to IMV had similar mortality to those with IMV since the admission, contrary to what was postulated regarding self-inflicted lung injury. We believe that these findings are related to the fact that patients with the combined approach had significantly lower APACHE II and higher pO2/FiO2.

-Despite what has been published regarding the importance of coagulopathy, according to the diagnostic scale for sepsis induced coagulopathy, our patients did not present coagulation disorders.

²Unidad de apoyo a la investigación, facultad de medicina, Universidad Francisco de Vitoria, Madrid, Spain

Correspondence: L. Castro-Bournissen

Intensive Care Medicine Experimental 2020, **8(2)**: 001518

Introduction: Carbapenemase-producing Enterobacteriaceae (CPE) can cause healthcare-associated infections with high mortality rates.

Objectives: We analysed an outbreak of NDM carbapenemase in an increased capacity (35 beds) usual 12-bed ICU during the COVID-19 pandemic peak in Madrid.

Methods: Retrospective cohort study of patients suffering from SARS CoV-2 infection admitted to the ICU and other areas converted into ICU in Hospital de Mostoles in Madrid, Spain, during the peak of COVID-19 pandemic from March to June 2020. We collected data from electronic medical records on demographics, Simplified Acute Physiology Score III (SAPS III), comorbidities, type of ICU where the patient was admitted, treatments received prior to the carbapenemase outbreak, length of ICU admission and mortality in ICU.

Results: 13 (15.85%) patients over 82 critically-ill patients with SARS CoV-2 infection admitted to ICU suffered from carbapenemase infection (69%) or colonisation (31%). Mean age was 61 and 84.6% were men. All patients except one had been admitted first to an ICU-converted area (92%), including operating theatre, before moving, eventually, to our ICU.

COVID 19-specific treatment, administered according to our Hospital protocol, included Ceftriaxone and Azithromycin in 92.3% of the 13 patients, only one received Ceftriaxone alone; 100% received Lopinavir/Ritonavir, Hydroxychloroquine and steroids (Methylprednisolone or Dexametasona), 53% Tocilizumab and Baricitinib and 15% Anakinra and Beta-Interferon. All 13 patients had received, during ICU admission, broad-spectrum antibiotics. Mean length of stay in ICU was 24.2 days. Carbapenemase infection included 38.5% pneumonia, 15.4% tracheobronchitis and one UTI. All patients were treated with Ceftazidime-Avibactam plus Aztreonam as in vitro synergy was proven in the Hospital Lab. Mean SAPS III score 60.1 and mortality 38.5%.

Conclusion: A significant number of our critically ill SARS CoV-2 patients suffered from different multidrug resistant bacterial infections. 13 (15.85%) patients of the entire cohort of 82 developed NDM-1 carbapenemase. They had a high mortality rate despite directed antibiotic therapy. Several factors may have contributed to the appearance of this outbreak in our Unit: high antibiotic selection pressure and extensive use of immunosuppressant therapy, workload burden, deficient implementation of infection control protocols generally in place in Spanish ICUs most possibly associated to working areas not usually used as ICUs (open wards and operating theatres, health professionals unfamiliar with protocols) and lack of active surveillance cultures.

Correspondence: P. Sánchez Díaz

Intensive Care Medicine Experimental 2020, **8(2)**: 001519

Introduction: Secondary infection in critically ill patients with COVID-19 is poorly understood. It is challenging to discriminate between

isolated COVID-19 viral and extra bacterial or fungal infection and there is paucity of data, mainly in critically ill patients (1). We investigated the secondary infection rate in COVID-19 critically ill patients, risk factors for infection and mortality.

Methods: We performed a retrospective analysis of critically ill COVID-19 patients admitted to the Critical Care Unit (CCU) of the Hospital Universitario La Paz (Madrid, Spain), a 1300-bed teaching hospital, between 16 March 2020 and 17 May 2020. In that period a total of 3002 patients with COVID-19 were admitted to hospital, and our unit had a total of 83 beds during the pandemic period. All patients that needed invasive mechanical ventilation were included. We recorded patient demographic data, microbiology data and incidence of secondary infection during CCU stay, including ventilator associated pneumonia (VAP) and nosocomial bacteremia (primary and secondary), according to Center for Disease Control (CDC) criteria.

A total of 107 patients with a mean age 62.210.6 years were included. Incidence of secondary infection during CCU stay was 43.0% (46 patients), including nosocomial bacteremia (32.1%, 34 patients) and VAP (32.7%, 35 patients).

Results: In univariate analysis, age and coronary arterial disease were related to development of secondary infection. Age remained as an independent predictor of secondary infection in multivariate analysis (OR 1.053, 95% CI 1.010-1.098, $p=0.015$). Nor the use of systemic corticosteroids and tocilizumab was related to secondary infection.

Overall hospital mortality by 30 June 2020 was 68.2%. Mortality was higher in older patients (mean age 65.0 8.1 vs. 56.112.8 years, $p=0.001$), in patients infected by antimicrobial resistant pathogens (94.1% vs. 63.3%, $p=0.012$) and in case of secondary infection (82.6% vs. 57.3%, $p=0.006$). Corticosteroids and tocilizumab administration was not related to mortality. Age and infection by antimicrobial resistant pathogens were independent predictors of mortality in multivariate analyses (OR=1.091, 95% CI 1.039-1.145, $p<0.001$; and OR=8.742, 95% CI 1.069-71.485, $p=0.043$, respectively).

The incidence of secondary infection in critically ill COVID-19 patients in our study is high (43.9%), higher than reported by Ferrando et al (4), with an incidence of respiratory bacterial infection and bacteremia of 27.15% and 26.24%, respectively, and Yang et al (5) (incidence of pneumonia and bacteremia of 11.5% and 2%, respectively). Feng et al declared an incidence of secondary infection of 34.4% in the more severe subgroup of COVID-19 patients (6). Our cohort includes only patients under invasive mechanical ventilation, what may explain partially these differences. An important finding of our study is the lack of relationship of corticosteroids and tocilizumab use and development of infections and mortality, in contrast to findings published by Sommers et al, with a lower mortality rate but a higher infection occurrence with tocilizumab use (10). Ferrando et al also showed no association between corticoids and tocilizumab use and mortality (4). To our knowledge, this is the first study that focus on secondary nosocomial infections in mechanically ventilated, critically ill patients with COVID-19. Our study has several limitations: the retrospective nature of the analysis; the lack of invasive modalities to help diagnose VAP (bronchoalveolar lavage) due to infection control measures; and the absence of data regarding antibiotic treatment since appropriate empiric antibiotic treatment affects mortality.

Conclusion: In conclusion, our data suggest that the incidence of secondary infection is very high in critically-ill patients with COVID-19. Infections by antimicrobial resistant pathogens may have a significant impact in prognosis. We cannot rule out that infections by resistant pathogens was simply a marker of severity. Further studies on larger populations are needed to investigate secondary infection in critically ill COVID-19 patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 001534

Introduction: Rapid identification of pneumonia-causing organisms is challenging in the emergency department setting. Delayed identification of organisms results in improper antibiotic selection and administration. A point-of-care, nebulized urea breath test for pneumonia caused by urease-producing bacteria could aid in proper antibiotic selection, but the safety of nebulized urea has not yet been established. We report initial safety outcomes and study feasibility in an ongoing investigation of this test. We further combine sputum and oropharyngeal microbiome data to assess the potential utility of the inhaled urea breath testing.

Methods: We enrolled a pre-defined safety cohort of 15 emergency department subjects with radiographic and clinical evidence of pneumonia, and who were planned for outpatient treatment. Subjects in this cohort completed inhalation of a nebulized preparation of 50 mg 13C-urea dissolved in 3 mL of sterile water. Breath samples were collected before and after inhalation of 13C-urea and analyzed for exhaled 13CO₂. Adverse events (AEs) were recorded from time of enrollment until completion of telephone follow-up at 48-96 hours post nebulization. Exhaled 13CO₂ was measured before and after 13C-urea nebulization to calculate a normalized change from baseline. Student's T-test was used to determine significance of change over

baseline. We further enrolled 54 subjects admitted for inpatient treatment of pneumonia in a broader safety and feasibility cohort. Forty-six patients completed telephone follow up. Tracheal aspirate and saliva samples were isolated from these patients for microbiome analysis.

Results: Initially, we screened 257 subjects for the study and excluded 242 for clinical signs of severe disease (Mild, self-limited cough was noted in 3 cases and nausea in one case after administration of 13C-urea. One episode of syncope was noted but was determined to be an exacerbation of a pre-existing condition and not related to the study product. From both cohorts, eight patients were determined to have significantly elevated exhaled 13CO₂ and were found in post-hoc chart review to have high suspicion for bacterial pneumonia including elevated procalcitonin levels or bilateral pneumonia on imaging.

Conclusion: Mild cough was common after urea administration, though all subjects were able to complete nebulization. There were no reports of clinical deterioration related to the study drug. This study establishes a preliminary safety profile of inhaled 13C-urea in subjects with pneumonia. We noted significantly elevated exhaled 13CO₂ in eight subjects and are currently analyzing sputum microbiome data to ascertain the potential utility of the inhaled urea breath test.

Performance characterization of a new tracheostomy tube with subglottic suction port

U. Borg¹; C. Cobb¹; K. Bull¹

¹Medical affairs, Medtronic Surgical Solutions, Boulder, United States of America

Correspondence: U. Borg

Intensive Care Medicine Experimental 2020, **8(2)**: 001537

Introduction: Introduction: Tracheostomy is a common procedure performed for the management of upper and lower airway conditions. There is evidence that secretions draining from the upper airways can collect on the top of the tracheostomy tube cuff and become a risk for tracheal aspiration resulting in infections [1]. Reports in the literature describes posterior tracheal wall injury from the subglottic suction port [2,3]. A new tracheostomy product (Voyager, Medtronic Boulder USA) has a suction port just above the cuff intended for evacuation of secretions collecting on top of the cuff. The new tracheostomy cannula has the suction port located in the lateral wall of the tube body. The purpose of this study was to characterize the suction performance and tracheal wall injuries in an animal model during mechanical ventilation.

Methods: Methods: 16 porcine underwent tracheostomy and received the Voyager tracheostomy tube. Eight animals (Group 1) had normal secretion viscosity (500centiPoise) liquid and 8 animals (Group 2) had thick simulated mucous (5000centiPoise) liquid infused at 3 ml/hour on top of the cuff. The subglottic space was suctioned every 15 minutes for the 4 hour duration of the study using the subglottic suction port. The suction method was 3 cycles of 15 seconds on and 10 seconds off at 100 cmH₂O negative pressure (Ohio Medical Push-To-Set™ Vacuum Regulator, OHIO Medical, Gurnee, USA)[4]. Fluoroscopic images and data collection were performed through 4 hours following placement of the device. At the completion, the trachea was removed with the Voyager tracheostomy tube in situ and the site of the suction lumen exposed. Changes in the tracheal wall was assessed through macroscopic observations and given scores of 0-4 where 0 is no injury and 4 is necrosis[5].

Results: Results: Both groups had equal amounts of secretions infused on top of the cuff, Group1 12.1 ml and Group 2 11.9 ml ($p < 0.29$) and in both groups secretion was recovered, Group1 10 ml and Group 2 8 ml ($p < 0.33$). Damage to the trachea from the suction port, Group 1 had 1 animal scored as 2 and 3 as 1 and Group 2 had 3 animals scored as 1. No secretions were seen below the cuff in any Group.

Conclusion: Conclusion: There were no technical issues with the subglottic suction system and the suction lumen was patent during the experiment. The suction performance was similar between the groups with slightly less recovery of the 5000centiPoise fluid as could be expected. Most animals in both Groups had no tracheal injury (0) or mild erythema (1) at the site of the suction port. One animal in Group 1 had edema (2) at the site of the suction port. The Voyager tracheostomy tube design with the suction port in the lateral wall allows for adequate removal of subglottic secretions. Only clinical studies will completely elucidate the long-term effect of the new design.

Managing critically ill patient in a French General hospital during a large COVID-19 outbreak

J.Y. Mootien¹; V. Pointurier¹; E. Viot¹; L. Jandeaux¹; G. Labro¹; A. Dureau¹; C. Ionescu¹; C. Mathien¹; L. Pinto¹; Y. Rabouel¹; A. Poiidevin¹; K. Kuteifan¹

¹Medical icu, GHRMSA, Mulhouse, France

Correspondence: J.Y. Mootien

Intensive Care Medicine Experimental 2020, **8(2)**: 001554

Introduction: The city of Mulhouse, situated in the Alsace region, has been one of the largest European clusters of SARS-CoV-2 infection after a gathering of more than 2000 people during several days. The Groupe Hospitalier de la Région de Mulhouse Sud-Alsace (GHRMSA) is a hospital complex with a total capacity of 2612 beds including 20 medical ICU beds and 16 surgical ICU beds respectively, covering the needs of about 480,000 people.

Objectives: The first patient was admitted in our medical ICU on March 2nd for severe acute respiratory syndrome and during the following first week 18 patients was admitted for the same reason. Our bed capacity was rapidly saturated. According to the occurring trend, quick interventions and innovations appeared to be more than essential so as to handle the expected coming tsunami.

Methods: During the first week Non - COVID -19 patients were transferred to the surgical ICU so as to admit only COVID -19 patients in our unit but by the end of the first week our medical ICU bed capacity was saturated. During the coming weeks, scheduled surgical and medical activities have had to be cancelled. The cardiac surgery ICU(4 beds) was transformed to a COVID-19 ICU, 16 additional beds were added in five operative and post-operative rooms and the surgical ICU was converted in a sole COVID-19 ICU too. During the third week a national as well as an international cooperation was set up in order to transfer ICU patients to other cities, regions and countries by air or by train so as to cope with the massive influx of critical patients. Finally on the fourth week patients were transferred to a 30-bed field military intensive care hospital deployed on the hospital car park by the French military medical service: l'Élément Militaire de Réanimation du Service de Santé

des Armées (EMRSSA). This stood as an unprecedented experience in France.

Results: More than 340 critically ill patients have been admitted in our general hospital where more than 1500 patients have been hospitalized up to now. More than 140 critically ill patients have been admitted in our medical ICU and about 50% of them have been transferred to another hospital. 47 patients have been admitted in the field military intensive care hospital deployed on the hospital car park.

Conclusion: The organization set up so as to cope with the massive influx of critically ill patient will stand as an unprecedented experience in this setting. ICU medical and non-medical staffs working hand in hand with other colleagues and hospital administrators so as to take quick decision leaving behind frontiers and barriers provided a way to our will.

Intensive Care Medicine Experimental 2020, **8(2)**: 001589

Introduction: A significant number of patients admitted in ICU for Covid-19 have had bacterial isolates in respiratory samples. Many of these isolates correspond to colonizations, but other patients have developed bacterial superinfections during their evolution in the ICU, such as ventilator-associated pneumonia (VAP). Data extracted from the ENVIN-HELICS registry.

Objectives: Our objective was to analyze the number of positive bronchial aspirates performed, the number of bronchial aspirates with a positive result, the rate of VAP and the most frequent microorganisms.

Methods: Descriptive, observational, and retrospective study of bronchial aspirates that were performed in patients admitted with Covid-19 during the months of March to May 2020 in the ICU of a third-level hospital.

Results: 49 patients on mechanical ventilation were included, of which 36 (62%) had a bronchial aspirate culture withdrawn during their ICU stay. In 28 of them (77%) it was positive. In total, 90 bronchial aspirates were performed. 74 microorganisms were isolated: 11 (15%) were Gram positive microorganisms, 35 (57%) Gram negative and 28 (38%) fungi.

Conclusion: In patients admitted for coronavirus, the bacterial superinfection rates have been high, probably due to the severity of the patients and a high rate of use of MV. Most are caused by Gram negative and fungi.

The data from our study, show us that even though we are facing a new virus and we are working in different conditions than usual, we should not forget the project "Zero pneumonia" as prevention of VAP.

Cardiovascular events after community-acquired pneumonia: a systematic review and meta-analysis of observational studies

A. Tralhão¹; P. Povoas²

¹Polyvalent Intensive Care Unit, Hospital de São Francisco Xavier, CHLO, Lisbon, Portugal; ²Polyvalent intensive care unit, Hospital de São Francisco Xavier, CHLO, Lisbon, Portugal, Lisboa, Portugal

Correspondence: A. Tralhão

Intensive Care Medicine Experimental 2020, **8(2)**: 001592

Introduction: Acute cardiovascular disease after community-acquired pneumonia (CAP) is a well-accepted complication for which definitive treatment strategies are lacking. These complications share some common features but have distinct diagnostic and treatment approaches.

Objectives: To determine the incidence of overall and individual cardiac complications after CAP and its impact on short-term mortality (< 90 days).

Methods: Systematic review of published studies (Medline) of adult non-immunocompromised patients with clinical and radiological evidence of CAP for whom outcomes were explicitly reported, followed by a meta-analysis of proportions, using the double-arcsine transformation and a random-effects model. Meta-regression analysis by year of publication was further performed.

Results: From 1984 to November 2019, thirty-nine studies were accrued, involving 92,188 patients, divided by setting (inpatients versus outpatients) and clinical severity (low risk versus high risk). Overall cardiac complications occurred in 14% (95% confidence interval (CI) 9.6–19), acute coronary syndromes in 4.5% (95% CI 2.9–6.5), heart failure in 9.2% (95% CI 6.7–12), arrhythmias in 7.2% (95% CI 5.6–9.0) and stroke in 0.71% (95% CI 0.1–3.9) of pooled inpatients. During this period, meta-regression analysis suggests that the incidence of overall and individual cardiac complications is decreasing. After adjusting for confounders, cardiovascular events taking place after CAP independently increase the risk for short-term mortality (range of odds-ratio: 1.4–5.5).

Conclusion: Despite a reduction in the last decades, the incidence of cardiac complications after CAP remains high. Our findings highlight the need for effective, large trial based, preventive and therapeutic interventions in this important patient population.

001593

Descriptive study of urine cultures in patients admitted to the ICU with COVID-19 during the months of March-May 2020

P. Fernandez Florido¹; A. Fuentes Calatayud²; D. García Huertas¹; CJF. Machado³

¹Intensive care unit, University Hospital Complex of Granada, Granada, Spain; ²Intensive care, University Hospital Complex of Granada, Granada, Spain; ³Intensive care unit, Hospital Virgen de las Nieves, Granada, Spain

Correspondence: A. Fuentes Calatayud

Intensive Care Medicine Experimental 2020, **8(2)**: 001593

Introduction: Bacterial superinfections have been a very frequent finding in patients admitted to the ICU diagnosed with COVID-19, some of them associated with devices, highlighting the catheter associated urinary tract infection (CA-UTI).

Objectives: Our objective with this abstract is to analyze the results of urine cultures in patients diagnosed with COVID-19 admitted in ICU.

Methods: Descriptive, observational, and retrospective study of urine cultures that were withdrawn in patients admitted with COVID-19, between March and May 2020 in the ICU of a third-level hospital. We analyze: demographic data, number of urine cultures withdrawn, number of positive urine cultures, percentage of gram positive, gram-negative and fungi and incidence density of CA-UTI.

Results: We included 60 patients, 48 (80%) were men and 12 women (20%), median APACHE II score 14.1 points, median age 60.47 years. In 40 patients (68.9%) a urine culture was withdrawn, with a total number of urine cultures of 77 samples. The number of patients with a positive result were 18 (31%), and the number of positive urine culture were 22 (28.5%); negative results were 55 (71.4%). Regarding the microbiological isolates, in 5 urine cultures (22.7%) gram positives were isolated, being all of them *E. faecalis*. In 4 positive urine cultures (18.1%), gram negatives were isolated, being all of them *E. coli*, 2 of which were ESBL. Also striking is the high percentage of fungal isolates, in a total of 13 urine cultures (59%). 11 of them were *C. albicans*, and the remaining 2 were *C. glabrata*. Of the 22 urine cultures with positive results, 14 of them were considered colonizations or contaminants, while 8 of them were considered bacterial superinfections. The total number of urinary catheterization days were 1118, with a total of 7.16 urinary infections for every 1000 days of urinary catheterization.

Conclusion: Our study shows a high percentage of urine cultures with negative results. Among positive results, the majority of isolates have been considered colonization or contamination, and not superinfection. These data can be explained by the presence of different confounding factors in these patients, since they are complex patients with high severity and extensive use of devices. Although most cultures are negative or contaminated, the urinary infection rate is above the results obtained in other series of patients not admitted for COVID-19 in our unit. This reminds us that although we work in different conditions than usual and with a new disease, we must not forget the prevention measures of CA-UTI Zero project.

COVID-19 and Bloodstream infections in ICU

A. L. Rios¹; N. R.¹; A. D.¹; A. Marques¹; P. Castelões¹

¹Medicina intensiva, Centro Hospitalar de Vila Nova Gaia/Espinho, Vila Nova de Gaia, Portugal

Correspondence: A. L. Rios

Intensive Care Medicine Experimental 2020, **8(2)**: 001612

Introduction: The coronavirus disease 2019 (COVID-19) is an emerging health threat.⁽¹⁾

Sepsis, respiratory failure, acute respiratory distress syndrome, heart failure, and shock are commonly observed in these critically ill patients.⁽²⁾

Bloodstream infections (BSI) in recent pre-COVID-19 studies has a reported rate between 3.5 and 5%⁽³⁾⁽⁴⁾. However Xiaochen Li *et al* found a rate of BSI of 14.1% in severe COVID-19 committed patients from Tongji Hospital.⁽⁵⁾

Objectives: To describe the rate and the pathogens involved in BSI in critically-ill COVID-19 patients, and to explore its impact in ICU outcomes.

Methods: Retrospective study of all critically-ill COVID-19 patients admitted in the ICU in a tertiary hospital in Northern Portugal.

Primary end-points: incidence of BSI, agent identification and primary infection site.

Secondary end-points: association with co-morbidities and admission scores of organ dysfunction. Evaluation of impact of BSI on ICU length of stay (LOS), organ-support requirements and mortality.

Results: Between March 17th and May 10th, 36 COVID-19 patients were admitted to our ICU, with median APACHE II 18.0 (IQR 10,75) and median SAPS II 42.0 (IQR 20,5). Median LOS was 16 days (IQR 16,5). 12 (33.3%) patients developed a BSI during ICU stay, with *Klebsiella pneumoniae* being the most frequently isolated pathogen (8,4%), followed by *Pseudomonas aeruginosa* (5,6%) and *MSSA* (5,6%). As for primary source, respiratory infection was the most frequent, accounting for 19,4% of all cases. Overall mortality was 25% (n = 9).

Severity of comorbidities, as measured by the Charlson Comorbidity Index, age and gender were not associated with the occurrence of BSI. Higher SAPS II score at admission was significantly associated with the occurrence of BSI (45 vs 34; p = 0,03). Patients who developed BSI during ICU stay had more severe respiratory insufficiency, as measured by the PO₂/FiO₂ ratio at admission (136 VS 171.5; p = 0,049).

There was no correlation in need for invasive mechanical ventilation or proning maneuvers; however there was an association with longer duration of mechanical ventilation (p = 0,002), need for tracheostomy and duration of vasopressor requirement (p = 0,029). Patients with BSI also had longer ICU LOS (27 VS 14 days; p < 0,001). Regarding treatment options, there was an association between corticoid use and BSI, even with low doses used for shock management. (OR 9,8; CI 95%). There was no impact on mortality.

Conclusion: In this sample, COVID-19 patients were more susceptible to BSI, which resulted in greater ICU LOS and greater length of invasive mechanical ventilation.

Main study limitations are the sample size and retrospective nature.

Intensive Care Medicine Experimental 2020, **8(2)**: 001620

Introduction: COVID-19 infection has been characterized by respiratory manifestations. After the experience of the current pandemic, it has been shown that the profile of manifestations of this infection is not limited exclusively to the respiratory system.

Objectives: To analyze the gastrointestinal manifestations of COVID-19 infection in patients.

Methods: A retrospective observational study was conducted in a ICU of a second level hospital. We collected demographic variables, severity scales on admission, comorbidities, analytical data, treatment received, and mortality. Statistical analysis was performed with IBM SPSS Statistics 25.

Results: 101 patients were admitted requiring transfer 26 due to the absence of beds in our Unit, so the sample of the present study is made up of 75 patients. Demographic variables, comorbidities, severity scales on admission to the ICU and treatment received are shown in Table 1. All were admitted with the diagnosis of severe respiratory failure secondary to atypical pneumonia due to SARS-CoV-2 without any clear digestive manifestation. The most frequent digestive complications are shown in Table 2. In the analysis by their group we found that age and obesity are associated with an increase risk of Ogilvie syndrome; those with a history of hypertension and cardiovascular disease more frequently developed diarrhea, lower gastrointestinal bleeding (LGB) and cholestasis; and dyslipidemic patients more frequently developed ischemic hepatitis. Regarding the treatment received, the use of lopinavir/ritonavir and tocilizumab was associated with an increase in cases of cytolysis; corticotherapy with the development of cytolysis and cholestasis; and interferon with constipation. It should be noted that in patients who developed AKI during their ICU admission had a higher incidence of mesenteric ischemia, ischemic hepatitis, LGB and cytolysis. When analyzing the inflammatory parameters, the determination of D-Dimer was significantly higher in patients with mesenteric ischemia, ischemic hepatitis and diarrhea; levels of IL-6 were higher in those with cytolysis, diarrhea, ischemic hepatitis, mesenteric ischemia, and adynamic ileus; ferritin levels in patients with cholestasis, LGB and ischemic hepatitis; CRP in patients with diarrhea and ischemic hepatitis; and finally patients with cholestasis and cytolysis presented more severe lymphopenia. It is relevant

in our sample that the patients who suffered mesenteric ischemia, diarrhea, cholestasis and cytotoxicity had a higher mortality than those who did not present these gastrointestinal complications.

Sex (♂)	67,6	Age (years)	59,66
Obesity (%)	80,3	Hypertension (%)	43,4
Dyslipidemia (%)	48,7	DM (%)	22,4
Bronchopathy (%)	29,9		
APACHE II	16,83	SOFA	6,8
Mechanical ventilation (%)	100	Neuromuscular blockers (%)	80,3
AKI (%)	46,1	Vasoactive support (%)	98,7
Lopinavir/ritonavir (%)	90,8	Darunavir/cobicistat (%)	11,8
Tocilizumab (%)	92,1	Chloroquine (%)	92,1
Corticosteroids (%)	80,3	Beta-interferon (%)	40,8
Enteral feeding (%)	94,6	Parenteral nutrition (%)	43,2

Cytotoxicity (%)	67,6	Cholestasis (%)	64,9
Adynamic ileus (%)	37,8	Diarrhea (%)	28,4
Constipation (%)	14,9	Ogilvie syndrome (%)	10,8
Ischemic hepatitis (%)	5,4	Mesenteric ischemia (%)	4,1
Low digestive bleeding (LDB) (%)	4,1	Upper digestive bleeding (UDB) (%)	1,4
Collecistitis (%)	0	Pancreatitis (%)	0

Conclusion: Despite the fact that the reason for admission was pulmonary involvement by SARS-CoV-2, the development of various gastrointestinal disorders was observed in our cohort, with an increase in mortality in certain cases. The development of ARF increases the risk of GI complications as well as the use of lopinavir/ritonavir, tocilizumab and corticosteroids. Inflammatory parameters can be useful to identify patients at risk of GI manifestations.

Point of Care Ultrasound is highly predictive in the diagnosis of COVID-19

J. Powys-Lybbe¹; C. Moxey¹; O. Blackford¹; L. Tong¹; O. Valencia¹; G. Zilahi¹; H. Aya¹; J. Aron¹

¹General intensive care unit, St George's Hospital, London, United Kingdom

Correspondence: P.L. James

Intensive Care Medicine Experimental 2020, **8(2)**: 001625

Introduction: The COVID-19 pandemic continues to threaten populations across the world [1]. Delay in the diagnosis of COVID-19 can cause exponential harm. Lung ultrasound can quickly identify a COVID-19 phenotype as interstitial syndrome of the lung [2]. Combined with focused echocardiogram to rule out left ventricular (LV) impairment as a cause, it can be used to quickly identify patients highly likely to have COVID-19.

Objectives: We aimed to assess a describe a system for the diagnosis of COVID-19 by focused heart and lung ultrasound.

Methods: We performed a prospective observational study on all patients admitted to a tertiary hospital Intensive Care Unit over a three-week period. Each patient received a point of care ultrasound (POCUS) scan consisting of focused echocardiogram and 6-point lung ultrasound (using FUSIC guided scoring system [3]). Patients were diagnosed with COVID-19 using two swab positive PCR. The primary outcome was the association between COVID-19 diagnosis and phenotype of COVID-19 defined by two category 2 regions on Lung ultrasound (interstitial syndrome) in the absence of LV impairment. We

used fisher's-exact test for comparison of the two groups. A p-value of less than 0.05 was considered significant.

Results: Of 69 patients admitted to ICU, 61 patients were eligible for inclusion in our study with adequate POCUS. 43 patients (70%) were swab positive for COVID-19, 18 were negative. 33 out of 43 (76.7%) swab positive patients had a positive COVID-19 phenotype on focused ultrasound, 10 /43 (23.3%) did not. 16 /18 (88.9%) swab negative patients had a negative COVID 19 phenotype on focused ultrasound, 2/18 (11.1%) had a positive phenotype. P-value = 0.000002. Area under the Curve 0.83 (CI 0.71 – 0.94). Accuracy 0.8 (0.71 – 0.91). Positive Predictive value 0.94 (0.81 – 0.98). Negative Predictive Value 0.62 (0.43 – 0.78). Likelihood ratio of 6.91 (CI 1.85 – 25.8).

Conclusion: Focused lung ultrasound is highly predictive of COVID-19 when looking for Interstitial syndrome of the lung and excluding patients with LV failure.

Thrombocytosis in COVID-19 patients admitted to the ICU

M. Fazzi¹; M. Nijsten¹

¹Department of critical care, University Medical Center Groningen, Groningen, Netherlands

Correspondence: M. Nijsten

Intensive Care Medicine Experimental 2020, **8(2)**: 001627

Introduction: Some of the most severe aspects of COVID-19 may be related to expression of interleukin-6 (IL-6). IL-6 is a key mediator of thrombopoiesis and thrombocytosis in acute and chronic inflammation [1]. COVID-19 patients may thus manifest IL-6 induced thrombocytosis.

Objectives: Examine the time course of platelet counts (PLC) in a cohort of COVID-19 patients admitted to our ICU and compare this time course with that of non-COVID ICU-survivors and non-survivors from a large published cohort [2]. Since COVID-19 patients have relatively long ICU-stays we used only non-COVID patients with an ICU-stay of ≥ 14 days.

Methods: Over the first 30 ICU days median daily PLC in COVID-19 patients were compared with non-COVID hospital survivors and non-COVID hospital non-survivors.

Results: A total of 90 COVID-19 patients were compared with 2682 non-COVID-19 ICU-survivors (S) and 1149 non-COVID-19 non-survivors (NS) who had an ICU-stay of ≥ 14 days. A total of 89,000 PLC were analyzed. Median PLC in COVID-19 patients followed a markedly different time course from both S and NS non-COVID patients. COVID-19 patients had a higher PLC at admission: 295 $10^9/L$ vs 175 $10^9/L$ and 172 $10^9/L$ in S and NS respectively ($P < 0.001$). Subsequently the nadir in PLC observed between ICU day 1 and 5 in S and NS alike was absent in COVID-19 patients. The rise in PLC observed in non-COVID-19 during the second ICU week was also observed in COVID-19 patients, although the maximal PLC in COVID-19 patients was higher: 486 $10^9/L$ compared to 366 $10^9/L$ and 249 $10^9/L$ in S and NS respectively ($P < 0.001$). In contrast to S and NS non-COVID patients, even after 30 days median PLC was still above the reference range (150 to 350 $10^9/L$) in COVID-19 patients.

Conclusion: COVID-19 patients display a pronounced thrombocytosis during the first ICU month compatible with the thrombopoietic action of IL-6. Ongoing trials with IL-6 receptor inhibitors in may establish the causality of IL-6 in thrombocytosis in COVID-19 patients.

Comparison of time courses of albumin and total protein levels in COVID and non-COVID patients: evidence of marked gamma-globulin production in addition to acute phase proteins in COVID-19

L. Hulshof¹; M. Nijsten¹

¹Department of critical care, University Medical Center Groningen, Groningen, Netherlands

Correspondence: M. Nijsten

Intensive Care Medicine Experimental 2020, **8(2)**: 001644

Introduction: COVID-19 patients display several responses related to severe and sustained inflammation. Interleukin-6 (IL-6) is considered to be a key mediator among the cytokines released during COVID-19. One of the actions of IL-6 is the stimulation of polyclonal immunoglobulin production by B-cells [1].

Objectives: Analyze the secondary components of the acute phase response as can be derived from routine laboratory measurements. Over a 1 month period we compared the time course of albumin, total protein and fibrinogen in COVID-19 patients with that observed in non-COVID ICU patients. We also specifically looked at the difference between total protein and albumin as a reflection of the (immuno-) globulin fraction.

Methods: From a large database of ICU-patients and laboratory data built in our center for the ICU-Labome study [2], we selected only patients with a prolonged ICU-stay (i.e. ≥ 14 days). This was done for better comparison with the COVID-19 patients who tend to have relatively long ICU stays. We compared COVID-19 patients (C) with non-COVID hospital survivors (nC-S) and non-COVID non-survivors (nC-NS). All available fibrinogen, albumin and total protein levels were analyzed. To estimate the non-albumin proteins, albumin was subtracted from total protein. Median levels are reported and comparisons were performed with non-parametric tests.

Results: The nC-S and nC-NS groups consisted of 2682 and 1149 patients respectively. These were compared with 90 COVID-19 ICU patients treated till May 2020. 3400 and 129,000 laboratory measurements were used. At ICU-admission, fibrinogen levels were already considerably higher ($P < 0.001$) in COVID-19 patients: 7.6 g/L compared with 2.5 and 2.9 g/L in nC-S and nC-NS. Only after 2 weeks of ICU admission fibrinogen in COVID had decreased to levels similar to S and NS. The time course of albumin in COVID-19 patients was similar to that nC-S. Total protein levels were much higher at admission in COVID-19 than either nC-S and nC-NS ($P < 0.001$), with admission levels of 61 g/L vs 50 and 50 g/L respectively, with only limited subsequent changes. The estimated non-albumin fraction at admission in COVID-19 was 34 g/L compared to 23 and 25 g/L in nC-S and nC-NS ($P < 0.001$). The estimated non-albumin fraction stayed 9 to 10 g/L higher than nC-S and nC-NS over the observation period ($P < 0.001$) and rose to 40 g/L at day 30.

Conclusion: In addition to the well-described components of the acute phase response in COVID-19 such as elevated CRP and fibrinogen, there is a pronounced and sustained rise in total protein that points to the production of other acute phase proteins or gamma-globulins. This response is markedly different from that seen in other critically ill patients. Ongoing trials with IL-6 receptor inhibitors may indicate if IL-6 responsible for these peculiar reactions.

Intensive Care Medicine Experimental 2020, **8(2)**: 001649

Introduction: In December 2019, the first cases of respiratory pathology (COVID-19) caused by the new coronavirus (SARS-CoV-2) were reported in Wuhan. Since then, COVID-19 has spread exponentially throughout the world, having been recognized by the World Health Organization (WHO) as an international public health emergency on January 30, 2020. On March 11, 2020, the WHO has officially declared the COVID-19 pandemic.

In our country the first case of COVID-19 was confirmed on March 2, with causalities starting on March 18.

The differences between countries or different Intensive Care Units (ICU) are still under investigation for the disparities in regional admissions and the severity of illness. This illustrates how natural evolution of COVID-19 and its prognosis are still not fully understood.

Conscient that there is an important impact of public health restriction and confinement in local evolution and transmission, there is relevancy in mentioning that National Emergency State was declared on March 18, and a national calamity on May 3, resulting in closure of not essential public stores.

There was an adjustment of our ICU organization, with the creation of a separate cohort, named COVID ICU exclusively dedicated to these patients.

Objectives: Characterization of the population of patients infected with SARS-Cov-2 admitted to Intensive Care Unit at a university affiliated hospital, during the COVID-19 pandemic. Analysis of a district hospital experience during an outbreak (from preparation to the results).

Methods: This is a retrospective and descriptive study that includes only data from the usual clinical practice. All positive COVID-19 patients admitted to the ICU from March 2, 2020 to June 26 were included. Patients were followed from admission to discharge from the ICU.

Results: Over the last 3 months, coincidentally with the national spike and the so-called "first wave" of cases, there was an adjustment of the ICU organization, with the creation of a separate cohort exclusively dedicated to this patients.

With a total of 169 patients admitted to our hospital, we had 13 admissions (12 patients, but one readmitted).

The mean age of the patients was 74 years, and 66.6% were men. Of the 12 patients, 2 had no symptoms but had known risk contact and presented with silent hypoxemia. Length of stay varied from 1 to 25 days.

Laboratory results showed the usual highly elevated c- reactive Protein levels and lactate dehydrogenase.

At admission, patients had a mean PaO₂/FiO₂ ratio of 169, with a minimum of 52. Five had mechanical ventilation since the admission with an average of 14 days of ventilation.

Patients who developed an ARDS (5 patients) were treated according to the recommendations.

All patients were treated with hydroxychloroquine following the recommendations in force until the hospitalization.

Four of the 12 patients didn't survive (33.3%).

Conclusion: The pandemic has tested public health measures as the functioning and responsiveness of health services worldwide. The ICUs, in the role of manager of the critical patient, have a particularly important role in the approach of these patients considering the risk of flooding ICU during outbursts, and the consciousness that intensive care support is crucial for the surviving of severe cases. The lack of knowledge and the limit of resources are factors of added difficulty in the approach of patients with COVID -19. The variability between centers is still not understood. The lack of evidence has originated different strategies around the world.

Intensive Care Medicine Experimental 2020, **8(2)**: 001260

Introduction: Fluid bolus therapy (FBT) is our most common ICU intervention [1], however there is little agreement on when and how this therapy should be used. FBT is often needed to maintain organ perfusion, but excess fluid has been associated with increased long-term morbidity [2-5]. Also, there are indications that the response to fluid is usually smaller than anticipated [6, 7]. What triggers are used and what would constitute a significant response vary. Therefore, we conducted a prospective clinical trial in Sweden and Australia to describe accuracy and precision of clinical expectation compared to actual response to FBT.

Objectives: To describe the accuracy and precision of clinicians' expectations of the hemodynamic effect of fluid boluses (FB) on physiological variables at completion of a FB and after one hour. To investigate triggers for FBT and to what extent clinicians' expectations are met.

Methods: We evaluated 77 ICU patients at Austin Hospital, Melbourne Australia and Södersjukhuset, Stockholm Sweden. Patients were included if they were planned to receive a FB of ≥ 250 ml of resuscitation fluid over ≤ 30 minutes. The treating physician then completed a questionnaire asking for primary and secondary triggers for FBT from a list. Also, they were asked what physiological responses to the FB they expected at the end of the FB and one hour later.

Clinicians' responses were then compared to the measured values at these time-points. Data was collected directly from the electronic monitoring systems and the electronic medical records regarding physiological variables, lab values etc. Levels of vasopressors and sedation was collected to statically correct for these.

Results: 18 patients were recruited in Australia and 59 in Sweden. 46 were males and 31 females. Mean SOFA score was 8.2. Mean bolus size (SD) was 352.0 ml (107.6) over 22 minutes (11.8). 57.1% of boluses were Ringer's Acetate and 42.9% Albumin 40-50 g/L. 54.5% of patients had infusions of noradrenaline and 37.7% had infusions of propofol.

Hypotension was the most common trigger for a FB (46.8%), followed by poor urine output (20.8%). The most common secondary triggers for a FB were tachycardia and poor urine output (each 16.9%).

At the end of the FB, 25% of expectations were within 10% of measured mean arterial pressure (MAP), and 52.1% within 10% of measured heart rate (HR).

One hour later, 37.5% of expectations were within 10% of measured MAP, and 39.2% within 10% of measured HR, and 8% of expectations were within 10% of measured urine output.

The mean difference between expected and measured MAP (SD) was 9.1 mmHg (8.7), the difference in HR (SD) 7.1 bpm (8.9), the difference in urine output (SD) 44 ml (52.6) and the difference in cardiac index (CI) (SD) 0.32 (0.30) at the end of the bolus.

33% of patients had an increase in MAP >10% at the end of a fluid bolus, and 29.3% at 1 h, whereas only 13% had an increase in CI > 10% at end of bolus but 45.5% after 1 h and 6.6% had a decrease in HR >10% at end of bolus and 10.4% after 1 h.

Correction for levels of sedation or pressors led to no significant change of these values.

Conclusion: The most common reasons for administering a FB was to improve MAP and urine output, followed by resolving tachycardia. Clinicians' expectations were only accurate in 25-51% of cases and were often not met, with a mean difference of 9 mmHg between expected and measured MAP. Further research might be needed into how FBs are used in the ICU and what expectations we have of them, so that we might choose to use them more judiciously.

Intensive Care Medicine Experimental 2020, **8(2)**: 001262

Introduction: Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) has spread across the globe. Among infected patients, causes mild respiratory disease in most have a mild disease course, however a significant minority require hospitalisation. Of those hospitalised, between 5-15% of those in hospital requiring admission to the intensive care unit (ICU)1.

Secondary infection is well described in ICU patients with other viral respiratory illnesses such as influenza2, Severe Acute Respiratory Syndrome (SARS)3 and Middle East Respiratory Syndrome (MERS) 4, and may lead to increased mortality. Although data is limited, it is likely that SARS-CoV-2 predisposes to co-infection. ICU admission and organ support such as mechanical ventilation are risk factors for infection, independent of COVID-19. Furthermore, many established pre-morbid conditions such as diabetes mellitus and obesity which pre-dispose to co-infection in ICU have also been described as risk factors for severe SARS-CoV-2 disease1. Finally, patients with severe COVID-19 appear to have significant immune dysregulation, with lymphopaenia, abnormal levels of inflammatory cytokines and features of T cell immune "exhaustion"5. This abnormal immune response and associated lung damage can may leave patients vulnerable to bacterial proliferation.

Objectives: 1. Characterisation of the co-infections in SARS-CoV-2 patients admitted to Tallaght Hospital ICU.

2. Description of the effect of co-infection on patient outcomes.

Methods: This is a single centre retrospective observational study of patients admitted to a single ICU with COVID-19 from January to June

2020. Patients were followed until discharge from ICU. Patient demographics, microbiology, clinical/pharmacological treatment were recorded until discharge from ICU. The primary analysis compared patients with bacterial co-infection to those without. recorded from paper and electronic chart. Co-infection was defined as any positive bacterial culture during ICU admission requiring antimicrobial treatment. Proportions and continuous variables were compared using Fisher's exact test and independent samples t testing respectively.

Results: Twenty-five patients were admitted during the study period. Thirteen (52%) developed co-infection. Baseline demographics and co-morbidities were similar between patients groups. Organism's identified as co-infections are detailed in Table 1. A highly resistant ESBL producing *Klebsiella pneumoniae* was isolated in 3 patients. *Staphylococcus aureus* pneumonia was identified in the respiratory tract of 3 patients. Two patients who underwent prolonged mechanical ventilation developed *Stenotrophomonas maltophilia*. MRSA and VRE were identified in 3 and 2 patients respectively. There were no cases of *C. difficile* colitis, despite extensive use of empiric cephalosporins (68%) amongst the patients. Patients who developed co-infection spent a significantly longer time mechanically ventilated and on vasopressor therapy than those who did not. ICU length of stay was also prolonged in co-infected patients (Table 2).

Table 1: Isolated Pathogens

Respiratory	Blood	Urine	Resistant Organisms on Screening
MRSA	3	<i>S. Epidermidis</i>	1
<i>P. Aeruginosa</i>	1	ESBL producing <i>K. Pneumoniae</i>	1
<i>S. Epidermidis</i>	1	ESBL producing <i>K. Pneumoniae</i>	2
ESBL producing <i>K. Pneumoniae</i>	2	MRSA	3
Methicillin Sensitive <i>Staphylococcus Aureus</i>	2	VRE	4
<i>S. Maltophilia</i>	3	<i>Clostridium Difficile Colitis</i>	0
<i>E. Cloacae</i>	1		
<i>K. Aerogenes</i>	1		
<i>Chryseobacterium Indologenes</i>	1		

MRSA: Methicillin Resistant *Staphylococcus Aureus*, ESBL: extended spectrum β lactamase, MSSA: Methicillin Sensitive *Staphylococcus Aureus*, VRE: vancomycin resistant enterococcus

Table 2: Outcomes

Co-Infection	No Co-Infection	All	p-value	
ICU Length of Stay (Mean, SD)	22.38 (12.31)	12.83 (4.00)	17.3 (10.33)	0.0174
Mechanical ventilation (No., % total)	13 (100%)	11 (92%)	24 (96%)	0.480
Days intubated (Mean, SD)	22 (12.75)	10.08 (4.08)	16.28 (11.22)	0.005
Days on vasopressor support (Mean, SD)	12.77 (10.26)	5.58 (4.52)	9.32 (8.69)	0.036
Days on renal replacement therapy (Mean, SD)	2.69 (6.18)	1.33 (4.62)	2.04 (5.42)	0.543
Proned	8 (62%)	6 (50%)	14 (56%)	0.700
Death	1 (8%)	3 (25%)	4 (16%)	0.322

Conclusion: Co-infection increases duration of mechanical ventilation, ICU stay and vasopressor dependence in ICU patients with COVID-19.

Correspondence: M.C. González

Intensive Care Medicine Experimental 2020, **8(2)**: 001263

Introduction: Septic cardiomyopathy is a serious complication in the course of sepsis. A prognostic association between patients who, in the context of impaired cardiac contractility, maintain increased diastolic volumes has been described by different authors. Furthermore, the emergence of various minimally invasive technologies has allowed access to different indicators of hemodynamic status that have become relevant in recent years.

Objectives: The objective of our work was to determine if the global final diastolic volume (VDFG) and the global ejection fraction (FEG) could be associated with a worse prognosis in septic patients with hemodynamic failure, and if the association between systolic dysfunction due to septic cardiomyopathy and dilatation of cardiac chambers had a better prognosis in that population.

Methods: Aperture measurement was included retrospectively for all patients requiring minimally invasive hemodynamic monitoring using the transpulmonary thermodilution technique with the Ed 1000 EV equipment.

Age, sex, height, weight, Apache II, SOFA, diagnosis, cardiac index, indexed global final diastolic volume, indexed systolic volume, extravascular pulmonary water index, pulmonary vascular permeability index, central venous pressure, variability of systolic volume were measured, index of indexed systemic vascular resistance, mean arterial pressure, heart rate. The patients were subsequently classified into patients with impaired contractility and increased or decreased diastolic volumes.

A univariate analysis was performed with the student t test for continuous variables and chi² for categorical variables. Subsequently, the variables were included in a multivariate analysis to test their association with mortality.

Results: After multivariate analysis, the only factor that was independently associated with mortality was overall final diastolic volume. Those patients had no associated contractility disorders.

		SURVIVOR	NOT SURVIVOR

Effects of combined intravenous immunoglobulins and vitamin C for the treatment of severe Community acquired pneumonia

M. Benlabeled¹; S. Benlabeled²; R. Gaudy³; S. Nedjari⁴
¹Anesthesiology and Intensivecare, Lille University, Lille, France; ²Erasme hospital, Université Libre de Bruxelles, Bruxelles, Belgium; ³Anesthesiology and intensivecare, Lille Catholic University, Lille, France; ⁴Anesthesiology, Algiers university, Alger Centre, Algeria, Algeria

Correspondence: M. Benlabeled

Intensive Care Medicine Experimental 2020, **8(2)**: 001284

Introduction: The use of intravenous immunoglobulins (IVIG) as adjunctive therapy for the treatment of infections, and particularly pneumonia, is controversial but there is less controversy for intravenous vitamin C (IVvit-C) associated with antibiotics to treat sepsis since the study of Fowler et al. published in JAMA 2019. However, we never observed in the literature the combination of IVIG and IVvit-C for treatment of severe sepsis or community acquired pneumonia.

Objectives: So the objective of our study was to assess the administration of IVIG and IVvit-C in patients with severe community acquired pneumonia and to evaluate the effectiveness of this association in terms of outcome including morbidity and mortality. So, we

hypothesized that the combination of IVIG and IVvit-C would be more effective than IVIG alone or placebo.

Methods: We conducted a prospective observational study from march 2018 to march 2020 and enrolled a total of 45 patients suffering of severe hypoxemic community acquired pneumonia and under invasive mechanical ventilation (IMV). They were 60±13 years old and presented the same apache II score. All the patients received the first of dose of antibiotics in the emergency room and were infused with norepinephrine. We randomized the patients in 3 groups.

A first group of 15 patients receiving IVIG 1 g/kg the first day, 0.5 g/kg the next two days and IV-vitC 50 mg/kg/6 h during 96 h, administered 2 hours after the first dose of IVIG.

A second group of 15 patients receiving immunoglobulins alone at the same dose as previously described.

And finally a third group receiving placebo alone. We performed a blood level of vit-C and immunoglobulins (IG) at 96 h in each group. We recorded for each group: SOFA score day1 and day4, duration of vasopressors, duration of invasive mechanical ventilation (IMV), ICU stay, dosage of immunoglobulins and vit-C and finally ICU mortality.

Results: Statistical analysis was performed using Student 's t test. Results were expressed as mean ± standard deviation.

SOFA score day1 was not different between the 3 groups and calculated at 4 but SOFA score day4 was, respectively, in the IVIG-vitC group significantly lower than in the IVIG group and placebo group (4.53±0.74 vs 7.33±0.72 vs 12.13±0.74) p<0.0001. Similarly, duration of IMV was respectively shorter in IVIG-vitC group than in IVIG and placebo groups. (6.76±0.71 vs 9.86±0.29 vs 12.73±0.59) p<0.0001. Duration of vasopressors (days) was shorter respectively in IVIG-vitC group than IVIG and placebo group (1.96±0.12 vs 3.03±0.22 vs 5.06±0.17) p<0.001. ICU length of stay was also shorter in IVIG-vit-C group than in IVIG and placebo groups. (11.93±0.45 vs 15.86±0.51 vs 19.73±0.7) p<0.0001. Blood levels of immunoglobulins at 96 h were obviously and respectively lower in the placebo group than in the IVIG-vitC and IVIG group (4.99 g/l±0.63 vs 14.66 g/l ±0.89 vs 14.8 g/l±0.86) P<0.0001. Blood levels of vit C were low in the 3 groups before administration (99 µmol/l±2.2) and reach at 96 h a value of 703 µmol/l±3.2 in the IVIG-vit-C group. ICU mortality was significantly lower in the IVIG-vit-C group than in the IVIG group and placebo group, respectively 26%, 40% and 66%.

Conclusion: The administration of high dose of IVIG combined with IV vit-C improved SOFA score day4 increases the ventilator free days, ICU free days, and decreases ICU mortality compared with immunoglobulins alone or placebo. Early infusion of this therapeutic associated with antibiotics for the treatment of severe community acquired pneumonia improves outcome. A large Randomized Controlled Trial is needed to confirm these preliminary results.

Intensive Care Medicine Experimental 2020, **8(2)**: 001390

Introduction: To study the evolution and mortality of postsurgical bacteremia due to *Acinetobacter baumannii* resistant to carbapenems and sensitive to colistin in the critically ill patient.

Methods: Retrospective, multicenter cohort study. We analyze post-surgical patients (previous surgery 30 days) who had monomicrobial bacteremia due to *Acinetobacter baumannii* carbapenems resistant and sensitive-colistin. We use logistic regression for multivariate analysis. The main variable was mortality on day 14 and 30 after the diagnosis of bacteremia.

Results: Of the total of patients, 41 (35%) presented postoperative bacteremia detected during the study time, 61% men with a mean age of 61 ± 11 , APACHE II at admission 23 ± 9 and Charlson index 3 ± 2 . This type of Bacteremia was more frequent in patients undergoing abdominal surgery: 18 patients (44%). Bacteremia appeared on day +12 after initial surgery (8 vs. 26). Most frequent comorbidities: diabetes mellitus 15 (36%) and chronic kidney failure 8 (20%). The most frequent type of bacteremia was secondary (33/41): pneumonia associated with mechanical ventilation 49% (20/41) and peritonitis 32% (13/41). 71% of the patients presented septic shock. In this group of patients, 29 required renal replacement therapy. The treatment administered was: monotherapy with colistin 73% (30/41) and combination therapy with tigecycline-colistin in 27% (11/41). Mortality at 14 days was 32% (13/41) and at 30 days it was 63% (26/41). There is no statistically significant difference between mortality in postoperative bacteremia and non-postoperative bacteremia.

Conclusion: Post-surgical bacteremia in our patients is similar with that of non-postoperative bacteremia. Empirical treatment with colistin did not reduce 30-day mortality after this type of bacteremia. Mortality at day 14 and day 30 is similar to that which occurs in non-postoperative bacteremia.

Intensive Care Medicine Experimental 2020, **8(2)**: 001396

Introduction: Ventilator-associated pneumonia (VAP) is a serious complication in critically ill patients. The usual etiology of these pneumonias is usually similar in the same complexity units.

Objectives: To determine whether the isolates in pneumonia that were observed in the following 72 h after an episode of orotracheal tube (OTT) obstruction directly compared to those common in VAP.

Methods: Single-center retrospective study. Patients with confirmed SARS-CoV 2 pneumonia (COVID-19) who required mechanical ventilation (VM) for more than 48 hours from March 6 to May 6 in the Intensive Care Unit (ICU) in a medium complexity hospital. The microbiological isolates of those patients who required one or more changes of OTT and developed a VAP in the following 72 h were recognized.

Results: 47 patients were included. Two patients who died in the first 36 hours of admission with bacterial pneumonia associated with SARS-VOC 2 were excluded. The mean age was 61.7 years, 35 (74.4%) men and 12 (25.5%) women. The average APACHE 2 was 15, the average SAPS 2 was 35.6. 60% of patients affected a VAP in the following 72 hours. The isolates found were *Enterobacter* 5 (29.4%), *E. faecalis* 3 (17.6%), methicillin sensitive *S. aureus* 3 (17.6%), methicillin resistant *S. aureus* (MRSA) 2 (11.8%), *Pseudomonas aeruginosa* 2 (11.8%), *Candida* spp 1 (5.9%), Others 1 (5.9%).

Conclusion: The development of VAP in the first 72 hours after OTT obstruction has been a frequent finding in COVID patients. The most frequently isolated microorganism was *Enterobacter* with a higher percentage than that found in published series, followed by *E. faecalis*, which also has a higher than expected presence. Germs more commonly related to VAP, such as *Pseudomonas* and SAMR, have presented in the usual proportions for patients intubated in the ICU.

Intensive Care Medicine Experimental 2020, **8(2)**: 001464

Introduction: Positive culture of the heart valve could be associated with severity and condition worse prognosis of the disease.

Objectives: To assess if surgical patients with endocarditis and microbiological isolation in the infected valve, present any clinical or evolutive differences from the others patients.

Methods: We evaluated endocarditis patients from two hospital centers (Fundación Jimenez Diaz and Hospital Rey Juan Carlos in Madrid) operated by the same surgical team between 2010 and 2019.

Patients were divided in two groups according to the microbiological findings in the infected valve: GROUP 1 with a negative culture (NC) and GROUP 2 with a positive culture (PC). Any value of $p < 0.05$ is considered significant.

Results: 103 patients were included, 30 with PC (29.4%).

Comparing the groups (NC vs PC) we observe:

Personal history: alcohol-drugs (2.8% vs. 6.7%; $p = 0.357$), mellitus diabetes (27.8% vs. 43.3%; $p = 0.126$), arterial hypertension (54.2% vs. 66.7%; $p = 0.244$), dyslipidemia (43.1% vs. 63.3%; $p = 0.062$), COPD (9.7% vs. 23.3%; $p = 0.069$), renal failure (26.4% vs. 56, 7%; $p = 0.004$), previous cardiac surgery (31.9% vs 46.7%; $p = 0.159$), paroxistic atrial fibrillation (4.2% vs 13.3%, $p = 0.095$) permanent Atrial fibrillation (23, 6% vs. 13.3%; $p = 0.242$), coronary artery disease (8.3% vs. 13.3%; $p = 0.439$), cardiogenic shock (12.5% vs. 16.7%; $p = 0.577$), recent urological handling (2.8% vs. 13.3%; $p = 0.039$), cancer (0 vs. 6.7%; $p = 0.027$), bicuspid valve (12.5% vs. 3.3%; $p = 0.156$).

Disease data: vegetations > 15 mm (19.4% vs 31%; $p = 0.213$), pre-intervention antibiotic time (10.36 ± 9.90 vs 8.56 ± 8.38 days; $p = 0.386$), Logistic EUROSCORE II (29.20 ± 22.45 vs 35.56 ± 19.38 ; $p = 0.178$) and type of surgery (mitral valve 38.9% vs 33.3%, aortic valve 30.6% vs 43.3%, mitral and aortic valve (22.2% vs. 13.3%); $p = 0.551$).

Evolutive data: intubation time (189.86 ± 1047.94 vs 187.40 ± 365.55 hours); $p = < 0.001$), ICU stay time (6.61 ± 10.59 vs $12.76 \pm 16, 26$ days; $p = 0.026$), tracheostomy (8.3% vs. 16.7%), pleural effusion (4.2% vs. 10%; $p = 0.254$), reoperation because bleeding (5.6% vs. 13.3%; $p = 0.183$), postcardiotomy shock (0 vs 6.7%; $p = 0.027$), renal failure (26.4% vs 40%; $p = 0.173$), lower gastrointestinal bleeding (0 vs 10%; $p = 0.006$), liver failure (1.4% vs. 10%; $p = 0.041$), polyneuropathy (1.4% vs. 16.7%; $p = 0.003$), pericarditis (0 vs. 6.7%; $p = 0.027$) and state of death at hospital discharge (13.9% vs. 16.7%; $p = 0.718$).

Conclusion: Patients with positive culture in infected valve have higher incidence of Renal failure, recent urological handling and previous cancer. They present longer intubation and ICU stay times and more complications: cardiogenic shock, upper gastrointestinal bleeding, liver failure, severe polyneuropathy, and postoperative pericarditis. However, we did not find significant differences before surgery or in mortality at hospital discharge.

001465

Relation between the age and the severity assessed by SOFA upon the admission to the ICU of the patients with coronavirus infection

JJ. Rios Toro¹; LB. Yaguez Mateos²; C. Aranda Martínez³; M. Guerrero Marin²; M. Ruiz Garcia⁴

¹Medicina intensiva, Serrania de Ronda Emergency Hospital, Ronda, Spain;

Intensive Care Medicine Experimental 2020, **8(2)**: 001465

Introduction: To evaluate the influence of the age and multiorganic fail of patients at the moment of being admitted at the ICU for coronavirus on the mortality.

Methods: Prospective cohort study of patients with coronavirus admitted to the ICU at the Hospital Universitario de Jaén, Hospital San Agustín de Linares and the Hospital Infanta Margarita de Cabra. Continuous variables are expressed as median (25th percentile, 75th percentile) and qualitative variables with absolute and relative frequencies. U Mann Whitney was used for comparison of continuous variables and X² for qualitative variables. P < 0.05 was considered as statistically significant (s.s.).

Results: We have studied 63 admitted patients AT ICU by coronavirus INFECTION, 44 of them to the Jaén hospital ICU, 11 at Cabra hospital and 8 at Linares hospital. The average age was 58 (37,62). The evaluated severity with APACHE II was 12 (9,17) points and the same evaluation but using SOFA was 6 (4,8) points at the first day. 63,5% (n = 40) required tracheal intubation on their first day and 82,5% (n = 52) during the entire ICU stay. Mortality in the ICU was a percent of 38 meanwhile in the hospital was 39,7. Those patients who deceased were older than the survivors, 64 (60,72) vs 60 (52,70) years old, but the differences weren't statistically significant (s.s) (p = 0.16.). These ones also showed most acutely according to Apache II, 18 (14,23) vs 14 (12,18) points (p < 0,005), and a higher SOFA at the admission 7 (4,8) vs 6 (3,8) points, but without being statistically significant (p = 0.09).

Later, we classified the severity evaluated with the SOFA and age in intervals for a better evaluation of the relation of both variables with age and in suspicion that the relation was not linear. Patients were classified according to the SOFA upon admission as 7 or more points (n = 32, 51.6%) and another group if it was less than 7 points (n = 30, 48.4%). In the 32 patients with SOFA at admission of less than 7 points, 9 died (28.1%) and in the 30 with SOFA of 7 or more points, 16 died (53.3%) (p = 0.043).

The patients were classified according to the age, over 60 years (n = 40, 64.5%) or less or equal to 60 years (n = 22, 35.5%). Mortality in those over 60 years old was higher, 47.5% vs. 27.3% but the differences were not s.s. (p = 0.12). Then, the influence of the age on mortality was analyzed according to the severity evaluated with the SOFA at admission. And it was observed that the mortality of patients with SOFA of 7 or more points was high in the two age groups, 55.6% of 9 patients aged 60 years or younger and 52.4% of 21 with ages over 60 years, without s.s. differences. Then the influence of the age to the mortality.

Nevertheless, in patients with less severity (SOFA lower than 7 points) mortality was high in those who were older than 60 years old (42.18% of 119 patients) but in youth people was much lower (7.7% of 13 patients) (p = 0.033). SOFA of the 13 patients with SOFA less than 7 points and age less than or equal to 60 years was (2 points: 15.4%, 3 points: 30.8%, 4 points: 30.8% and 6 points: 23.1%) and 69.2% required intubation.

Conclusion: In ICU patients admitted for coronavirus infection, the ICU evaluation of SOFA and age allows identification of a group of patients with lower mortality than the rest. They are also those with low SOFA (less than 7 points) and age less than or equal to 60 years. Mortality in this group was less than 10% in our series. In the rest of the patient groups, with high SOFA regardless of age and low SOFA but with age over 60 years, mortality is much higher than the aforementioned group.

Use of human albumin solution in septic and non-septic critically ill patients

Y. H. Y. Chong¹; A. A. C. Waite¹; I. D. Welters¹

¹Intensive care unit, Royal Liverpool University Hospital, Liverpool, United Kingdom

Correspondence: A. Waite

Intensive Care Medicine Experimental 2020, **8(2)**: 001468

Introduction: Albumin is known to be associated with outcomes in critically ill patients, but the use of human albumin solution (HAS) has a less clear role. As a mortality benefit has not been demonstrated

in large clinical trials, HAS is currently reserved for particular patient cohorts and otherwise its use remains clinician dependent.

We have previously described 7-day trends of serum albumin in septic and non-septic critically ill patients [1]. In this study we aimed to evaluate the use of human albumin solution (HAS) in the same population, and to assess the effect of HAS administration on outcomes.

Methods: We retrospectively assessed the records of 755 patients admitted to the Royal Liverpool University Hospital Intensive Care Unit (ICU) between 2008 and 2014, who had seven days of albumin data available. Sepsis was identified in 513 patients (67.9%) of patients. The overall mortality rate at day 28 was 20.3%. We collected demographic data, including age, sex and APACHE II scores, 28 day mortality rates. We also noted the degree of hypoalbuminaemia during the first 7 days of ICU admission, and the first day patients received HAS. IBM SPSS 25.0 was used for statistical analysis; X² tests or Fisher's Exact test were used for categorical data, and Student's t-test or Mann-Whitney U test were used for continuous variables.

Results: Data for HAS administration was available for 719 of the 755 patients. 64 patients received HAS (8.9%). 4.4% (10/226) of non-septic patients and 11% (54/493) of septic patients received HAS. Amongst septic patients, HAS was more commonly administered to patients with albumin levels < 20 g/L (47 patients, 87.0% vs 7 patients, 13.0% of patients with serum albumin 20-34 g/L, p = 0.001); and most patients were given HAS during the first 4 days of their admission (43 patients, 79.6%). There was no significant difference in APACHE II score or age between septic patients who did or did not receive HAS, but there was a difference in the minimum albumin level, which was lower in patients who received HAS (p < 0.01). We found higher mortality rates amongst septic patients who received HAS compared to those who did not (p = 0.006).

Conclusion: We found that septic patients were more likely to receive HAS than non-septic patients; and the majority of septic patients received HAS during the first 4 days of their ICU admission. Higher mortality rates were noted amongst septic patients receiving HAS in our study, though they also had lower minimum levels of albumin. More research is required for the development of evidence-based recommendations to guide HAS administration to septic critically ill patients during the resuscitative and de-resuscitative phases of their ICU admission.

Long-term outcomes in septic shock patients: an observational study

I. Semproni¹; M. Barbera¹; E. Antonucci¹

¹Intermediate care unit, Ospedale "Guglielmo da Saliceto", Piacenza, Italy

Correspondence: E. Antonucci

Intensive Care Medicine Experimental 2020, **8(2)**: 001479

Introduction: Septic shock is a well-known clinical condition associated to high mortality rate and impaired quality of life. Some studies showed that age, comorbidities, functional status and the type of pathogen may affect the prognosis of septic patients. Although many studies have examined short-term outcomes in septic shock, long-term outcomes in this field have been poorly investigated in the literature.

Objectives: We hypothesized that septic shock patients show poor long-term outcomes such as high rates of mortality, hospital readmission and condition of frailty at the discharge.

Methods: We performed a retrospective analysis, reviewing all patients admitted for septic shock in our Intermediate Care Unit (IMCU) from January 1st 2016 to December 31st 2019. The inclusion criteria were age ≥ 18 years old; diagnosis at IMCU admission of septic shock (according to SEPSIS-3 criteria) requiring norepinephrine (or other vasopressors) for 24 hours at least. We collected demographic

characteristics and we evaluated long-term outcomes such as rates of mortality at 28 days, 6 months and 1 year; rate of hospital readmission in the first year and condition of frailty at the first discharge from the hospital (i.e. rate of bedridden patients; pressure ulcers; percutaneous endoscopic gastrostomy/nasogastric tube; urinary catheter).

Results: We reviewed 113 patients and 79/113 respected the inclusion criteria. Demographic characteristics are shown in the Table 1. 39/79 (49.4%) patients died at 28 days from the hospital admission; other 18/79 (22.8%) patients died at 6 months while a single patient died at 1 year (see Figure 1). Total mortality rate at 1 year was 59/79 (73.4%) patients. We found a total of 17 hospital readmissions (8/17 in Intensive Care Unit; 4/17 in IMCU; 5/17 in general wards). About condition of frailty, 3/79 (3.8%) patients showed percutaneous endoscopic gastrostomy/nasogastric tube; 29/79 (36.7%) showed urinary catheter; 10/79 (12.7%) showed pressure ulcers; 27/79 (34.1%) patients were bedridden.

Demographic characteristics	Values
Age, years old (mean \pm SD)	73 \pm 12
Male (n; %)	45/79 (57%)
ICU stay, days (mean \pm SD)	4 \pm 1
SAPS score (mean \pm SD)	51 \pm 13
SOFA score (mean \pm SD)	10 \pm 7
Norepinephrine doses, mcg/min (mean \pm SD)	8 \pm 5
Type of infection:	
Respiratory (n; %)	25/79 (31.6%)
Urinary (n; %)	19/79 (24.1%)
Abdominal (n; %)	16/79 (20.3%)
Skin (n; %)	2/79 (2.5%)
ESKAPE pathogen (n; %)	36/70 (45.6%)
MDR bacteria (n; %)	30/79 (38%)

Table 1 - Demographic characteristics

Figure 1 - Cumulative mortality at 1 year

Conclusion: In our observational study, septic shock patients showed poor long-term outcomes with high rates of mortality, hospital readmission and condition of frailty at the discharge.

Intensive Care Medicine Experimental 2020, **8(2)**: 001513

Introduction: COVID-19 infection can range from asymptomatic infection to life-threatening illness. Severe disease commonly manifests as Adult Respiratory Distress syndrome (ARDS) (1) but may also cause immune dysregulation (2), which may be difficult to distinguish from superimposed bacterial infection. Procalcitonin (PCT) is a biomarker that is released in response to bacterial infection and strongly correlates with severity (3). COVID-19 itself does not appear to increase PCT levels (4). Therefore, a raised PCT in these patients could identify a superimposed bacterial infection (5,6) and guide appropriate initiation and cessation of antimicrobial therapy (7).

Methods: We included adult ICU patients with proven or highly suspected COVID-19 infection who had a PCT sent as part of clinical care. Demographic, clinical and laboratory data were obtained from medical records. The Median and Interquartile Range (IQR) were calculated for White Cell Count (WCC), neutrophils, C-reactive protein (CRP) and PCT. Mann-Whitney-U test was performed to compare patients who died with those who survived. Spearman correlation coefficient was used to demonstrate correlation of PCT results with the other inflammatory markers.

Results: Forty PCT tests were performed on 26 patients, of which eight died. Mean age was 57.8 \pm 12.5 years with a mean length of stay of 26.8 \pm 19.0 days. PCT testing was performed for a variety of reasons: "fever" for 14 tests; "clinical deterioration" in eight tests; "comparison with previous test" for six tests; "difficult wean" for three tests; and "to stop antibiotics" for one test. There was no documentation for eight requests.

PCT levels correlated with WCC ($r=0.515$, $p=0.007$), lymphocyte count and CRP levels ($r=0.423$, $p=0.044$). Survivors had significantly lower PCT results (0.57 ng/mL, IQR: 3.95) than patients who died (2.82 ng/mL, IQR: 7.35, $p=0.047$). Similarly, CRP was lower in survivors (109 mg/L, IQR: 3.62 versus 270 mg/L, IQR: 186.5 $p=0.003$). A change in treatment was made following 9 of 40 (22.5%) test results. On three occasions, antibiotics were commenced, antibiotics were stopped on one occasion and a change in antibiotics occurred on five occasions. High-dose steroids were started in six patients after PCT results had become available.

Conclusion: Our results, albeit in a small population, confirm the previously described correlation between PCT and traditional inflammatory markers, WCC and CRP. PCT levels were significantly higher in non-survivors from COVID-19.

Although treatment was changed after nearly a quarter of PCT tests, it remains unclear on how many occasions treatment would have been changed based on WCC and CRP alone. Further research is warranted to fully elucidate the usefulness of procalcitonin in patients with COVID-19 for initiation of immunomodulatory therapy, high-dose steroids, diagnosis of superimposed bacterial infection or change in antibiotic regimen.

Intensive Care Medicine Experimental 2020, **8(2)**: 001531

Introduction: Evaluation of the relation between APACHE II and mortality on patients admitted to the ICU for Coronavirus.

Methods: Prospective cohort study of patients with coronavirus admitted to the ICU at the Hospital Universitario de Jaén, Hospital San Agustín de Linares and the Hospital Infanta Margarita de Cabra. Continuous variables are expressed as median (25th percentile, 75th percentile) and qualitative variables with absolute and relative frequencies. U Mann Whitney was used for comparison of continuous variables and X² for qualitative variables. Discrimination was evaluated with the area under the ROC curve. $P < 0.05$ was considered as statistically significant (e.s.).

Results: We have studied 52 admitted patients at ICU by coronavirus INFECTION, 41 of them at Jaén hospital ICU, 11 at Cabra hospital. The average age was 63 (58,71). The evaluated severity with APACHE II was 12 (9,16) points and the same evaluation but using SOFA on the first day was 6 (3,8) points. 62,5% (n = 32) required tracheal intubation on their first day and 78,8% (n = 41) during the entire ICU stay. 9 (17,3%) of them didn't manifest any of the evaluated records (cirrhosis, cardiac, renal, respiratory, neurological, oncological, hematological or surgical pathology) and 43 patients (82.7%) showed 1 or more records. Mortality in the ICU was a percent of 38,5 and (meanwhile) at the hospital was 38,5%. Deceased patients had higher APACHE II 14 (12,18) vs 10 (8,15 points, (p = 0.007)), and bigger SOFA on the day of the admission, but without statistically significant differences 7 (4,8) points vs 6 (3,7) points (p = 0.227). Predicted mortality by APACHE II according to the original equation was 16% and that observed was less than expected, specifically 38,5%.

Conclusion: On ICU patients admitted for coronavirus, the severity assessed by APACHE II is bigger in those who die than in those who survive. Anyway, APACHE II statistics of these ill people are not very high, being the observed mortality higher than predicted for patients with the same APACHE II score and admitted to the ICU for acute respiratory distress.

001581**Clinical and Biological evaluation of patients with septic shock according to their immunosuppression state**

Introduction: Biological evaluation of septic shock.

Objectives: To describe and analyse the biological profile, risk of development of multiorgan dysfunction (MODS), and mortality of critically ill patients with septic shock and a previous state of immunosuppression (IS).

Methods: We performed a retrospective analysis of prospectively collected data of patients with respiratory, abdominal and urinary septic shock, according to their immunocompetent (IC) or immunosuppressive (IS) state (1). We include patients identified through the in-hospital activation of Sepsis Code (SC) and admitted in the ICU in

septic shock. Samples were stored in the Sepsis Bank between 2017 and 2018.

We analysed the demographic variables, acute severity scores (APACHE II), development of multiorgan dysfunction (MODS) defined by a Sequential Organ Failure Assessment (SOFA) score > 9, in-hospital and ICU mortality, the vital status at day 28 and the biological profile through the measurement of cytokine levels (IL-1, IL-2, IL-6, IL-8, IL-10, IL-12, INF, TNF α), and inflammatory biomarkers (PCT, CRP, MR-proADM). Categorical data were expressed as proportions, and quantitative data were expressed as mean (SD) or median (interquartile range), according to data distribution. The comparison of qualitative data was performed using the Chi-square test. The comparison of quantitative data was performed using the Mann Whitney U test or the Student t test. The Institutional Ethical Committee approved the present study (CEIC (PR (AG) 11/2016, PR (AG) 336/2016)), and the patients or their representatives signed the informed consent.

Results: During the study period, 758 SC activations were registered; a total of 76 patients fulfilled the inclusion criteria. Fifty-one patients (67.1%) were men, age 62 (14.5) years, the mean of SOFA 9.2 (2.5) and the APACHE 23.5 (6.9). 41 of patients (53.9%), were considered IS, mainly by solid organ transplant under immunosuppressive treatment (26.9%). The most frequent focus of infection was respiratory (39.5%). In-hospital mortality was 28.9%, and ICU mortality was 18.4%. 63.2% developed MODS during the index episode of ICU admission. The ICU mortality, 28-day mortality and in-hospital mortality of IS vs. IC groups were 31.7% vs. 2.8% (p = 0.01), 29.3% vs. 0% (p < 0.01), 41.4% vs 14.2% (p = 0.08), respectively. In-hospital mortality was 41.4% vs 14.2% (p = 0.08) in the IC group and IS group, respectively. ICU Mortality was 31.7% vs. 2.8% (p = 0.01). 28-day mortality was (29.3% vs. 0% (p < 0.01), in the IC group and the IS group, respectively. There were no significant differences in the development of MODS (56.3% vs. 43.8% (p = 0.38) between both groups. There were not significant differences in the biological profiles between IC and IS patients. We obtained the following plasma levels of cytokines in both groups: IL1 β (11.8 [6] vs. [12.1 [3.8] pg/mL p = 0.67), IL2RA (2610 [91] vs. 3310.3 [461] pg/mL p = 0.21), IL6 (2618 [45.4] vs. 2399.2 [11] pg/mL p = 0.78), IL8 (165.9 [77] vs. 158 [22] pg/mL p = 0.84), IL10 (291.1 [12] vs. 199.5 [13] pg/mL p = 0.20), IL12 (24 [3.8] vs. 31.6 [1.8] pg/mL p = 0.11), INF (41.6 [9.5] vs. 47.2 [5.7] pg/mL p = 0.97), TNF α (153.7 [4.8] vs. 200.3 [3.8] pg/mL p = 0.85); inflammatory reactants: PCT (7.6 [3.9] vs. 16 [9] ng/mL p = 0.83), CRP (19.9 [3] vs. 28 [1.9] ng/mL p = 0.16), MR-proADM (5.3 [3.1] vs. 6.6 [4.1] nmol/L p = 0.84).

Conclusion: We found an association between the IS state of critically ill patients with septic shock and mortality; however, it was not associated with increased risk for the development of MODS. Besides it seems that IS state was not associated with a different inflammatory response (cytokine levels and biomarkers). There may be other factors related to the prognosis in these patients.

Introduction: Biological evaluation of septic shock.

Objectives: To describe the impact of the Neutropenia (NT) in the biological profile, development of Multiorgan Failure (MOF), and mortality in critically ill patients with septic shock (SS).

Methods: We performed a retrospective analysis of prospectively collected data of patients with respiratory, abdominal, and urinary SS and evaluated the presence of NT at the admission and the first 48 h. We include patients identified through the in-hospital activation of Sepsis Code (SC) and admitted in the ICU in septic shock. We analysed the demographic variables, acute severity scores (APACHE II), development of MOF defined by a (SOFA score) > 9, day 28 mortality, the presence of NT (1.0×10^9 /litre) and the biological profile through the measurement of cytokine levels (IL-1, IL-2, IL-6, IL-8, IL-10, IL-12, INF, TNFa), and inflammatory biomarkers (PCT, CRP, MR-proADM).

Results: 758 SC activations were registered with a total of 76 septic shock patients. Fifty-one patients (67.1%) were men, age 62 (14.5) years, the mean of SOFA 9.2 (2.5) and APACHE 23.5 (6.9). Respiratory was more frequent focus (39.5%) of infection. 41 patients (53.9%), presented a state of immunosuppression, mainly by solid organ transplant (26.9%). 18 patients (23.7%) presented NT, at 48 h, 4 (22.2%) have recovered and 12 (75%) have persisted. 28 days mortality was 19.7% and 63.2% developed MOF during the index episode of ICU admission. There were no significant differences in the development of MOF (27.1% vs. 17.9% $p = 0.26$), and 28 days mortality [68.2% vs. 31.8% ($p = 0.21$)], between Non-Neutropenic (NN) and Neutropenic (NT) group respectively. The assessment of the biologic profile showed no significant differences between NN and NT group: IL1 β (13.8 [6] vs. [13.1 [2.8] pg/mL $p = 0.63$), IL2RA (2691.5[93] vs. 3311.3 [467] pg/mL $p = 0.24$), IL6 (2818.3 [35.4] vs. 2344.2 [12] pg/mL $p = 0.78$), IL8 (165.9 [77] vs. 158.4 [21] pg/mL $p = 0.84$), IL10 (251.1 [11] vs. 199.5 [13] pg/mL $p = 0.19$), IL12 (23.9 [3.8] vs. 31.6 [1.9] pg/mL $p = 0.13$), INF (42.6 [9.5] vs. 47.8 [5.7] pg/mL $p = 0.95$), TNFa (173.7 [4.8] vs. 190.5 [3.8] pg/mL $p = 0.84$); inflammatory biomarkers: PCT (7.5 [3.9] vs. 14.5 [10] ng/mL $p = 0.84$), CRP (19.9 [3] vs. 25.7 [1.9] ng/mL $p = 0.19$), MR-proADM (5.3 [3.2] vs. 6.6 [4.7] nmol/L $p = 0.84$). There were no significant differences in the persistent NT in the inflammatory profile.

Conclusion: Septic shock patients with neutropenia and persistent neutropenia, not presented a significantly difference in the mortality, developing of MOF. In addition, the degree of neutropenia does not influence the levels of cytokines and biomarkers.

Disordered collagen metabolism is associated with elevated plasma high sensitive cardiac troponin T in septic shock

B. Bollen Pinto¹; A. Herpain²; L. Brunelli³; K. Bendjelid⁴; R. Pastorelli³; M. Ferrario⁵

¹Anesthesiology, Hôpitaux Universitaires de Genève (HUG), Genève, Switzerland; ²Department of intensive care, Université Libre de Bruxelles, Bruxelles, Belgium; ³Laboratory of mass spectrometry, Istituto di Ricerche Farmacologiche Mario Negri IRCCS, Milano, Italy; ⁴Intensive care medicine, Hôpitaux Universitaires de Genève (HUG), Genève, Switzerland; ⁵Department of electronics, information and bioengineering, Politecnico di Milano, Milan, Italy

Intensive Care Medicine Experimental 2020, **8(2)**: 001276

Introduction: Release of cardiac troponins (cT) can occur when myocytes are damaged by a variety of conditions, such as exposure to toxins, inflammation and necrosis. Sepsis is frequently associated with release of cT and the levels of cTs are independently associated with in-hospital and short-term mortality after sepsis [1].

Objectives: The objective of the work was to investigate associations between circulating high-sensitive cardiac troponin T (hs-cTnT) and quantitative mass spectrometry-based metabolomics profile of plasma and cardiac tissues in an animal model of septic shock. This is an ancillary study, the data from the animal experiments were previously published [2,3].

Methods: Septic shock (SS) was induced in anesthetized, instrumented and ventilated adult swines by polymicrobial peritonitis (6 SS and 3 sham pigs). Metabolites were quantified in the myocardium and

in plasma with quantitative targeted metabolomics. Circulating hs-cTnT was measured using the Elecsys[®] assay. Fold-change in hs-cTnT from baseline and after full resuscitation (fluids and vasopressors) was used to stratify the animals. Univariate and multivariate analyses were performed.

Results: No sign of myocardial infarction or contractility reduction was detected in this animal model. Hs-cTnT wasn't significantly different between SS and sham animals at each time point, but hs-cTnT fold-change was higher in septic versus sham animals. In harvested heart tissues, proline and glycine levels were significantly higher in the high hs-cTnT fold-change group, i.e. in those animals with a more severe degree of myocardial injury. By stratifying animals on the basis of hs-cTnT fold-change, proline and hydroxyproline were among the first ranked circulating metabolites in multivariate models to explain the severity of myocardial injury.

Conclusion: Evidence of myocardial injury occurs in the early phase of shock, as indicated by the hs-cTnT fold-changes in the animal study. As collagen is an abundant reservoir for proline and hydroxyproline, we may infer that sepsis-associated myocardial injury could be associated with collagen destruction and/or dysregulated metabolism. In a longitudinal study [4] markers of collagen metabolism were increased in patients with sepsis. The authors showed that serum increasing collagen propeptide levels were associated with the development of multiple organ failure and death. Our results reinforce the concept that collagen degradation could be one of the important mechanisms that contributes to myocardial injury secondary to septic shock.

Intensive Care Medicine Experimental 2020, **8(2)**: 001560

Introduction: In sepsis, enteral feeding is avoided or trophic enteral feeding is recommended especially in the early period when hemodynamics is impaired. There are no clear recommendations in the international nutritional guidelines for parenteral nutrition and lipid content in sepsis, largely due to lack of evidence.

Objectives: Multiple organ injury due to free radicals and decreased mesenteric blood flow are the consequences of septic shock. We investigated and compared whether different Parenteral Lipid Emulsions could attenuate the deleterious effects of endotoxin, such as mesenteric hypoperfusion, inflammatory oxidative damage and multiple organ damage in a mouse model of sepsis.

Methods: Swiss-albino mice (20–40 g) were administered subcutaneously sterile saline (NaCl 0.9%, w/v), fish oil (Omegaven), soybean oil (Kabiven) or olive oil (Oliclinomel) in 50 ml kg⁻¹ dosage 10 min after they have received *E.coli* endotoxin (LPS, O55:B5, 10 mg kg⁻¹) or its solvent sterile saline. Four hours later, mice were anaesthetized, mesenteric blood flow values were measured, spleen and liver weight/body weight ratios were determined and the organs were examined histopathologically. Oxidative stress index was also calculated according to total antioxidant status (TAS) and total oxidant status (TOS) measurements which were done from tissue homogenates and serum by ELISA assay (Oxidative stress index (OSI) = TOS/TAS). Results are expressed as mean \pm SE. Statistical analysis was performed with one-way ANOVA or Kruskal-Wallis.

Results: Endotoxin decreased mesenteric blood flow (ml min⁻¹, saline: 3.02 \pm 0.10; endotoxin: 1.44 \pm 0.10; n = 12, P < 0.05), increased the weight of liver (g per kg body weight, saline: 47.51 \pm 1.05; endotoxin: 56.46 \pm 1.46; n = 12, P < 0.05) and spleen (g per kg body weight, saline: 4.41 \pm 0.17; endotoxin: 8.92 \pm 0.80; n = 12, P < 0.01) while it inflicted significant histopathological injury to both organs. Although fish oil emulsion treatment abrogated the decrease in mesenteric artery blood flow, none of the parenteral lipid emulsions reversed the wet weight gain in liver and spleen. Histopathological examination of the liver revealed portal inflammatory reaction, intrasinusoidal congestion, intrasinusoidal lymphoreticular reaction, hepatocellular injury, ballooning degeneration and congestion was observed in spleen in endotoxin-treated mice. Lipid emulsions, at the doses used, lead to histopathologically harmful effects in the liver and spleen of the control group (saline-saline). Fish oil emulsion treatment has abolished some of the deleterious effects of endotoxin only in liver. OSI was increased in liver, kidney, lung, spleen and serum after endotoxin challenge. The protective effects of some emulsions were observed only in kidney and spleen.

Conclusion: The main finding of this study is that fish oil emulsions containing high omega-3 fatty acids abrogate the decrease in mesenteric blood flow and prevent liver damage in the experimental sepsis model. All of the lipid emulsions, including fish oil, may cause organ damage in healthy animals, even in protective doses.

Intensive Care Medicine Experimental 2020, **8(2)**: 001562

Introduction: Citrulline and intestinal fatty acid binding protein (iFABP) are proposed as biomarkers to detect acute gastrointestinal injury which is commonly unrecognized in critically ill.

Objectives: To evaluate role of citrulline and iFABP to predict acute gastrointestinal dysfunction (AGD) in critically ill septic patients admitted to a medical ICU.

Methods: Critically ill patients admitted to a medical ICU with sepsis were evaluated for AGD in accordance with ESICM recommendations. Patients with chronic renal disease were excluded. Blood samples for

citrulline and iFABP were collected between 48–72 hours of admission. Patients were grouped as with or without AGD. Healthy controls were included from outpatient clinics.

Results: A total of 51 patients and 51 controls were included in the study. Mean age of patients was 70.1 years. There were 19 males (37.3%). All were medical admissions. Mean APACHEII score was 24.8. Mean SOFA score was 8.2. Acute renal injury developed in 41 (80.4%) of patients. Citrulline levels in septic patients were significantly lower than the controls (11.6 vs 13.0; p = 0.004). There was a moderate, positive correlation between citrulline and iFABP in septic patients (r:0.567, p < 0.001). AGD score was higher in patients with hypocalcemia (p = 0.016) and hyperthermia (p = 0.049). Patients with higher AGD score were less likely to attain nutritional goals (p < 0.001). When patients with and without AGD were compared, no significant difference was found for citrulline and iFABP. Citrulline and iFABP levels were not associated with mortality.

Conclusion: This study with critically ill medical patients have shown that citrulline and iFABP levels alone may not be adequate to detect acute gastrointestinal injury presenting as a component of multiorgan dysfunction syndrome.

Intensive Care Medicine Experimental 2020, **8(2)**: 001377

Introduction: Vitamin D deficiency has been associated with an increased risk of respiratory infections such as respiratory syncytial virus infection, tuberculosis and influenza [1, 2]. Sufficient vitamin D level may decrease the risk of death from COVID-19 [3]. However, the vitamin D level in patients with COVID-19, its optimal cut-off value to predict mortality has not been evaluated yet.

Objectives: The aim of the present study was to evaluate vitamin D level in patients on admission to intensive care unit (ICU) as a predictor of mortality in COVID-19 infection.

Methods: The retrospective study was conducted in Federal Research and Clinical Centre. 40 adult patients were enrolled from April 06, 2020 to April 27, 2020. Blood samples were collected within 24 hours after admission to ICU to perform routine laboratory tests and level of 25-hydroxyvitamin D (25(OH)D). Continuous and categorical variables were presented as mean \pm standard deviation or median (Inter-quartile range), as appropriate. The optimal vitamin D cut-off point was evaluated by receiver operator characteristic (ROC) curve.

Results: In present study 40 patients of 67 \pm 16.5 years were enrolled, 13 (32.5%) of them were males. The average 25(OH)D level on admission was 12 (9; 15) ng/ml.

A significant difference in vitamin D level between the dead patients (n = 13) and the survivors (n = 27) was revealed 9 [7.35; 11.5] and 14 [10; 16], respectively, p = 0.004 (the Mann-Whitney test). The area under the ROC curve was 0.79 (95% confidence interval (CI) [0.62; 0.95]), p = 0.004. The optimum cut-off value for vitamin D was 9.45 ng/ml. The predictive accuracy of mortality in patients with 25 (OH) D of less than 9.45 ng/ml had a sensitivity of 85% and a specificity of 62%, figure 1.

Figure 1. ROC curve for vitamin D level for predicting a risk of mortality among patients with COVID-19 infection.

Patients with vitamin D deficiency (25(OH)D of ≤ 9.45 ng/ml) had a 7-fold higher risk of death compared with 25(OH)D levels > 9.45 ng/ml (Odds Ratio 7.04, 95% CI [1.6-30.9]).

Conclusion: ICU COVID patients had deficiency of vitamin D. 25(OH)D level on admission less than 9.45 ng/mL could predict in-hospital mortality in patients with COVID-19. Interventional study is warranted to elucidate whether vitamin D supplementation is useful for treatment of COVID-19.

Intensive Care Medicine Experimental 2020, **8(2)**: 00384

Introduction: Covid 19 infection is an emerging disease that has become a worldwide pandemic. Some patients develop a severe pneumonia that evolves in acute respiratory distress syndrome and therefore in a long stay in ICU.

Objectives: To describe the main nutritional characteristics of mechanical ventilated patients with covid 19 pneumonia admitted to Virgen de Las Nieves Hospital’s ICU.

Methods: We perform a retrospective observational study with 50 patients that required mechanical ventilation (MV) in ICU.

Results: Among the 50 patients, 76% were men, the mean age was 60 +/- 10 years, APACHE at the admission in ICU was 14.7 +/- 6, and the mean of MV were 22 +/- 17 days. Mortality rate in ICU was 36%, without significant differences between men and women when they required MV ($p < 0.26$, CI 0.11-1.79).

Enteral nutrition was given to 97% of patients, while only 12.2% received parenteral nutrition. Protein intake was 44% of daily recommended (0.57 g/kg/day) and caloric intake was 59.9% (1198 +/- 355 kcal/day). Mean IMC was 30.4.

MRC (muscle power assessment scale) at ICU exit was > 48 in 78% of the patients, which implies a lack of intensive care unit-acquired weakness.

Caloric intake was a protective factor against mortality ($p < 0.99$, CI 0.994-0.999). Meanwhile, poor glycemic control was an independent risk factor for mortality ($p < 0.03$, CI 1.00-1.03).

Table 1: Sample’s baseline characteristics

	Total (n)	Percentage %
Sex	50	Male 76% (n=38), Female 24% (n=12)
Diabetes	19	38%
Dyslipidemia	21	42%
Hypertriglyceridemia TG >500 mg/dl	9	18.8%
ICU mortality	18	36%
Hospital mortality	20	40%
Enteral nutrition	40	97%
Parenteral nutrition	5	12.2%

Table 2: Sample’s baseline characteristics

	Total (n)	Mean + SD
Age	50	60 +/- 10.7 years
BMI	50	30.4 +/- 4.3
Apache	50	14.7 +/- 6
SOFA	50	7.8 +/- 2.7
MV	50	22.1 +/- 17.5 days
Neuromuscular blockade	50	6.3 +/- 5.2 days
Prone position	50	2.94 +/- 4 days
Corticosteroids	49	6 +/- 5.1 days
Trigliceryds first 48 hours	48	335 +/- 242 mg/dL
Trigliceryds first week	46	445.6 +/- 263
Caloric intake	38	54.9 +/- 20 %
Protein intake	37	44.4 +/- 20.1 %
Blood sugar	50	161.6 +/- 46.35 mg/dL
MRC	30	52.2 +/- 10.4

Table 3: Multivariable analysis with Cox regression; dependant variable: mortality

Variable	HR	p
Blood sugar	1.023 (CI 1.008-1.039)	0.003
Caloric intake	0.997 (CI 0.994-0.999)	0.017

Conclusion: An appropriate nutrition in ICU allowed better results in patients with covid 19 infection.

- Mortality rate was higher in patients with hyperglucemia and lower in patients with higher caloric intake.
- Hypertriglyceridemia is frequent in patients with covid 19 pneumonia in MV (18% of patients with TG > 500 mg/dL).
- The incidence of intensive care unit-acquired weakness in patients with covid 19 infection was 22% (MRC < 48).

Intensive Care Medicine Experimental 2020, **8(2)**: 001395

Introduction: Relate nutritional status with the presence of complications and mortality in patients undergoing pancreatic oncological surgery admitted to our Intensive Care Unit (ICU).

Methods: Retrospective cohort study of patients undergoing pancreatic oncological surgery at the University Hospital of Jaén, admitted to the ICU for postoperative management from December 2017 to December 2019. Nutritional risk was evaluated using the NUTRIC (NUTrition Risk in Critically ill) score. A descriptive analysis was performed and multivariate analysis.

Results: 47 patients, 29 were male. The median age was 69 (43-86) years, APACHE II 12 (5-29), SOFA score 6 (1-15), Charlson index 3 (2-9) and Nutric score 4 (2-9). Median days of ICU admission was 2 days (1-37). Comorbidities: 55% arterial hypertension, 36% diabetes mellitus, 11% atrial fibrillation, 8% ischemic heart disease, 6% COPD and 4% chronic kidney disease.

32 patients had pancreatic neoplasia. In 87% (36/41) the type of surgery performed was cephalic duodenopancreatectomy. Complications intraoperative: 36% (17/47) hemodynamic instability, 23% (11/47) bleeding intraoperative and of these 5 required polytransfusion. Surgical complications: 7 Suture dehiscence and 6 pancreatic fistula. 16 patients had a NUTRIC of high risk and in 13 of them early parenteral nutrition was started.

Six patients re-admitted in the ICU and 4 of them died on re-admission, median of re-entry days was 6 (2-15) from ICU discharge. ICU mortality was 12% and hospital mortality of 23%.

In the multivariate analysis we observed a statistically significant relationship between the high nutritional risk (NUTRIC score 5-9): history of chronic kidney disease (p.044; OR 0.31 (0.20- 0.48)), ICU readmission (p.044; OR 0.31 (0.20-0.48) and ICU Mortality (p.001; OR 0.26 (0.16-0.44).

Conclusion: We have observed that a high-risk nutritional status can relate to the mortality of our sample, in addition readmissions of these patients were more frequent. A multidisciplinary team has been created management of these patients with the aim of improving the state nutritional and consequently prognosis and morbidity and mortality.

Creatine trials in Critically Ill patients: review of literature

J. Deen¹

¹Intensive Care, ZNA Middelheim, Antwerpen, Belgium

Correspondence: J. Deen

Intensive Care Medicine Experimental 2020, **8(2)**: 001467

Introduction: Many critically ill patients experience a long rehabilitation course due to prolonged ventilatory support and inflammatory state. Creatine has a pivotal role in ATP formation and increasing muscular performance, when combined with resistance training (1). Supplementation might enhance the recovery of the critically ill patient.

Objectives: A review of the literature assessing the possible roles of creatine supplementation in rehabilitation in critical illness.

Methods: A PubMed search was conducted, only articles in English, on adult humans were withheld. Case reports were excluded. Cochrane database was searched. Ongoing trials in the ICU were assessed. (clinicaltrials.gov, controlled-trials.com).

Results: 42 articles were withheld: no trials in the ICU were found. Only 18 of these were clinical trials. Cochrane reviews were found on creatine in cardiovascular disease and (neuro)muscular disorders.

Conclusion: The muscular performance-enhancing effect of creatine supplementation is preserved in age related sarcopenia(2), disuse muscle wasting(3), cachexia(4) and muscular disorders(5), but only when combined with resistance training. No clear benefit was found in neuromuscular(6), mitochondrial(7) or motor neuron disease(8). Creatine's effect on ICU acquires weakness will depend on whether myopathy or polyneuropathy predominate. Creatine's free-radical scavenging and post-ischemic protein synthesis enhancing properties might attenuate the muscular effects of systemic inflammatory conditions(9).

Both pulmonary and cardiac dysfunction might impair rehabilitation tolerance. Creatine supplementation does not ameliorate

COPD patient's quality of life or exertional performance(10), yet the underlying pathophysiology of COPD is different than that of respiratory weakness after prolonged ventilation. A reduction of dyspnea and orthopnea in heart failure have been noted after months of creatine intake(11). Cognitive performance, neuroprotection and post-traumatic stress disorder have been improved after creatine administration(12).

Meta-analysis confirms the safety and low incidence of side effects(13). Meta-analysis could not show any changes in plasma creatinine(14), nor urea excretion. The effect on urinary output is unclear, but kidney function can be tested by biomarker or urinary albumin excretion. A decreased endogenous creatine synthesis in chronic kidney disease might require supplementation(15).

There are no studies into creatine supplementation in the ICU, only two reviews advocate its further study(16,17). Other creatine supplementation studies in specific populations are often lacking in patients and are relatively few in number. Dosing regimens vary amongst studies making comparison harder. Creatine supplementation might have multiple positive effects on rehabilitation of critically ill patients when combined with resistance training. Studies establishing its applications and safety in the ICU are needed.

Albumin Is Not a Buffer in Human PlasmaM. Krbec¹; K. Koudelkova¹; F. Duska¹¹Department of anaesthesia and intensive care medicine, Third Faculty of Medicine, Charles university and FNKV University Hospital, Prague, Czech Republic**Correspondence:** M. Krbec*Intensive Care Medicine Experimental* 2020, **8(2)**: 001572

Introduction: Physiology textbooks consider albumin to be an important buffer in human plasma and blood. (1) According to traditional definition buffers are substances which by their presence in solution increase the amount of acid or alkali that must be added to cause unit change in pH. (2) Contrarily, Stewart's quantitative physicochemical theory predicts that weak acids such as albumin actually cause H⁺ to change more rapidly with addition of acid (defined as change in strong ion difference or pCO₂). (3) However, this theory has not yet been experimentally verified.

Objectives: Our aim was to prepare an experiment to assess which of the aforementioned theories better describes the effect of albumin on pH in human plasma.

Methods: We used lyophilized albumin from human serum, sodium chloride, sodium bicarbonate and water to prepare 5 solutions of artificial plasma with varying concentrations of albumin (10, 30, 50, 70 and 90 g/L). Strong ion difference of all samples was 39–41 mEq/L and osmolarity was 252–284 mOsmol/l. Using CO₂ tonometer, we exposed the samples to varying levels of pCO₂ (2–16 kPa) at 37°C. The pCO₂ and corresponding pH were immediately measured using standard blood gas analyser. At least 15 measurements were performed on each sample. In physiological pH range the dependency of H⁺ on pCO₂ in plasma is linear, therefore the buffer power of each solution was estimated according to slope of the H⁺/pCO₂ line. To increase biological plausibility of the model the whole process was than reproduced with addition of red blood cells (RBC) of a healthy volunteer thus creating solutions resembling whole blood.

Results: As shown in the figure, increasing the concentration of albumin caused the solution to be more acidic (observed as shift to higher H⁺ concentrations). At the same time, increasing concentration of albumin caused the H⁺ to change more rapidly (observed as steeper H⁺/pCO₂ line). The same phenomenon was observed in presence of RBC.

Conclusion: The results of our experiment confirm Stewart's predictions that albumin, as a weak non-volatile acid, does not make the solution more resistant to pH changes, but rather sets a baseline value from which the pH changes of the solution are derived. Despite being recognized by Stewart's approach enthusiasts, this fact is not well known by majority of physiologists and clinicians. Consequently, patients with hypoalbuminaemia and respiratory failure might be less prone to acidifying effects of CO₂ accumulation, but clinical relevance of this phenomenon needs further investigation.

Dysnatraemia in patients with COVID-19K. Kohler¹; D. Patel²; P. Featherstone²; R. Goudie³; J. Preller²; A. Conway-Morris⁴¹Division of anaesthesia, Department of medicine, University of Cambridge, Cambridge, United Kingdom; ²Intensive Care, Addenbrooke's Hospital, Cambridge, United Kingdom; ³Department of biostatistics, University of Cambridge, Cambridge, United Kingdom; ⁴Department of anaesthetics & intensive care medicine, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom**Correspondence:** D. Patel*Intensive Care Medicine Experimental* 2020, **8(2)**: 001442

Introduction: Hypernatraemia in COVID-19 patients is multi-factorial. Known reasons include increased insensible losses due to pyrexia, tachypnoea, and use of diuretics to achieve negative fluid balance. However, it is possible that COVID-19 independently causes hypernatraemia through an undetermined pathway.

Objectives: To determine the prevalence and potential associations of hypernatraemia in COVID-19 patients admitted to acute medical wards compared to intensive care (ICU).

Methods: Data including sodium (Na), base excess (BE), haematocrit, use of diuretics and renal replacement therapy were extracted for 230 COVID-19 patients admitted to a ward and 70 COVID-19 patients admitted to a single ICU. COVID-19 status was confirmed by PCR.

Results: The mean Na for ICU patients was 143, for ward patients 139 (p < 0.001) (Fig.1a). Very severe dysnatraemia (Na >160/ Na < 120) was seen in 10.0%/ 2.9% of ICU patients and 1.3%/ 0.9% of ward patients, whilst severe dysnatraemia (Na >150/ Na < 130) was seen in 48.6%/ 25.7% of ICU patients and 5.7%/ 10.9% of ward patients respectively. This effect was largely independent of diuretic use (Fig.1b). There was a weak positive correlation firstly between base excess and sodium (adjusted R² 0.14), and secondly between urea-creatinine elevation ratio (UCR) and sodium (adjusted R² 0.14) (Fig.1c).

Conclusion: Dysnatraemia was common, especially amongst critically ill patients, and this was more likely to be hyper- rather than hyponatraemia. Although there is a correlation between elevated sodium and markers of dehydration, which was mostly seen in critically ill patients, these did not completely explain the degree of hypernatraemia seen. We hypothesise that dysnatraemia may be a consequence of COVID-19 specific sodium retention, and that this is more pronounced with increasing severity of illness.

001591**A descriptive study of nutritional treatment of patients affected by SARS-CoV-2 admitted in the ICU of the Consorcio Hospital General Universitario from Valencia in Spain**C. Palau Marti¹; R. Rubio Haro¹; L. Alós Zaragoza¹; I. Cobo Ciurlizza¹; P. Solis Albamonte¹; J. Gandia Llopis¹; J. De Andrés Ibáñez¹; C. Ferrer Gómez¹¹Anaesthesiology, Critical Care and Pain Therapy Service, Consorcio Hospital General Universitario de València, València, Spain**Correspondence:** C. Palau Marti*Intensive Care Medicine Experimental* 2020, **8(2)**: 001591

Introduction: Up until today, the acute patient affected by COVID 19 disease presents with a severe acute inflammatory disease, mainly affecting the respiratory system. The severely acute patients need admission to Intensive Care Units (ICU), in order to receive respiratory support, for at least 48 hours. Due to this complications, COVID 19 is related to high nutritional requirements and at the same time the need to avoid volume overload. Moreover, patients affected by COVID 19, need muscular relaxation and prone positions maneuvers as part of the treatment, as well as the administration of rather unusual medication via nasogastric tube. Additionally, this unusual medication, is rarely used in ITU and has higher risk of interaction with other medication. On the basis of the above, the acute patient affected by SARS-CoV-2 infection has higher risk of malnutrition, with all the consequences associated with it. This patients might benefit from a nutritional protocol specific for ITU patients.

Objectives: To describe and analyse if patients affected by SARS-CoV-2 admitted in the ICU of the Consorcio Hospital General Universitario from Valencia (CHGUV) during the pandemic period from February to May 2020 reached the 80% of the nutritional requirements obtained by weight.

Methods: Observational, descriptive, retrospective and longitudinal design to evaluate the accomplish of estimated nutritional requirements in positive COVID-19 patients admitted to the ICU of the CHGUV.

Results: A sample of 29 patients was obtained. 24.1% started enteral nutrition early. 28.6% of the patients reached the nutritional requirements before day 10, while 35.7% did not reach the nutritional requirements at any time. 6.9% reached nutritional requirements before day 15 and 17.2% before day 20. 12.6% was not evaluable because oral tolerance was not possible. Furthermore, 10.34% received complementary parenteral nutrition, 33.3% for failing to meet the requirements.

Conclusion: In our study, data collection such as height and weight was not accurate enough, so the exact BMI was unknown. Besides, the pandemic situation provoked a different behaviour and more difficulties to accomplish the nutritional standards. That means, our patients were no table to get the nutritional requirements. Finally, it is very important to create new protocols to help us to understand our context and improve it.

001607**Muscle relaxation does not reduce CO2 production in mechanically ventilated COVID patients**M. Renes¹; M. Nijsten¹¹Department of critical care, University Medical Center Groningen, Groningen, Netherlands**Correspondence:** M. Nijsten*Intensive Care Medicine Experimental* 2020, **8(2)**: 001607

Introduction: COVID-19 respiratory failure frequently causes severe pulmonary gas exchange disturbances. Neuromuscular blockade

(NMB) can be employed to improve ventilatory mechanics. However, it may also be beneficial to reduce oxygen consumption although there are conflicting reports [1,2].

Objectives: To assess the shortterm effect of NMB on metabolism reflected by carbon dioxide minute production (VCO₂) as measured by mechanical ICU ventilators.

Methods: Most of our ICU ventilators report VCO₂ measurements (Evita Drager V500, Evital Drager XL, Maquet Servo-I, Maquet Servo-U). Our electronic health record records device measurements at one minute intervals. From all (n=94) initial ICU admissions to our ICU during the first wave of the COVID-19 pandemic in the Netherlands (March 19th, 2020 until May 1st, 2020) we analyzed VCO₂ measurements in the 3 hour time window ending 30 minutes before the start of the first administration of continuous NMB and compared those with VCO₂ measurements in the 3 hour time window starting 30 minutes after the start of continuous NMB. We excluded all patients ventilated less than 12 hours before or 4 hours after initiation of NMB, or patients who received any dose of NMB in the 12 hours before start of continuous NMB. Before and after VCO₂ difference were compared using paired samples Student t-test. Rocuroniumbromide was used exclusively for NMB.

Results: Our selection criteria identified 17 patients out of 94 tested for inclusion. 12(70%) were male with a mean ± SD age of 62.8±8.8 years. Mean weight and BMI were 94.1±16.3 kg and 30.1±4.7 kg/m². 12(70%) patients survived until hospital discharge. Mean VCO₂ was 260±65 mL/min (2.79±0.68 mL/kg/min) before initiation of NMB and 264±66 mL/min (2.82±0.65 mL/kg/min) after (p=0.413).

Conclusion: In this cohort of mechanically ventilated COVID-19 patients the initiation of continuous NMB using rocuronium did not significantly change VCO₂. Therefore, it is unlikely that initiation of NMB has significant effects on O₂-consumption and energy expenditure.

001588**Prospective investigations of patients demographic and clinical characteristics with chronic liver disease in intensive care unit**M. Aslan¹; EN. Karaoglu¹; M. Caliskan¹; M. Yildirim¹; S. Temel²; M. Sungur²; K. Gundogan²¹Department of internal medicine, Erciyes University, School of medicine, Kayseri, Turkey; ²Department of internal medicine, Division of intensive care, Erciyes University, School of medicine, Kayseri, Turkey**Correspondence:** K. Gundogan*Intensive Care Medicine Experimental* 2020, **8(2)**: 001588

Introduction: The aim of this study is to prospectively evaluate demographic and clinical parameters of patients with critical chronic liver disease (CLD) followed in the intensive care unit (ICU).

Methods: Patients with CLD who were admitted to the ICU and older than 18 years old were included in this study. The demographic and clinical information of the patients, the etiology of CLD, the indications for hospitalization, and the mortality status were investigated.

Results: A total of 75 patients were included in the study. The mean age was 66 ± 13 years. The most common reason for ICU admission was gastrointestinal (GIS) bleeding (34%) and hepatic encephalopathy (32%). The most frequent causes of CLD were hepatitis C (24%) and hepatitis B (20%). Mean APACHE II score was 15 ± 7. The median SOFA score of the patients was 5 (min: 0 max: 16). Mean MELD score of all patients was 18 ± 8. Mechanical ventilation was needed 27% of patients during ICU period. A total of 24% patients received

vasopressor treatment. Acute kidney injury (AKI) was developed in 33% of patients. We determined new site infections in 23 patients (31%). Cancer as additional co-morbidity (β (SE): 0.711, OR (low, up): 9.874 (2.451-39.783), $p = 0.001$) and increased age (β (SE): 0.032 OR (low, up): 1.096 (1.029-1.167), $p = 0.004$) was determined as an independent risk factor for ICU mortality. ICU mortality was 27%.

Conclusion: As a result of this study, the most common cause of CLD was hepatitis C and the most frequent reason for hospitalization was GI bleeding. Cancer and older age were determined independent risk factor for mortality with critical chronic liver disease patients in ICU.

Intensive Care Medicine Experimental 2020, **8(2)**: 001192

Introduction: Patients with severely head-injured have worst outcomes. Moderate and severe disability occurred around a sixth of these patients. Moreover, about 33% of them do not survive and the remaining patients usually end up with persistent vegetative state. Decompressive craniectomy (DC) is recommended as a second level treatment of Traumatic Brain Injured (TBI) patients with refractory intracranial hypertension (ICH). The outcome of DC still remains controversial.

Objectives: To analyze factors related to disability and mortality at 6 months after ICU discharge, in TBI patients with refractory ICH with DC.

Methods: A retrospective study was performed in TBI patients admitted to the ICU from May 1, 2009 to December 31, 2018, who had DC after a TBI with refractory ICH. Demographic variables and risk factors associated with mortality were analyzed. demographic data; neurological data (clinical examination and Glasgow Coma Score: GCS); hypotension type of craniectomy and DC complications; Rankin scale, and Glasgow outcome scale (GOS) at ICU discharge and 6 months after ICU discharge and 30 days after it; hypo and hyperglycemia; application of mannitol or hypertonic saline solution before and after DC and other related factors. The percentages were compared with the X2 test or Fisher's exact test, the means with the t-test and the medians with the Wilcoxon test for independent data. A multidimensional logistic analysis of mortality was performed 6 months after ICU discharge.

Results: Twenty eight out of 230 TBI and 105 polytrauma patients, with associated severe TBI, were included. Hospital mortality was 28.6% and ICU mortality was 10.7%. Factors associated with mortality that showed statistically significant differences ($p < 0.05$) were among others (Table 1a and 1b): age ($p = 0.002$), APACHE II ($p = 0.006$), Higher GCS at ICU admission ($p = 0.013$), midline displacement on cranial CT, GOS and Rankin Scale, both at ICU discharge ($p = 0.005$ and $p = 0.001$, respectively) and 30 days after ICU discharge ($p = 0.004$ and $p = 0.005$, respectively). GOS values were 3 at ICU discharge and 30 days after it Rankin was 5 at ICU discharge and 30 days after it was 3. Factors that were independently associated with mortality, at 6 months after ICU discharge, were diabetes mellitus, hypertension, orotracheal intubation in the prehospital setting, no reactive pupils before and reactive after DC (Table 2). The most common observed complications were nosocomial pneumonia (67.9%), extraaxial hematoma at the surgical site (57.1%) and hydrocephalus (39.3%).

Conclusion: Patients with TBI and ICH refractory to medical treatment and undergoing DC, had a low mortality rate at ICU discharge, but with severe disability. Factors independently associated with mortality at 6 months after ICU discharge were diabetes mellitus, arterial hypertension, orotracheal intubation in the prehospital setting, none reactive pupils before DC and both reactive pupils after DC.

Intensive Care Medicine Experimental 2020, **8(2)**: 001257

Introduction: Significant variability exists among physicians, in the prophylactic use of anticonvulsants in severe Traumatic Brain Injury (TBI).

Objectives: The purpose of this study was to evaluate the degree of compliance to the Brain Trauma Foundation guidelines in the administration of anti-epileptic prophylaxis and to determine the incidence of post traumatic seizures (PTS) in a cohort of critically ill patients with TBI.

Methods: A retrospective analysis of adult patients with traumatic brain injury, admitted to a level III Intensive Care Unit (ICU) over a period of 4 years, was carried out. Details on the demographic data, severity of injury, CT severity grades, use of EEG monitoring and the administration of anti epileptic prophylaxis were determined. The incidence of post-traumatic seizures was compared between the groups of patients who received anti-epileptic prophylaxis and those who did not.

Results: 562 patients were included in the study. Anti-seizure prophylaxis was given to 77% of the patients with severe TBI. Serum phenytoin levels were measured in only a minority of patients (13.1%) and 34% of them were at a sub-therapeutic level. Standard EEG monitoring was performed in 26% of patients and epileptiform activity was found in only 3% of them. Continuous EEG monitoring was employed in only 0.5% of the study population. 13.3% of the study population developed post traumatic seizures (PTS). The incidence of early PTS was 7.3% and that of late PTS was 3.6%. Post-traumatic seizures occurred at a significantly higher rate in the group of patients who received anti-epileptic prophylaxis (20.2% vs 3.1%, $p = 0.000$).

Conclusion: Post-traumatic seizures occur despite the prophylaxis with anti-epileptics. Administration of phenytoin should be guided with serial measurements of serum phenytoin levels and continuous EEG monitoring.

Intensive Care Medicine Experimental 2020, **8(2)**: 001291

Introduction: Spontaneous intracranial hemorrhage (SICH) is the second most frequent type of cerebrovascular accident with an incidence of 10-15% and a high morbidity and mortality worldwide. To differentiate patients at higher risk of mortality may improve its management and result in better outcomes.

Objectives: To describe the characteristics of patients with SICH as well as treatment strategies and mortality.

Methods: Observational, descriptive and prospective study of 1321 patients who were admitted to a neurocritical ICU between March 1996 and March 2020. We analyzed demographic and clinical characteristics (Glasgow Coma Scale (GSC), Intracranial Hemorrhage Score (ICH), hydrocephalus and pupils). The volume and location of the hematoma, intraventricular extension, treatment strategy and mortality were analyzed too.

Results: Mean age was 58,8 years (SD 15,1) and 62,6% were males with a mean ICU stay of 7,2 ± 9,3 days and hospital stay of 25,7 ± 35,1 days. Mean GSC score at ICU admission was 6 (SD 3) with 8 points or less in a 66,3% of patients and mean ICH score was 2,37 (SD 1,38). Only 1 patient (0,1%) was admitted with an ICH score of 6. Most of patients (73%) presented with normal pupillary reflex and only 11% were admitted with nonreactive bilateral mydriasis. Mean hematoma volume was 54,6 cc (SD 51,1) and the most frequent location was supratentorial (78,3%), being basal ganglia specifically the most prevalent (40,8%). Intraventricular hemorrhage developed in 70,7% but less than half (45,1%) suffered from hydrocephalus. 22,8% of patients were under surgical treatment and an external ventricular drainage was placed in 14,8% of patients. ICU mortality was 45,4% and hospital mortality was higher (50,5%).

Conclusion: Patient with SICH who is admitted at our neurocritical ICU is usually a male in his sixties with high risk of mortality (high bleeding

volume with low GSC score). Major mortality rate happened at ICU during the acute phase and this results are consistent with that published in the literature.

Intensive Care Medicine Experimental 2020, **8(2)**: 001345

Introduction: Non-traumatic subarachnoid hemorrhage (SAH) is a disease with high mortality and disability rates. 1 Identification of risk factors and initial management decisions may affect outcome. 2.

Objectives: To investigate the association of clinical characteristics and early interventions with outcome in patients with severe non-traumatic SAH.

Methods: This study is an observational, retrospective, single-center study conducted in a level III intensive care unit (ICU) of a tertiary referral hospital in Greece. Population of the study was comprised of 29 patients that were admitted in the ICU between July 2018 and February 2020 with the diagnosis of non-traumatic SAH. Outcome was assessed with the Glasgow Outcome Scale Extended (GOS-E) at 28 days, 3 months and 6 months after admission. A favorable outcome was defined as a GOS-E score of 5 or higher at last available assessment. The clinical parameters that were evaluated as potential predictors of outcome were age, gender, Acute Physiology And Chronic Health Evaluation (APACHE) II score and Glasgow Coma Scale (GCS) on admission. Initial treatment and monitoring options under investigation were external ventricular drainage (EVD) catheter, surgery before ICU admission and intracranial pressure (ICP) monitoring. Fisher's exact test was used for comparison and univariate logistic regression models were fitted to the data.

Results: We present our results as preliminary because of limited sample size. Mean age of participants was 62.3 (\pm 8.5) years and the majority (72.4%) were females. Median GCS on admission was 6 (IQR 5) indicating severity and mean APACHE II score was 20.34 (\pm 5.38). A trend of age being negatively associated with favorable outcome was observed ($p=0.126$, $p>0.05$, OR 0.87, 95%CI 0.73, 1.04). Likewise, increased APACHE II score on admission exhibited a negative impact on favorable outcome ($p=0.224$, $p>0.05$, OR 0.86, 95%CI 0.67-1.1). Increased GCS on admission had a significant positive relationship with favorable outcome ($p=0.02$, $p<0.05$, OR 1.74, 95%CI 1.09, 2.27). In our population male gender was related with unfavorable outcome but that was not significant ($p=0.9$, $p>0.05$, OR 0.86, 95%CI 0.08, 9.69). Regarding interventions, surgery for SAH during admission was associated with a trend towards favorable outcome ($p=0.483$, $p>0.05$, OR 2.36, 95%CI 0.21, 25.91). In the majority of our patients (86.2%) EVD was placed so EVD was not related with type of outcome ($p=1$, $p>0.05$). ICP monitoring was beneficial regarding outcome ($p=0.55$, $p>0.05$).

Conclusion: In our population of patients with non-traumatic SAH, severe clinical presentation assessed with decreased GCS and increased APACHE II score were associated with unfavorable outcome.

Younger patients and females showed a trend toward more favorable outcome. EVD was not related with outcome and ICP monitoring exhibited a positive effect on outcome of patients with SAH. Early surgery was beneficial in our population but that was not significant. As our cohort of patients increases, we aim to clarify our results and study more specific subgroups of patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 001348

Introduction: Stroke's incidence has decreased by 42% in developed countries in the last 4 decades due to improvements in health prevention. Conversely, morbidity and mortality have not suffered positive changes despite the efforts.

Objectives: To compare the characteristics and results of 2 series of patients with spontaneous intracranial hemorrhage (SICH) and to analyze the differences in terms of severity, treatment strategies and mortality.

Methods: Observational and prospective study which compares 2 temporal cohorts of patients with SICH. The first one consists in 1208 patients recruited between March 1996 and June 2016 and the second one consists in 113 patients recruited between March 2018 and March 2020. Both groups were admitted to a neurocritical ICU. Variables analyzed were clinical variables, SICH characteristics, treatment strategy and mortality. Statistical analysis with Chi-squared test for qualitative variables and Student's T-distribution for quantitative variables.

Results: Age was significantly higher in the second cohort of patients (61,8 \pm 11,4 years) with respect to the first one (58,6 \pm 15,3 years) $p=0.007$ without differences in sex between them. Regarding severity scores; APACHE-II and APACHE-III were significantly lower in the second cohort ($p=0.003$ for APACHE-II, $p=0.001$ for APACHE-III) but for SAPS-II score difference was not significant (44 \pm 22 cohort 1, 42 \pm 19 cohort 2, $p=0.229$). Mean ICU stay in the first cohort was 7,2 \pm 9,5 days and 7,3 \pm 7,4 days in the second one ($p=0.108$). Mean hospital stay was 25,6 \pm 35,6 days in the first cohort and 26,9 \pm 29,9 days in the second one ($p=0.096$). Both groups had similar SICH characteristics in terms of volume ($p=0.096$), location ($p=0.169$), intraventricular hemorrhage ($p=0.354$) and hydrocephalus ($p=0.189$). No differences were found as well in treatment strategy. Surgical intervention was 21,9% in the first cohort and 32,7% in the second one ($p=0.08$). Ventricular drainage was placed in 14,4% of the first and 18,6% of the second cohort ($p=0.231$). Regarding mortality there were not statistically significant differences in ICU mortality (46,1% first cohort, 38,1% second cohort, $p=0.102$) or hospital mortality (51,2% first cohort, 42,5% second cohort, $p=0.075$).

Conclusion: We can conclude that the characteristics of the patients with SICH have been similar over time except age that is higher in the most recent cohort. Results are similar in both groups in terms of

ICU/Hospital stay, treatment strategy and mortality. Despite failing to achieve statistically significant differences, there is a statistical trend in the second cohort of patients to lower ICU/Hospital mortality as well as to higher surgical intervention and ventricular drainage placement as treatment options.

Correspondence: J. Rhodes

Intensive Care Medicine Experimental 2020, **8(2)**: 001437

Introduction: Deep Venous Thrombosis (DVT) is common in patients with TBI and correlates with poor outcome, increased number of days of mechanical ventilation and length of admission [1,2]. An increased number of VAEs has been described in these patients. The TARDIS (Traumatic Brain Injury Associated Radiological Deep Vein Thrombosis Incidence and Significance) study has been designed to investigate incidence (via compression ultrasound) of DVT in patients with moderate/severe TBI who require ventilation. The association between DVT and acute lung injury (ALI), VAEs, ICU length of stay and short or long-term survival and disability outcomes are secondary objectives. Severe trauma patients, including TBI, present coagulation abnormalities with increased morbidity and mortality [3]. Conventional coagulation tests have many limits while TEG displayed a potential diagnostic and prognostic role [4].

Methods: Following consent, ventilatory associated events (new x-ray infiltrates, worsening of oxygenation or increased secretions, signs of inflammation, need to commence patients on antibiotics with or without microbiological confirmation) were recorded to 10 days post injury in ventilated patients with brain trauma admitted to intensive care unit, as part of the TARDIS study protocol. A compression ultrasound scan (USS) of both legs was performed and repeated on alternate days up to Day 10 from injury; clinical, ventilatory and laboratory variables were collected daily. TEG was performed at admission, as per the manufacturers' instructions. Clinical and viscoelastic variables were correlated with the incidence of VAE. Data is described as mean (standard error of the mean) and median (interquartile range) as appropriate. Proportions were analysed by t-student and Chi square test, p < 0.05 are considered significant.

Results: Preliminary data from a single Institution are included. Six out of 15 (40%) patients developed VAE during the first 10 days of admission. No significant correlation was observed between gender, age, GCS and Marshall scores at admission and VAEs.

Variables	Overall (n=15)	VAE (n=6)	NO VAE (n=8)	P value
K 0,8-2,1 >2,1	6 (42,86%) 8(57,14%)	2 (33,33%) 4 (66,67%)	4 (50,00%) 4 (50,00%)	0,62
Alpha 63-78 <63	5(35,71%) 9(64,29%)	1 (16,67%) 5 (83,33%)	4(50%) 4(50%)	0,30
K >2,1 and Alpha <63	8(57,14%)	4 (66,67%)	4 (50%)	0,62

TEG displayed increased K and reduced Alpha angle values (see Table). Mean values were altered in both groups, but contingency test showed a high percentage of patients with VAEs with prolonged K (66%) and reduced α (83%). Four out of 6 patients (66%) had both values altered.

Conclusion: VAEs are frequent in our cohort of patients with TBI requiring mechanical ventilation. Despite no statistical significance,

our data suggest that a hypocoagulable profile recorded via TEG seems associated with increased risk of developing VAEs. This work requires further confirmation and is continuing in the TARDIS study.

Intensive Care Medicine Experimental 2020, **8(2)**: 001448

Introduction: In the neurocritical care setting catheter associated ventriculitis (CAV) is a frequent complication associated with increased morbidity and mortality. Precipitating risk factors are still under discussion.

Objectives: To investigate potential CAV "triggers" and secondary to record for microbial etiology and incidence in our cohort.

Methods: Single center study on adult neurocritical care patients requiring urgent EVD insertion (January 2018 - April 2020). Exclusion criteria were: prior hospitalization, CNS infection or hydrocephalus and CSF leakage. All catheters were antibiotic impregnated connected to a drainage system placed in the operating theatre. Periprocedural antibiotics were given in all. Dressing change performed every 2 days. CSF samples were obtained from the EVD as clinically indicated. CAV defined as CSF: positive culture \pm pleocytosis \pm hypoglycorrhachia (IDSA guidelines 2017). Patients were divided into two groups (non CAV/CAV). Demographics, Charlson comorbidity index (CCI) score, GCS, APACHE II, neurosurgical intervention, EVD related data, CSF sampling count, CAV incidence, bacteria cultured, intraventricular antibiotic use and concurrent infection were recorded. Student t-test or Mann Whitney U test used for quantitative data and the Pearson chi-squared test for qualitative data as necessary. The level of significance was set at P < 0.05.

Results: We retrieved 52 medical records with 76 EVD insertion procedures for a total of 804 EVD days (mean age 61.65 \pm 11.51 years). The indication was TBI (5.7%), aSAH (63.5%) and ICH/IVH (30.8%). CAV confirmed in 9 patients (17.3%). Each of them experienced only one episode of EVD infection while 3 (33.33%) had a co-infection. CAV rate estimated as 11.2/1000 days. Gram stain had findings in 3 of them (33.3%). Major CSF pathogens were: *Acinetobacter baumannii* (n = 5, 55.6%), coagulase-negative staphylococci (n = 2, 22.2%), *Enterococcus* species (n = 1, 11.1%) and *Klebsiella oxytoca* (n = 1, 11.1%). Intraventricular antibiotics used as an adjunct in 5 (55.6%).

Baseline characteristics (gender, age, CCI, GCS) and indication of EVD insertion were similar in both groups (p > 0.05). Univariate analysis showed that CAV patients received more EVD catheters (p < 0.001) and had longer total drainage duration (13.93vs22.77; p = 0.016) but retention of the drainage system > 10 days was not correlated with increased risk of infection (p = 0.81). Indeed in most CAV patients

(6/9; 66.6%) infection documented during the time period of the first inserted EVD. Among other tested variables potential “triggers” were neurosurgical intervention ($p=0.01$), CSF sampling >1 time ($p<0.001$) and the simultaneous presence of intraparenchymal ICP monitoring devices ($p=0.021$).

Conclusion: Neurosurgical operation and recurrent sampling, but not shunting duration, were factors associated with EVD infections. Interestingly enough, concurrent existence of intraparenchymal ICP monitoring devices seems to have a correlation with the presence of CAV in our cohort. These results are in agreement with previous studies and confirm the need to focus on minimizing potential “triggers” in order to overcome the CAV obstacle in neurointensive care patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 001453

Introduction: Positive CSF culture is the cornerstone of EVD related infections (ERI) diagnosis. However it is time consuming while prompt antimicrobial therapy is crucial. Several conventional CSF parameters have supplementarily used but their diagnostic accuracy especially in case of hemorrhagic CSF is uncertain. Under these limitations the cell index, a formula to correct for blood contamination, and the CSF/serum glucose ratio have been proposed as alternatives.

Objectives: To evaluate and compare the utility of cell index over the CSF/serum glucose ratio in early diagnosis of ERI in patients with hemorrhagic CSF.

Methods: We reviewed data of consecutive adult neurocritical patients who received an EVD in an emergency setting from January 2018 to April 2020. We enrolled patients with raised clinical suspicion for ERI in whom at least one CSF sample and complete blood count send for analysis at the same day. Samples were obtained from the EVD system. Patients who excluded were those who had prior hospitalization or CNS infection. All included patients received antimicrobial impregnated EVD catheters at the operating theatre and protocol based antimicrobial prophylaxis as well with no further antibiotic exposure until CSF sampling. ERI was defined based on CSF positive cultures. We assigned patients into two groups according to presence or absence of ERI. Data concerning demographics, indication of EVD insertion, GCS, Charlson Comorbidity Index (CCI) and APACHE II were collected. Peripheral blood (WBC, RBC, glucose) and CSF (WBC, RBC, glucose, culture) cytochemical/microbiological analyses at the time of clinical suspicion of ERI were retrieved. We calculated for each sample the cell index [(CSF leukocytes/CSF erythrocytes)/(blood leukocytes/blood erythrocytes)] and the CSF/serum glucose ratio. Categorical variables were tested using a chi-square test and continuous variables using the Student t test or Mann Whitney U test. The level of significance was set at $P<0.05$. The predictive ability of the CSF tests of interest was estimated using an area under the receiver operating characteristic curve (AUC-ROC) analysis.

Results: 28 patients met study criteria (mean age 62.21 ± 11.59 ; females 60.71%). 19 of them were classified as non ERI whereas 9 as ERI (32.14%). Indications for drain placement were TBI (1vs0), aSAH (11vs7) and ICH/IVH (7vs2). No differences were observed in

baseline characteristics (gender, age, GCS, CCI, APACHE II) or in indication of EVD insertion between the groups ($p>0.05$). In patients with ERI the median cell index was 15.14 vs 0.61 for the rest of patients ($p<0.001$). No statistical difference was noted in CSF/serum glucose ratio when comparing ERI and non ERI patients (0.53 vs 0.76 respectively; $p=0.058$). Discriminatory power of cell index was excellent (AUC:0.927; 95%CI:0.763-0.991; $p<0.001$) in confirming ERI at the time of clinical suspicion whereas that of the CSF/serum glucose ratio was fair (AUC:0.722; 95%CI: 0.522-0.874; $p=0.069$).

Conclusion: In the context of hemorrhagic CSF, cell index calculation had an excellent diagnostic accuracy in confirming ERI in our cohort as compared to the widely used CSF/serum glucose ratio. Our results extend knowledge from previous studies. Further research should be carried out in order to incorporate this costless index in every day clinical practice.

Diagnostic experience of patients with stroke mimic in a Latin American University Hospital

JD. Villalobos-Ibarra¹; A. Vargas-Villanueva¹; JA. Carrizosa¹

¹Department of critical and intensive care medicine, Fundacion Santa Fe de Bogota University Hospital, Bogotá, Colombia

Correspondence: A. Vargas-Villanueva

Intensive Care Medicine Experimental 2020, **8(2)**: 001483

Introduction: One-third of the patients that present to the emergency room with stroke symptoms are stroke mimics (SM) (1), leading to stroke code activation, several diagnostic tests required, unnecessary treatment, and high costs to the health system before the diagnosis of a stroke mimic can be confirmed (2).

Objectives: This study aimed to describe the patient’s characteristics, risk factors, diagnostic tests, and types of mimic presenting to a university hospital at Bogota, Colombia.

Methods: This was a single-center cross-sectional study of patients admitted to the emergency room with stroke symptoms and further diagnosis of SM. Data were obtained from January 2017 to March 2020 from a clinical database. Patients excluded if the stroke code was not activated or the admission at the emergency room (ER) was not due to stroke symptoms. FABS and Telestroke score for SM prediction were calculated.

Results: The study included 111 patients, being women 54.1% of them. The clinical characteristics on admission to the ER were similar between men and women. The mean time between the onset of symptoms and admission at ER was 4.7 ± 8.5 hours, and the mean-time of stroke code activated was 2.1 ± 2 hours. The most common disease in medical history was hypertension (49.5%), followed by dyslipidemia (19.8%) and cancer (15.3%). In most patients, the diagnosis of mimic was made between 1 and 4 hours from the ER admission (64.9%), MRI was the most frequent first neuroimage that allows the identification of SM (57.7%). Only 4.5% of cases did not require a neuroimage at ER because the diagnosis of SM was predominant over stroke. The mean score of Telestroke and FABS score was 15.8 ± 6.2 and 2.1 ± 0.6 , respectively, with a high probability of being a mimic according to both scores in 84.7% and 99.1% of cases, respectively. The most common etiology of mimic among women were migraine (18.3%) followed by a transient ischemic attack (16.7%) and conversion disorder (11.7%) with no cases of conversion disorder among men. The most common cause of SM among both sexes was also migraine (15.3%). Administration of tissue plasminogen activator was done in 0.9% of patients, being only men.

Conclusion: Both FABS and Telestroke seem to easily stratify patients with a high probability of having an SM at the ER. This pathology is

most common in women and predominantly confused with migraine symptoms. It is crucial to identify the population at risk of SM to reduce the unnecessary administration of stroke treatments.

Intensive Care Medicine Experimental 2020, **8(2)**: 001497

Introduction: The diagnosis of meningitis is a clinical challenge in intensive care, even more in neurocritical patients. This population has an increased risk of meningitis, related to cerebral damage, surgical intervention and use of intracranial devices.

However, the classical clinical diagnosis of meningitis is compromised in neurocritical patients, due to impaired neurological status, and difficult valuation of cerebrospinal fluid (CSF).

Objectives: To describe and analyse the determinant factors to diagnose meningitis in neurocritical patients: risk factors, interventions/intracranial devices, clinical signs and CSF analysis.

Methods: Retrospective analysis of adult neurocritical patients admitted in an intensive care unit (ICU) from a 3-year period in which meningeal infection was suspected and CSF analysis was done.

Results: Twenty-seven surgical patients were included, with a mean age of 49 years old. Seventy percent of the patients were male. The ICU mortality was 11%. Meningitis was diagnosed in more than 65% of the sample. There were no significant association between any risk factor, intervention/intracranial device or clinical sign and the diagnosis of meningitis. When analysing the CSF, there was a significant association between cell counting and the diagnosis of meningitis, with a mean cell counting of 122/mL vs 923/mL ($p < 0.05$).

Conclusion: Classical signs of meningitis are of little use in neurocritical intensive care patients. Risk factors and interventions or the use of intracranial devices may be an alert to doctors but were not significantly associated with the diagnosis. The most crucial parameter to better diagnosis of meningitis is the cell number of CSF analysis.

Evaluation of the effect of early administered neuroprotective drug on treatment results in patients after traumatic brain injury- PILOT trial

K. Kojder¹; K. Jarosz¹; A. Agata²

¹Anesthesiology and intensive care, Pomeranian Medical University, Szczecin, Poland; ²Anesthesiologist and intensive care, University Hospital 1 Szczecin, Szczecin, Poland

Correspondence: K. Kojder

Intensive Care Medicine Experimental 2020, **8(2)**: 001546

Introduction: TBI (Traumatic Brain Injury:traumatic brain injury) is associated with one of the highest rate of deaths and setbacks in the recovery and return to life in society. The latest reports of the medical literature emphasized the need for further research in terms of methods for treatment of patients with TBI. One of the drugs with positive impact on prognosis in this group of patients is cerebrolysin. This drug is a component produced from a homogeneous, purified pig brain, containing different protein molecules of low molecular weight, which have neuroprotective and neurotrophic effects in vitro and in vivo. In the existing literature there are no reports describing the effect of early cerebrolysin administration in patients with TBI, in correlation with neuropsychological tests and neuroimaging results.

Objectives: Evaluation of the impact of early administration of neuroprotective drug (cerebrolysin) on outcome of patients after a TBI, who were treated neurosurgically and under the conditions of the ICU .

Methods: 10 patients were included in the study according to inclusion criteria: TBI diagnosis (subarachnoid, epidural, or subdural hemorrhage) in patients, who were qualified for neurosurgical treatment (decompressive craniectomy,implantation of ventricular drainage), age 40-65y, GCS <8, time from the injury less than 6 h. After randomisation patients were assigned to two groups (Group 1early drug administration, Group 2 control group). After the qualification the neuroprotective drug was administered in Group 1 (Cerebrolysin - intravenous infusion **50 ml** for 21 days, first dose in first 6 hours after the injury). After the neurosurgical treatment the patients of both groups were hospitalized in the ICU where standard intensive care was provided in both groups. The condition of the patients was monitored by neuroimaging (Computed Tomography), and neuropsychological tests (Barthel scale: evaluation of the efficiency of the patient, Mini -Mental State Examination :the scale of assessment of cognitive disorders).

Results: The results of the study contain the results of general outcome of the patients, GOC, the neuroimaging and psychological tests results.

Conclusion: The effects of early administration of neuroprotective drug (cerebrolysin) in correlation with neuroimaging results and neuropsychological test results of patients after TBI need further research on larger group.

001558**Functional situation of patients who enter the ICU by Traumatic Brain Injury at 3-4 years of follow-up**

T. Amat Serna¹; C. Aranda Martínez²; M. Delange Van Der Kroff²; M. Guerrero Marin¹; M. Prieto-Palomino⁴

¹Medicina intensiva, Hospital of Jaen, Jaén, Spain; ²Medicina Intensiva, Hospital of Jaen, Jaén, Spain; ³Intensive care, Hospital Comarcal Axarquía, Vélez-Málaga, Spain; ⁴Intensive care, Hospital Carlos Haya, Málaga, Spain

Correspondence: C. Aranda Martínez

Intensive Care Medicine Experimental 2020, **8(2)**: 001558

Introduction: To study in patients admitted to the ICU with traumatic brain injury (TBI), the long-term functional situation (3-4 years) and analyze whether the evaluation one year after admission in ICU reflects what your situation will be in the future.

Methods: Prospective cohort study of patients with TBI admitted to the ICU of the Regional Hospital of Malaga during the years 2004 to 2008, collection of data at hospital admission and subsequent follow-up with telephone call to evaluate functional situation. GOS (Glasgow Outcome Scale) was used to assess the functional situation. X² was used for proportion comparison and $p < 0.05$ was considered statistically significant.

Results: A total of 531 patients, age 35 (22.56) years, APACHE II 17 (13.23) points, Glasgow 7 (4.10) points, were included in the study. Mortality in the ICU was 25% and in hospital mortality was 28.6%.

Of the 379 patients admitted to the hospital, follow-up could be performed at one year in 363 patients and their functional situation was as follows: GOS 1 (deceased): 38 (10.5%), GOS 2: 15 (4.1%), GOS 3: 98 (27%), GOS 4: 99 (27.3%) and GOS 5: 113 (31.1%).

At 3-4 years, a new follow-up of patients was performed and 445 patients (86 missing) could be evaluated. The classification according to the Glasgow Outcome Scale shows that 181 patients (171 per year and 10 thereafter) had died (GOS 1). At 1 year, 40.2% of the 445 patients evaluated had good functional status (Normal (GOS 5) or Disfunction but Self-sufficient (GOS 4)). At 3-4 years, 45% (N=200) had good functional status (GOS-4-GOS 5) and 64 (14.38%) of the patients followed and who had not died had a poor functional status (Vegetative (GOS 2) or Disfunction and not Self-Sufficer (GOS 3)). Among the patients who had no died, only 1 patient had worsened their functional status between the year and 3-4 years and 65 patients had improved their functional status (14.6% of the total 445 patients evaluated per year and 23.7% of the patients who had not died per year and who were followed at 3-4 years).

GOS 1st year	GOS 3rd-4th years				
	1	2	3	4	5
1	171	-	-	-	-
2	0	10	1	0	0
3	5	0	52	25	2
4	2	0	0	43	37
5	3	0	0	1	93
	181	10	54	68	132
X = 1200 , p<0.001					

Conclusion: In patients admitted to the ICU with TBI, the year-end evaluation of the functional situation does not reflect what their functional situation will be in the future. And these patients show an improvement in their functional situation between the periods of 1 year and 3-4 years in a fairly high group of patients.

001567**A correlation of gastrointestinal motility disorders and acute brain injury in the patients admitted to the ICU in one year period**

F. Kunovac¹; S. Kvolik¹; N. Nenad¹; T. Turk²; A. Cicvaric¹; D. Muzevic³

¹Anesthesiology and icu, Osijek University Hospital; Medical Faculty, Osijek, Croatia; ²Radiology, Osijek University Hospital; Medical Faculty, Osijek, Croatia; ³Neurosurgery, Osijek University Hospital; Medical Faculty, Osijek, Croatia

Correspondence: S. Kvolik

Intensive Care Medicine Experimental 2020, **8(2)**: 001567

Introduction: Gastrointestinal motility (GI) disorders were frequently observed in the patients with neurodegenerative diseases and in the critically ill patients. The incidence of both gastroparesis and constipation in the neurosurgical patients in the intensive care units (ICU) was rarely reported and was not correlated with brain swelling in the area of the vagal nuclei.

Objectives: The aim of this cross-sectional study was to evaluate the incidence of gastroparesis, constipation and stress ulcers in neurosurgical patients, and the correlation between acute brain injury in the area of the vagal nerve and GI motility disorders.

Methods: An institutional ethics committee approval was obtained prior to the study. Electronic database and medical records of 207 neurosurgical patients hospitalized at ICU of the University Hospital Centre Osijek from November 2018 to November 2019 were analyzed. Demographic data, total opioid consumption per patient, drugs used for GI stimulation, and brain CT images were correlated with gastroparesis and constipation. A subgroup of 69 mechanically ventilated (MV) patients who stayed in the ICU for ≥ 4 days was investigated up to the day 15. Total opioids were calculated as morphine equivalents (ME). Brain lesions involving the vagal nuclei area was graded by neuroradiologist as follows: 1 no edema, 2 edema present, 3 edema with midline shift. Gastroparesis and constipation were considered if delayed emptying without evidence of mechanical obstruction was present.

Results: A total of 113 emergency and 94 elective patients were admitted in the ICU. In the subgroup of 69 MV patients (63 emergency and 6 elective) who stayed ≥ 4 days in the ICU brain edema was registered in 57 (82.6%) patients. Gastroparesis was observed in 48 (69.6%), constipation in 67 (97.1%) and stress ulcers in 4 (5.8%) of MV patients. During their ICU stay patients had GI stimulation for 463 days (39%), and had stool in 306 days (25%) out of 1183 ICU days. The first stool, despite stimulation was registered later in patients with brain edema compared to those who did not have edema (7.0 ± 3.1 vs 3.5 ± 2.6 days; $P = 0.012$). Patients with swelling in the vagal nuclei area had common paroxysmal hypertensive episodes and needed more opioids for sedation as compared to patients without edema (12.7 ± 12.1 vs. 46.2 ± 35.9 ME; $P < 0.001$).

Conclusion: Patients with brain edema had more GI dysmotility disorders than patients without edema. Randomized controlled studies comparing different sedation protocols, opioid vs. nonopioid may more accurately confirm an occurrence of GI dysmotility disorders, and their correlation with brain edema, and opioid and non-opioid sedation in the ICU.

001570**Synocarotid syndrome in carotid angioplasty with stenting**

R. Polishchuk¹; Y. Ryabinkina¹; M. Piradov¹; I. Luneva¹

¹Icu, Research Center of Neurology, Moscow, Russia, Russia

Correspondence: I. Luneva

Intensive Care Medicine Experimental 2020, **8(2)**: 001570

Introduction: Stroke is the most important medical and social problem. One of the primary prevention methods is transluminal balloon angioplasty with stenting of the internal carotid arteries (ICA TBA) for stenosing atherosclerosis as the most common cause of ischemic stroke. A significant risk of surgery is carotid sinus syndrome (SCS).

Objectives: To determine of the frequency and timing of the development of SCS to ensure its personalized prevention and treatment

in patients with atherosclerotic stenosis of the internal carotid arteries when performing TBA.

Methods: The prospective study included 120 patients with atherosclerotic carotid stenosis, who underwent TBA. The indications for surgical treatment were "symptomatic" stenoses of 50% or more and "asymptomatic" stenoses of 70% or more. All patients underwent invasive (Blood Pressure [BP]) and non-invasive monitoring (BP, heart-beat [HB], sPO₂, respiratory rate [RR]) during and after surgery. The diagnosis of SCS was established according to the generally accepted classification.

Results: SCS developed in 70% of cases of ICA TBA (n=84), significantly more often in men - 71.4% (n=60) than in women - 28.6% (n=24), (p<0.05). The median age was 68 (44:91). The predominant type of SCS was mixed than cardio-inhibitory or vasodepressor (p<0.05). It took place in 63% of cases and was characterized by the almost simultaneous occurrence of sinus bradycardia (or asystole) and hypotension. In a little more than half of cases, 54.7% (n=29) SDS developed in response to balloon dilatation, in 11.3% (n=6) patients within 1 hour after dilatation, and in 34% (n=18) - in more distant terms, on average after 6 hours (from 2 to 11 hours). The cardio-inhibitory type was observed in 20% of cases (n=17) and in the majority of patients 82% (n=14) manifested sinus bradycardia both during balloon dilatation and within the first hour after it. Atrioventricular [AV] block of I and II degrees took place in 2 patients (11.7%). Asystole for more than 3 seconds without loss of consciousness was noted in 1 patient for balloon dilatation (6.3%). The vasodepressor type was observed in 17% of cases (n=14). In half of cases - 50% (n=7) arterial hypotension occurred immediately on balloon dilatation, in 5 patients - within the first hour after dilatation, and in 2 patients - at more distant periods (after 2 and 5 hours).

Conclusion: The work performed showed that three out of four patients with elective surgical endovascular intervention on the internal carotid arteries develop SCS, which is most often manifested by the almost simultaneous development of arterial hypotension and sinus bradycardia. In some cases, surgery is accompanied by cardiac arrest. These symptoms can occur not only during balloon dilatation, but also hours after surgery. This requires maximum awareness and preparedness of the anesthesiologist-resuscitator to provide the necessary assistance to patients, including the correct maintenance of blood pressure and heart function in order to prevent stroke and myocardial infarction.

Critically ill patients with encephalitis in ICU

I. Luneva¹; R. Polishchuk¹; Y. Ryabinkina¹; M. Piradov¹

¹Icu, Research Center of Neurology, Moscow, Russia

Correspondence: I. Luneva

Intensive Care Medicine Experimental 2020, **8(2)**: 001585

Introduction: Encephalitis is a severe pathology of the nervous system that is difficult to diagnose and treat. Currently, there are a number of limitations for verifying the etiology of encephalitis. The most common symptom is a change in behavior, a decrease in the level of consciousness up to coma, epileptic seizures, and focal neurological pathology. Often, with viral encephalitis, there is a hemorrhagic transformation of the inflammation focus, interstitial edema in the area of

the focus, often with a displacement of the mid-stem structures, which may require decompression craniotomy.

Objectives: To investigate the peculiarities of diagnosis and treatment of encephalitis of various etiologies.

Methods: We observed 5 patients with encephalitis of various etiology. All patients underwent MRI of the brain at admission and in the medical examination. To exclude myelitis, MRI of the cervical spinal cord was performed. Also, all patients underwent a general study of cerebrospinal fluid, PCR of cerebrospinal fluid (CSF) for the presence of DNA viruses and intrathecal synthesis of oligoclonal antibodies. Also, taking into account the volume and level of lesion of the foci, all patients underwent EEG, and a number of patients underwent blood tests for the presence of antibodies to NMDA receptors.

Results: In the neurological status, all patients had behavioral changes, and later a decrease in the level of consciousness to coma in 4 patients and 1 patient developed mutism. Upon further examination, the following etiology of encephalitis was established: in 2 cases, herpetic encephalitis (PCR for *Herpes simplex virus* types 1 and 2 was positive), in 1 case, bacterial ventriculomeningoencephalitis (PCR for *Listeria monocytogenes* was positive), in 1 patient, necrotizing encephalitis associated with Influenza virus, and 1 case - multiple sclerosis (intrathecal synthesis of oligoclonal antibodies was determined in the CSF). In the general analysis of CSF, all patients had an increase in protein and cytosine. EEG in 3 patients out of 5 revealed epileptiform activity, which required the appointment of anticonvulsant therapy. All patients received glucocorticosteroid therapy and antiviral therapy 3 out of 5, antibiotic therapy in 1 patient. IVL was performed in 4 out of 5 patients. 1 patient with herpetic encephalitis underwent decompression trepanation, 1 patient received external ventricular drainage. The outcome in all patients is favorable. (fig MRI).

Conclusion: Thus, MRI and CSF examination are necessary diagnostic methods for detecting encephalitis and verifying its etiology. Also, neurosurgical treatment can improve the outcome of patients with progressive ventriculitis or laterally displaced encephalitis.

001566

Asses functional situation at year of patients with Traumatic Brain Injury (TBI)

T. Amat Serna¹; C. Aranda Martínez²; M. Delange Van Der Kroff³; M.

Guerrero Marin¹; M. Prieto-Palomino⁴

¹Medicina intensiva, Hospital of Jaen, Jaén, Spain; ²Medicina Intensiva, Hospital of Jaen, Jaén, Spain; ³Intensive care, Hospital Comarcal Axarquía, Vélez-Málaga, Spain; ⁴Intensive care, Hospital Carlos Haya, Málaga, Spain

Correspondence: C. Aranda Martínez

Intensive Care Medicine Experimental 2020, **8(2)**: 001566

Introduction: Study in patients who are discharged from the Intensive Care Unit (ICU) with a diagnosis of traumatic brain injury (TBI), if the situation neurological evaluated with the Glasgow coma Scale at discharge from ICU and other variables known at admission and during their stay at ICU are related to the situation functional at one year evaluated with the Glasgow Outcome Scale (GOS).

Methods: Prospective cohort study of patients with TBI admitted to the ICU of the Regional Hospital of Malaga during the years 2004 to 2008, data collection at hospital admission and monitoring of the functional situation with a phone call. Descriptive analysis using programme R.

Results: A total of 531 patients, age 35 (22.56) years, APACHE II 17 (13.23) points, Glasgow on admission 7 (4.10) points were included in the study. 398 patients from the total of those admitted were discharged to the ward (6 of them to other hospitals). Follow-up at one year was made of 491 patients, 34 were lost to follow-up. 177 patients died from hospital admission (133 in the ICU, 19 in the hospital ward and 19 in the following year). Using the "R" program, through the

"randomForestSRC" program and the function "Vimp" we have studied the variables with the highest relationship with the dependent variable "Functional situation at one year", classified as good or bad situation. The most related variables in order of importance were: Glasgow Coma Scale score at discharge from ICU, Age, APACHE II, Glasgow Coma Scale Score at ICU a mission. The following table shows the relationship with these variables categorized in intervals.

	GOS 1st year		p
	Good situation (GOS 4 y 5)(N=209)	Bad situation (GOS 1, 2 y3) (N=282)	
Glasgow discharge ICU			
<11 p (N=230)	17 (8%)	210 (92%)	
≥11 y ≤14 puntos (N=190)	115 (65%)	61 (35%)	<0.001
15 (N=105)	77 (88%)	11 (12%)	
Age			
<35 years (N=257)	133 (55%)	109 (45%)	<0.001
≥35 y 66 years (N=189)	65 (37%)	109 (63%)	
≥ 66 years (N=79)	11 (15%)	64 (85%)	
APACHE II			
<18 (N=266)	155 (64%)	87 (36%)	<0.001
≥ 18 (N=259)	54 (22%)	195 (78%)	
Glasgow at admission ICU			
<5 p (N=192)	25 (13%)	161 (87%)	<0.001
≥6 y ≤11 (N=227)	124 (56%)	91 (42%)	
12-15 p (N=106)	60 (67%)	30 (33%)	

With these variables it was possible to create a predictive model with "randomForestSRC" with a discrimination evaluated with the Area under the ROC curve 0.818 (0.73-0.90).

Conclusion: The patients with the best functional situation at one year are patients who have a Glasgow score on admission to the ICU greater than or equal to 6 points, with an age of less than 66 years, an APACHE II score of less than 18 points and a Glasgow discharge at discharge of ICU greater than or equal to 11 points. We can observe that in those patients who are discharged from the ICU with a Glasgow score of less than 11 in 92%, the functional situation is poor at one year (death, vegetative state or severe disability).

Trans cranial doppler (TCD) in Covid-19 patients (C-19 P) admitted in Intensive Care Unit shows marked abnormalities of the cerebral blood flow (CBF)

J. Richecoeur¹; N. Verrier¹; D. Combaux¹; A. Sagnier¹; R. Mercier¹; R. De Bock¹; C. Caplin¹; C. Soullignac¹; M. Toutoundjian¹; D. Luis¹

¹Mixed ICU, Hospital Center Simone Veil De Beauvais, Beauvais, France

Correspondence: J. Richecoeur

Intensive Care Medicine Experimental 2020, **8(2)**: 001250

Introduction: Neuropsychological dysfunction is reported in Covid-19 patients (C-19 P) (1).

This could be explained by CBF alterations.

TDC was performed in C-19 P to explore CBF and was compared to healthy control subjects (C).

Methods: 29 C-19 P and 50 C were included during a two months period (March to May 2020). Doppler samples were set at the middle cerebral artery (M1 segment of MCA). Transthoracic echocardiography

was used to record Velocity Time Integral at the left ventricular outflow tract (VTIAo).

Demographic data, reasons for admission in ICU, SAPS, sedative, vasopressor use and ventilator support were recorded as well as Mean Arterial Pressure (MAP), Systolic (Vs), diastolic (Vd) and mean velocities, (Vm), Pulsatility (PI) and Resistivity Indexes (RI). Velocity Time Integral MCA (VTIMCA) was sampled using TCD. Data were shown as median (interquartile: 25-75). T test or non-parametric test (if appropriate) were used. P < 0,05 was considered as significant.

Results: Reason for admission in C-19 P was ARDS. The main comorbidities were HTA, diabetes and obesity.

Sex ratio(M/F): 20/9 in C-19 P with SAPS II =47(38-62) and 26/24 in C. Age: 62 years (53-67) in C-19 P vs 40 years (30-52) in C. All patients but 2 had invasive respiratory and vasopressor support and sedative drugs.

Results are shown in table 1

	C (n=50)	C-19 P (n=29)	p
MAP mmHg	95,00 (89,00-98,00)	86 (77,00-96,00)	<0,001
VTIAo cm	21,50 (19,50-30,00)	21,17 (18,00-25,88)	<0,001
VTIMCA cm	51,75 (46-58)	34,85 (31,23-41,00)	<0,001
Vd cm/s	40,30 (35,00-50,00)	27,70 (21-37,25)	<0,03
Vm cm/s	58,50 (54,70-66,15)	50,70 (40-55,55)	<0,001
RI	0,55 (0,500-0,58)	0,66 (0,64-0,74)	<0,001
PI	0,86 (0,73-1,01)	1,24 (1,00-1,34)	<0,0001
VTIMCA/VTIAo	2,51 (2,15-3,09)	2,15 (1,91-2,64)	<0,001
HF*VTIMCA/BSA	1876 (1712-2219)	1422 (1164-1858)	<0,045

CF: Heart Frequency, BSA: Body Surface Area

All TCD classical parameters were altered.

The low values of VTIMCA/VTIAo ratio and HF*VTIMCA/BSA (might be a surrogate of the CBF for the later) showed an alteration of the CBF. For 15 C-19P, VTIMCA/VTIAo ratio was < 1,5 and suggested a depressed CBF autoregulation independently of CO. (Spearman: R2:0,62 p < 0,001).

13 C-19 P had delirium during the weaning and two had a fatal ischemic stroke.

Conclusion: CBF autoregulation in Covid -19 patients was markedly altered. Alteration of the vasomotor tone thought to be linked to endothelium dysfunction. The persistence of CBF abnormalities must be evaluated as well as the neuro-psychological and cognitive impact on the following.

Correspondence: K. Muradyan

Intensive Care Medicine Experimental 2020, **8(2)**: 001433

Introduction: One of the promising methods of non-invasive ICP assessment in the acute period of traumatic brain injury is the ONSD assessment based on CT data [1, 2, 3]. The advantages of the method are simplicity, relative availability, speed and reproducibility of ONSD assessment [5, 6, 7].

Objectives: The aim of the study was to assess the correlation between ONSD measured according to CT data, and invasive ICP value in patients in the acute period of severe TBI.

Methods: A retrospective analysis of 49 patients with severe TBI was made. Among them 38 were males and 11 females. Average age was 34 +/- 12 years, GCS (Glasgow coma scale) score - 5.7 +/- 1.8. Twenty-nine (59%) patients were operated, 17 of them underwent decompressive craniectomy. All victims were admitted to the ICU in the acute period of TBI: 2 +/- 1 days from the moment of injury. Upon admission, all patients underwent brain CT scan and invasive monitoring of ICP. ONSD was assessed at a distance of 3 mm from the posterior pole of the eyeball [3, 7, 8]. Statistical processing was performed using the StatSoft STATISTICA 7.0 package.

Results: A significant correlation was obtained between ONSD and the ICP value at the time of ICP sensor ($r = 0.39$; $r^2 = 0.15$; $p < 0.01$) implantation. The correlation between the maximum, average ICP value for the entire monitoring period and ONSD did not reach a significant level ($p > 0.05$), what can be explained by the influence of therapeutic and neurosurgical methods on the ICP value used for intracranial hypertension correction. There was a significant difference in ONSD in the groups of patients with normal and high ICP ($Z = -2.366$; $p = 0.017$).

Conclusion: In our research significant correlation between ONSD and ICP in the acute period of severe TBI was established. There is a further need for a more deeper analysis of the relationship between ONSD and intracranial hypertension duration, the role of aggressive methods for ICP correction [1, 4], as well as the prognostic value of ONSD in patients with various types of acute cerebral injury [4, 9, 10].

Perception assessment of blood transfusion criteria in neurocritical care patients

J. Barrero¹; A. Vargas-Villanueva²; JN. Carreño¹

¹Departament of critical and intensive care medicine, Fundacion Santa Fe de Bogota University Hospital, Bogotá, Colombia; ²Critical care department, Fundacion Santa Fe de Bogota University Hospital, Bogotá, Colombia

Correspondence: A. Vargas-Villanueva

Intensive Care Medicine Experimental 2020, **8(2)**: 001499

Introduction: Anemia incidence in neurocritical pathologies like subarachnoid hemorrhage (SAH) and traumatic brain injury (TBI) is around 30 and 46% respectively (1,2). Anemia is an important cause of secondary neurologic injury due to hypoxia(3). Despite its impact, the thresholds for red blood cell (RBC) transfusion in clinical practice guidelines are only based on hemoglobin values, with no clear recommendation in many cases (4-7).

Objectives: To identify the paraclinical parameters used by health care personal to decide the best moment to transfuse critical care patients with SAH or TBI.

Methods: Data were obtained from December 2017 to December 2019 through a google forms survey distributed by email and published at the "Asociación Colombiana de Medicina Crítica y Cuidado Intensivo (AMCI)" and Latin American Brain Injury Consortium (LABIC) web pages. The questionnaire used a format of multiple-choice and open-ended questions to assess socio-demographic information, literature support in which the contestants based their decisions, safe number of RBC units to transfuse in less than 24 hours, and optimal range of paraclinical tests variables appraising hemoglobin (Hb), brain tissue oxygen tension (PbtO2), jugular venous oxygen saturation (SjvO2) and arterio-jugular differences of CO2 (A-VYCO2). The entire dataset was stored in a spreadsheet (xlsx) gathering a total of 90 responses.

Results: The majority of responses came from intensivists (59%) with ages between 25-40 years old (55.4%). The countries involved in this study were Colombia (22%) and Mexico (11.1%). The type of intensive care unit where the responders work, was predominantly a mixed unit in 88.2%, with disponibility of blood bank in 85.1% of cases. The majority of the participants (72 and 76.6%) agree with less than 2 RBC units as a secure limit for blood transfusion in less than 24 hours for patients with TBI and SAH, respectively. Predominantly, there is no perception of medical literature guidance to conceal blood cell transfusion in patients with TBI (66.6%) or SAH (78.8%). The most common response at the moment to determine the optimal range of Hb for TBI and SAH was 9.1-10.0 g/dL (31.1%, 34.44%) (Fig.1), being this parameter used alone the most common referent to start RBC transfusion (57% for TBI and 60% for SAH). The prevailing values to start a RBC transfusion in patients for TBI and SAH were <7 g/dL for Hb (38.8% and 33.3%); 16-20 mmHg for PbtO2 (14.4% and 14.4%); <55% for SjvO2 (33.3% and 32.2%) and >8 for A-VYCO2 (22.2% and 16.6%) respectively. The majority of respondents use Hb alone for transfusion of RBC (Table 1).

TABLE 1. USE OF MULTIMODAL NEUROMONITORING TO START RBC TRANSFUSION

VARIABLE	SAH (n)	SAH (%)	TBI (n)	TBI (%)
A-VVCO2	3	3,3%	3	3,3%
Hb	54	60,0%	52	57,8%
PbtO2	7	7,8%	6	6,7%
SjvO2	3	3,3%	3	3,3%
Hb+A-VVCO2	1	1,1%	0	0,0%
Hb+PbtO2	1	1,1%	4	4,4%
Hb+SjvO2	6	6,7%	4	4,4%
PbtO2+SjvO2	1	1,1%	2	2,2%
SjvO2+A-VVCO2	1	1,1%	0	0,0%
Hb+PbtO2+A-VVCO2	1	1,1%	0	0,0%
Hb+PbtO2+SjvO2	1	1,1%	4	3,3%
Hb+SjvO2+A-VVCO2	3	3,3%	2	2,2%
PbtO2+SjvO2+A-VVCO2	0	0,0%	1	1,1%
Hb+PbtO2+SjvO2+A-VVCO2	6	6,7%	1	8,9%
No answer	0	2,2%	1	1,1%

Conclusion: It is important to promote the assessment of other para-clinical tests instead of just Hb to achieve a multimodal neuromonitoring for RBC transfusion in neurocritical care patients. This will allow us to understand more precisely the brain's metabolic and perfusion status and therefore to improve patients' outcomes.

The Need To Keep Our Staff Up To Date

N. Reza¹; D. Irvine²; B. Greatorex³; M. Mascarenhas³

Intensive Care Medicine Experimental 2020, **8(2)**: 001210

Introduction: At the beginning of the 21st century, proning had become unpopular in ICU's across the United Kingdom. This was felt to be due to the additional need for resources to carryout, and risk of adverse events (1). However, the ARDSNET trial in 2000 and PROSEVA trial in 2013, both showed mortality benefit for patients without serious adverse outcomes (2,3). The lack of harm was also confirmed by a recent Cochrane review in 2015 (4). In 2019, our remote district general ICU felt that proning should be used more frequently, and an education session was set up to try and improve the multidisciplinary teams' knowledge and ability to carry it out.

Objectives: Improve the knowledge of respiratory failure and acute respiratory distress syndrome (ARDS) amongst the ICU multidisciplinary team.

Teach all members of the multidisciplinary team how to prone and depronate a patient safely.

Empower the team to highlight when they feel a patient is deteriorating and requires proning.

Methods: The teaching sessions were commenced in October 2019. A pre attendance questionnaire was given to the attendees to test

their knowledge of respiratory failure, ARDS and proning. They then attended a proning education session where they were given a short lecture followed by a teaching session on how to prone and depronate a patient safely.

After the session the same knowledge questionnaire was given out. This allowed us to directly compare their knowledge and see if our intervention was successful.

Results: On average each staff member had proned around one patient in the past 12 months.

They also felt before the session that it would take around 30 minutes to prone someone and their main concerns were tube displacement, patient position, risk of injury to patient, line displacement and patient stability.

There were ten knowledge questions. All showed an improvement after the session. When the ten questions were averaged, the percentage of correct answers improved from 55.6% to 85.5%.

The staff's confidence to prone a patient, using a scale out of 10, improved from 4.0 to 8.9.

The staff's knowledge of the local protocol, using a scale out of 10, improved from 3.2 to 10.

Conclusion: Staff knowledge of respiratory failure, ARDS and proning was greatly increased following the session.

Staff confidence to perform the procedure was also greatly improved. After the success of these education sessions. We are looking to run further sessions on proning and other important aspects of ICU care.

The timing of this study was very fortuitous seeing as proning has become such an essential part of managing COVID-19 patients. Having done and taught the staff in our ICU before the pandemic started, it allowed the busy team to focus on other important and vital aspects of ICU care.

Building emotional capital through the staff huddles in Covid19 times: An appreciative inquiry

S. Lucena-amaro¹; H. Schroeder²; S. Schwarze¹; P. Subramanian¹; J. Whittaker¹; P. Fitch¹

¹Adult critical care unit, Barts Health NHS Trust, The Royal London Hospital, United Kingdom; ²Schroeder forbes, Schroeder Forbes Ltd, Welwyn Garden City, United Kingdom

Correspondence: S. Lucena-amaro
Intensive Care Medicine Experimental 2020, **8(2)**: 001235

Introduction: The Royal London Hospital is a major teaching hospital in East London (UK). The Adult Critical Care Unit (ACCU) comprises 44 beds, staffed by 210 nurses. During the Covid-19 pandemic, critical care services doubled in capacity. Critical care nurse to patient ratios were dramatically altered. At the same time, over 300 non-critical care nurses were redeployed into the department to accommodate this increased demand for critical care beds.

Objectives: The primary aim of this project was to offer nurses a collective reflection and processing space to enhance post pandemic wellbeing support. The secondary aim was to capture learning about processes that supported effective care delivery. Factors contributing to positive and effective working practices would inform preparedness for a potential second surge.

Methods: An Appreciative Inquiry model was used to guide small group reflective conversations (1). Critical care and redeployed nurses were invited to take part. Groups were distributed according to their clinical role. All the sessions were facilitated by an external coach, a clinical psychologist and senior staff from the ACCU. A thematic analysis approach was used to identify emerging themes.

Results: The sessions allowed staff the opportunity to discuss difficult experiences from working in the Covid-19 pandemic. Fifty nurses from each staff group participated in these discussions, which generated clear descriptions of what promoted effective working and patient safety. The views from the two different nursing groups about what they valued were complementary. Nurses reported an increased emotional load during Covid-19 with anxiety levels often higher at the beginning of the shift. These resulted from feeling overwhelmed and fearful of not being able to cope.

The staff huddle at the start of the shift emerged as a key event to enable effective working and promote nurses' psychological safety, although this was not consistently used. Redeployed nurses lacked the supportive structures of their familiar workplaces and therefore valued the welcoming and team working environment created by the ITU nurses.

Outcomes from these results include the development of a huddle template and education strategies for promoting staff wellbeing.

Conclusion: Appreciative Inquiry proved a valuable and accessible intervention for nursing staff to acknowledge the achievements and contributions during the Covid-19 pandemic. The staff huddle emerged as a vital part of staff wellbeing. It promoted effective working relationships, which in turn, are likely to impact positively on care delivery and patient experience. Ongoing work will focus on how to deliver further sessions more widely to other staff and training.

Intensive Care Medicine Experimental 2020, **8(2)**: 001317

Introduction: In the ICU, nursing notes represent the patient's narrative at the extremes of illness and are used to support decisions regarding the escalation or withdrawal of treatment. Their importance has recently been dramatically highlighted in a seminal paper that revealed that nursing notes can and do predict patients' probability of survival on ICU1.

Objectives: This is a multi-centre service evaluation investigating the nursing and medical attitudes towards nursing notes. We wanted to investigate how nurses perceived the attitudes of, and frequency with which doctor colleagues read their entries into the patients notes and if there were differences in attitudes across the different training hierarchies of nurses and doctors. In addition we wanted to characterise the perceived reasons that nurses attributed to this lack of attention.

Methods: This project used an anonymous web-based questionnaire that was sent to nurses and doctors in four ICUs in the East of England. Nurses reported their grade, how frequently they believed that doctors read their entries into the patients notes (Always/often/sometimes/rarely/never) and aspects of their notes they thought were important to the doctors. For the purpose of analysis, the frequency of note reviewing was divided into generally positive responses (always/often/sometimes) and generally negative responses (rarely/never). Doctors reported their grade, the frequency with which they read nursing notes and their views on nursing note contents and their utility. Responses were collected from 47 doctors and 120 nurses. Nurses were stratified by grade into five groups; Group 1 (<5 years nursing experience), Group 2 (>5 years experience), Group 3 (Sisters), Group 4 (CCOT and nurse specialists) and Group 5 (Ward managers and Matrons). Doctors were stratified by staff hierarchical grade into four groups (Foundation, SHO, Registrars and Consultants).

Results: Analysis of 121 nursing staff responses revealed differences in the perceived frequency that nurses reported that their doctor colleagues reviewed their notes. The frequency with which nurses believed doctors reviewed nurses entries appeared to vary with the grade of the nurse, with 66% of Group 4 nurses reporting positively. The most negative responses were that of the most senior nurses in Group 5 with 100% of responses falling into the negative response category. Analysis of the 47 doctors also revealed hierarchical differences, with doctors in training having more 'generally positive' results than consultants.

80% of nurses thought this was due to doctors not having enough time/not being interested in the content/not finding them useful. 49% of doctors made similar reports.

Conclusion: Nursing notes appear not to be perceived as serving their function to facilitate effective communication between allied health-care professionals. Writing notes reduces the time spent on direct clinical tasks, consideration for how to improve this needs to be made.

Intensive Care Medicine Experimental 2020, **8(2)**: 001334

Introduction: Functional electrical stimulation-assisted cycle ergometry (FESCE) enables in-bed leg exercise independently of patients' volition. We hypothesised that early use of FESCE-based intensified rehabilitation improves physical function in survivors of critical care after 6 months.

Methods: We enrolled mechanically ventilated adults estimated to need >7 days of ICU stay into an assessor-blinded single centre randomised controlled trial to receive either FESCE-based protocolised or standard rehabilitation that continued up to day 28 or ICU discharge.

Results: We randomised in 1:1 ratio 150 patients (Age 61 ± 15 years, APACHE II 21 ± 7) at a median of 21 (IQR 19-43) hours after admission to ICU. Mean rehabilitation dose delivered to intervention vs.

control group was 80 ± 35 vs. 56 ± 15 mins per day, $p < 0.01$. At six months 42 (56%) and 46 (61%) were alive in interventional vs. control groups ($p = 0.51$) and their physical component summary of SF36 (primary outcome) was not different [50 (IQR 21–69) vs. 49 (IQR 49–76); $p = 0.26$]. At ICU discharge, there were no differences in the ICU length of stay, functional performance, rectus femoris cross-sectional area or muscle power despite daily nitrogen balance 0.6 (95%CI $0.2-1.0$) g less negative in intervention group. There were more ICP elevations in intervention group (1.5 vs. 0 ICP elevations/day, $p = 0.018$) and significantly worse mental component summary score of SF-36 after 6 months [53 (95%CI 45;61) vs. 64 (95%CI 57;72), $p = 0.018$].

Conclusion: Early delivery of FESCE-based protocolised rehabilitation to ICU patients does not improve physical functioning at 6 months in survivors and may cause harm.

Intensive Care Medicine Experimental 2020, **8**(2): 001532

Introduction: Coronavirus disease (COVID-19) is a pandemic of international concern, cause severe respiratory failure and require invasive mechanical ventilation.

Early mobilization (EM) in the ICU is safe, feasible, and reduces the frequency and severity of complications in critical illness patients. Weakness is a frequent problem in ICU, even more evident in patients undergoing mechanical ventilation, patients with COVID-19 usually needs mechanical ventilation.

We purpose evaluate early mobilization as a facilitator of successful weaning from mechanical ventilation and post-extubation outcome in patients with SARS-CoV-2 pneumonia.

Objectives: We purpose evaluate early mobilization as a facilitator of successful weaning from mechanical ventilation and post-extubation outcome in patients with SARS-CoV-2 pneumonia.

Methods: This was a observational retrospective analysis performed form medical records of patients with SARS-CoV-2 pneumonia who required invasive mechanical ventilation (IMV) for more than 24 hours, and, after that, having passed the spontaneous breathing trial. They were divided into two groups: the first group that underwent early mobilization during the IMV period and the second group receive only passive range of motion (PROM). We defined as early mobilization the following conducts: sitting on the edge of bed, sitting out of bed, active standing, passive standing with a tilt table, and walking during IMV.

Results: We analyzed a total of 40 patients who were submitted tracheal extubation. Patients were divided in two groups, EM group 21 patients and PROM group 19 patients, with average mean age $56,1$ (SD $\pm 16,03$) and $66,3$ (SD $\pm 12,91$) respectively, the SOFA score mean was $4,52$ (SD $\pm 2,60$) versus $6,32$ (SD $\pm 2,71$), and the SAPS III was $53,29$ (SD $\pm 9,76$) versus $57,11$ (SD $\pm 9,24$), the duration of mechanical ventilation was $10,38$ (SD $\pm 4,48$) versus $10,42$ (SD $\pm 6,02$) respectively.

The primary outcome was rate of failed extubation that was in the EM group $2/21$ (10%) and PROM group $7/19$ (35%) (OR $0,18$ [IC $0,03-1,01$]), the rate of mortality was the second outcome, the EM group presented $(0/21)$ 0% versus $(4/19)$ 20% respectively.

Conclusion: Early mobilization was feasible, safe and maybe associated with a better outcome for extubated critical patients. Early mobilizations can be associated with lower mortality in COVID-19 patients, probably due the improve muscle strength that these patients develop.

The relation between early mobilization and successful weaning of mechanical ventilation in patients with COVID-19 should be further investigated in a large prospective study, that can measure objectively the force at the time of extubation.

Intensive Care Medicine Experimental 2020, **8**(2): 001580

Introduction: Subglottic devices, i.e. endotracheal tube (ETT) and tracheostomic cannula (CT) are used in critical care both to provide mechanical ventilation and to isolate airways from the gastrointestinal tract. A correct cuff pressure management is required while caring for critical care patients, in order to avoid ischemic damages coming from an excessive pressure, and to prevent the inhalation risk related to insufficient cuffing. Several studies investigated the influence of mobilization procedures on the cuff pressure, whilst the effects of other procedures (such as endotracheal suctioning) were rarely.

Objectives: The aim of this study was to determine the cuff pressure variations determined by caring interventions, in order to define an ideal cuff pressure monitoring interval and to highlight the procedures most frequently involved in generating cuff pressure out of recommended ranges (20–30 cmH2O).

Methods: Study design and setting. A prospective observational study was conducted within the three ICU of the Anesthesia and Intensive Care Department at the University Hospital of Udine, Italy.

Population. Patients carrying ETT or CT, aged ≥ 18 admitted to ICU between December 2019 and February 2020.

Variables. Cuff pressure was checked before and after caring procedures (changes in position, general hygiene care, oral care, tracheal suctioning, fibre-optic bronchoscopy, device's dressing). Other patients and devices variables were recorded.

Statistical analysis. Data were analyzed using the software GraphPad Prism 8.0 (GraphPad Software, San Diego, CA, USA). Descriptive measures were used to describe sample characteristics. Moreover, pressure variation after the procedures was calculated, and the percentage of inadequate (i.e. exceeding the range 20–30 mmHg, as recommended from the available literature) values was determined. Two-tailed rank Wilcoxon test was used to describe periprocedural pressure variation. Fisher exact test was used to determine associations between the independent variables "need for pressure adjustment prior to the procedure", "length of intubation ≥ 5 days", "body temperature $\geq 37.5^\circ\text{C}$ ", and the dependent variable "inadequate cuff pressure". Kruskal-Wallis test was used to describe cuff pressure variations during the days after

patients enrollment in the study. Statistical significance was considered when $p < 0.05$.

Results: 81 patients (58 males, 72%) were enrolled for observation. Globally, 601 paired observations (i.e. before and after the procedure) were conducted. Median number of observations per patient was 4 (range 1-35). Cuff pressure was out of recommended range in 351 (58%) observations prior procedure performance and in 178 (30%) after procedures. Median cuff pressure variation when pre-procedural adjustment was not required was -4 cm H₂O (range -20; 8 cm H₂O). Median cuff pressure variation when pre-procedural adjustment was required was -6 cm H₂O (range -23; 10 cm H₂O). Post-procedural cuff pressure was out of recommended range after postural change in 58% (7/12) of observations, after body hygiene in 31% (50/163) of observations, in 27% (33/123) of observations after oral care hygiene, in 28% (37/132) of observations after tracheal suctioning, in 33% (6/18) of observations after fibre-optic bronchoscopy, in 23% (45/193) of observations after ETT/CT dressing. Post-procedural cuff pressure reduction occurred in 510 (85%) of observations; particularly, in 62 observations cuff pressure values were ≤ 15 cm H₂O, and in 3 observations values were 5 cm H₂O. Median pressure decrease was 6 cmH₂O (range -23; 1 cmH₂O). In 65 (11%) observations cuff pressure had no variations and in 26 (4%) it increased. Median pressure increase was 6 cmH₂O (range 1-10 cmH₂O). Paired two tail Wilcoxon test revealed a statistically significant decrease for all paired observations (median difference -5 cmH₂O; $p < 0.0001$) and for single procedures. Fisher test highlighted that the risk for inadequate cuff pressure significantly decreased when pre-procedural adjustment was required (RR 0.58, 95% IC 0.45-0.74; $p < 0.0001$). Duration of intubation ≥ 5 days resulted in a lower risk for inadequate post-procedural cuff pressure, although the association was not statistically significant (RR 0.78, 95% IC 0.60-1.00; $p = 0.595$), whilst body temperature $\geq 37.5^\circ\text{C}$ slightly increased the risk for post-procedural inadequate cuff pressure (RR = 1.104, 95% IC 0.81-1.49; $p = 0.58$).

Conclusion: In most observations, a pressure reduction was observed after a procedure was performed, and the amount of procedures generating significant out-of-range pressures was not negligible. Therefore, cuff pressure should always be checked before and after each procedure generating potential variations. Further studies with larger samples might highlight the role of rarely investigated procedures (such as fibre-optic bronchoscopy and body hygiene) and other risk factors related to patient in generating inadequate cuff pressures.

IVAPP (ICU APP) – a support to patients and relatives, before – during and after the time at ICU

E. Åkerman¹; U. Malmstrom¹; M. Tennback¹; H. Laurinen-Ovelius¹; S. Cheviakova¹; AM. Sundfors¹; C. Vonknorring¹; M. Carlsson¹

¹Anesthesiology and intensive care, Karolinska University Hospital, Stockholm, Sweden

Intensive Care Medicine Experimental 2020, **8(2)**: 001616

Introduction: Patients and relatives have an increased need for information about what happens before, during and after a critical illness and the time at ICU. The knowledge can bring a sense of security and safety and also an opportunity to be more involved in the patient care, and also to be able to get back to the information and read it again during the care. The most common form to inform is an information booklet, but there are limitations as i.e. updating and availability. Today's technology gives an increased possibility for accessibility of information which can help the patients and relatives during the critical illness and recovery.

Objectives: to create an easily accessible, interactive web-application (IVAPP) with information that covers the time of care, before-during- and after ICU.

Methods: An interprofessional group with a physiotherapist, intensive care nurses, assistant nurses, physicians and management staff was formed. To collect and create content in the IVAPP, a search for current data, as existing information, research and web-sites was done. Contact was also made with various support functions and organizations for their input. Photographs from the ICU and equipment were taken to supplement the written text. Former ICU patients and relatives were invited at two times to review the draft and give feedback on what information they would appreciate to get during their ICU care. The final version was qualitatively reviewed by the ICU director and nursing manager before publishing.

The IVAPP was implemented in October 2019 and the information about the release was spread in Swedish national broadcasting, newspapers, in Karolinska Hospital ICUs and at open meetings for staff and patients. Also, all the care units that the ICU patients often stays before and/or after their ICU care was informed about the app.

Results: The feedback was positive both from staff, patients and relatives. The information obtained in the cellphone filled the needs, it was accessible for all, even to those that could not be in the ICU and it could be accessed on demand. The information could reduce anxiety, aid preparing for discharge from the ICU and hospital and individualize patient care. Statistics showed that "general information about the ICU", "to come home", "what happened during a day in the ICU", "working in ICU" and "", were the most visited sides.

Conclusion: IVAPP has been developed in an interprofessional collaboration together with patients and relatives. IVAPP is easily accessible and can give relatives and patients the opportunity to easily find information about intensive care before, during and after the care period.

Intensive Care Medicine Experimental 2020, **8(2)**: 001445

Introduction: The International Pediatric Sepsis Consensus defined septic shock as sepsis syndrome complicated with cardiovascular organ dysfunction, with myocardial and/or circulatory failure being leading causes of death. Indeed, septic shock is often characterized also by myocardial depression. The evaluation of cardiac function is important to detect early deterioration that can have important implications for treatment and prognostication. Critical Care Echocardiography (CCE) is an established noninvasive tool for the assessment of hemodynamic changes in adult patients with shock, and its use is increasing in the pediatric critically ill patient too. Several parameters describing left and right ventricular (LV and RV, respectively) function in septic newborns or children have been studied, from the most conventional ones to the use of Tissue Doppler Imaging (TDI) and strain echocardiography (STE). Therefore, we conducted a systematic-review in order to describe the echocardiography parameters most studied so far, and subsequently we performed a meta-analysis aiming at

investigating the prognostic value of echocardiography parameters and mortality in pediatric patients with sepsis.

Objectives: We conducted a systematic review and meta-analysis to investigate the prognostic value of echocardiographic parameters and mortality in pediatric septic patients.

Methods: Data Sources: MEDLINE, PubMed and EMBASE (last update April 5th, 2020). Study Selection: observational studies conducted on pediatric sepsis providing echocardiographic parameters according to mortality. Data Extraction: Echocardiography data were divided in those describing left ventricular (LV) systolic or diastolic function, right ventricle (RV) function and strain echocardiography parameters. Data were entered dividing studies in two subgroups: newborns and children. Analysis is reported as standardized mean difference (SMD) and 95% confidence interval (CI).

Results: We included data from 14 articles ($n=5$ newborns, $n=98$ children). The Fractional Shortening was the most commonly reported variables (11 studies, $n=555$ patients) and was not associated with mortality (SMD 0.22, 95%CI[-0.02, 0.47]; $p=0.097$, $I^2=28\%$). No association with mortality was seen also for LV ejection fraction (9 studies, $n=417$; SMD 0.06, 95%CI[-0.27, 0.40]; $p=0.72$, $I^2=51\%$), s' (4 studies, $n=178$; SMD -0.01, 95%CI[-0.34, 0.33]; $p=0.97$, $I^2=0\%$), and myocardial performance index (4 studies, $n=199$; SMD -0.37, 95%CI[-1.01, 0.26]; $p=0.25$, $I^2=65\%$). Regarding LV diastolic function, we found a significant association of mortality with E/e' ratio (4 studies, $n=189$, SMD -0.45, 95%CI[-0.80, -0.10]; $p=0.01$, $I^2=0\%$) or e' wave (3 studies, $n=159$; SMD 0.49, 95%CI[0.13, 0.85]; $p=0.008$, $I^2=0\%$). No association was found between E/A ratio (6 studies, $n=273$; SMD 0.28, 95%CI[-0.42, 0.99]; $p=0.43$, $I^2=81\%$) and s' measured at tricuspid annulus (3 studies, $n=148$; SMD -0.18, 95%CI[-0.53, 0.17]; $p=0.32$, $I^2=0\%$). Only few studies were conducted with strain echocardiography.

Conclusion: We found no association between mortality of septic pediatric patients and parameters evaluating LV systolic function and RV function. A significant association was found between mortality and higher E/e' or lower e', indicating a possible influence of worsened LV diastolic function. These findings are preliminary due to the high clinical heterogeneity of the studies included.

Intensive Care Medicine Experimental 2020, **8(2)**: 001380

Introduction: Elective intensive care unit (ICU) admission represents an important part of all ICU admissions. Critical care admission may be necessary for surgical patients requiring organ support or invasive monitoring in the perioperative period. Planned postoperative admissions aim to prevent complications arising in the postoperative period, reducing the risk of a poor outcome. Several prognostic indices have been used to predict the outcome of surgical critically ill patients. Among them, acute physiology and chronic health evaluation II (APACHE II) and simplified acute physiology score 2 (SAPS 2) are broadly used. Moreover, biological markers such as C-reactive protein (CRP), albumin, and blood lactate levels correlate with the degree of inflammation during the immediate postoperative phase and could be used as independent predictors.

Objectives: The purpose of this study is to demographically and clinically analyze all the elective surgical admissions between January 2018 and June 2020 and also to evaluate patients outcomes comparing the different predictive values of prognostic indices and biological markers in the outcome of 62 surgical patients admitted to the ICU in the postoperative phase.

Methods: A retrospective cohort study of all elective surgical admissions in a ten-bedded combined medical-surgical intensive care unit of a Portuguese hospital between January 2018 to June 2020. Comparison between albumin levels were performed using Man-Whitney U-test.

Results: In the period from January 2018 to June 2020, 62 patients were elective admitted to our ICU. The mean patient's age was 67.9 (19-88), being 50% of them men (31). Among the elective admissions the majority were after whipple procedure, representing 67.7% of all admissions. The median Charlson score was 5 points [0-11 points]. The median ICU length of stay was 3 days [2-4 days] and the median time with mechanical ventilation was 2 days [1-3 days], being that 34 patients needed less than 24 hours of mechanical ventilation. Regarding the prognostic indices the median SAPS 2 was 30 [23-43.3] and the median APACHE II was 13 [8.8-19]. As to biological markers the median admission C-reactive protein was 58 mg/dL [17.3-101.7] and the median admission lactate was 2,6 [2.1-3.3]. When analyzing albumin, the patients submitted to whipple procedure demonstrate a significant lower ICU admission albumin levels with a median of 26 g/dL than the patients undergone to other types of procedures with a median of 30 g/dL (P 0.004). As for the evaluation of sepsis during the length of ICU stay, 5 patients (8,1%) develop sepsis. According to the acute kidney injury classification (AKIN) 11,3% had a stage 1 acute kidney injury, 6,5% a stage 2, and 1,6% a stage 3. None of the patients analyzed needed renal replacement therapy. The overall ICU mortality was 3,2%, the hospital mortality was 6,5% and 49 patients were still alive after a 6 month follow up, representing 79% of patients.

Conclusion: This retrospective study conducted in a 10-bed intensive care unit shows that critical care admitted patients after elective surgery were mainly submitted to a whipple procedure and have a median charlson score of 5. The median length of stay in the ICU was

less than 4 days and the median mechanical ventilation time was 4 days. Regarding the prognostic indices we found low APACHE II and SAPS 2 values reflecting the fact that those patients were electively admitted and that most of them didn't develop any complication during the perioperative phase or during the hospital stay. We also found that postoperative albumin levels were low mainly in the group of patients submitted to a whipple procedure, probably reflecting the magnitude of surgery and the associated stress response. In addition, overall mortality was low in this patient population.

Predictors of mortality and outcomes of acute surgical admissions: a retrospective study

D. Castro¹; C. Roriz¹; F. Sequeira¹; N. Ferreira¹; L. Linhares¹; L. Pereira¹

¹Serviço de Medicina Intensiva, Centro Hospitalar de Leiria, Leiria, Portugal

Correspondence: D. Castro

Intensive Care Medicine Experimental 2020, **8(2)**: 001419

Introduction: Acute surgical patients account for a significant percentage of admissions in an Intensive Care Unit (ICU). Outcomes of these surgical patients must be assessed and several clinical scores are available to guide clinicians. Acute Physiology And Chronic Health Evaluation II (APACHE II) and Simplified Acute Physiology Score 2 (SAPS 2) have been used to predict the outcome of surgical critically ill patients. However, none of these scores have a 100% sensitivity or 100% specificity. Most of these patients are septic and serum lactate level is considered a sensitive marker for sepsis or septic shock reflecting a cell-based metabolism. C-reactive protein (CRP), albumin, CRP/Albumin ratio and blood lactate levels correlate with the degree of inflammation during postoperative care. These and potentially others biological parameters could be used as independent predictors of poor outcomes.

Objectives: The aim of this study is to compare prognostic value of two indices (APACHE II and SAPS 2 scores) and biological markers in the outcome of acute surgical patients admitted in ICU in the immediate postoperative care.

Methods: An observational retrospective study of all acute surgical admissions into our ICU in the immediate postoperative care from January, 1st to December, 31st 2018 and had a ICU length of stay longer than 24 hours. Data concerning the diagnosis, comorbidities and demographics were documented in medical records. The biological markers CRP, albumin, serum blood lactate, N-terminal pro-B type natriuretic peptide (NT Pro-BNP), leukocytes, platelets and Glomerular Filtration Rate were collected during the first 24 hours after patient's admission and prognosis indices (APACHE II and SAPS 2) were recorded. Patients were divided into survivors and non-survivors. Comparisons between survivors and non-survivors were performed using the Student-T test or Man-Whitney U-test for quantitative variables (parametric and non-parametric variables, respectively) and Pearson Chi-square test for qualitative variables.

Results: Sixty surgical patients admitted into our ten-bed ICU in the immediate postoperative care were retrospectively studied. Patients were divided into survivors (n=33) and non survivors (n=27) as described. The ICU and overall in-hospital mortality were 30% and 15%, respectively. Non-survivors were older than survivors (76 vs 69

years old, p=0.024) and males died more than females (males 63% vs 36,4%, p=0.042). Comorbidities were performed by Charlson's score and non-survivors had a statistically higher Charlson's score (score 5 vs 3, p=0.001). There were no statistical differences in ICU length of stay between groups. APACHE II (27 vs 19, p<0.001), SAPS (61 vs 46, p<0.001), serum lactate (4,8 vs 3,2; p=0.015) were significantly higher in the non-survivors group. Glomerular Filtration Rate in ICU admission was lower in non-survivors (17,4 vs 56,3; p=0.001) and the need of Renal Replacement Therapy was higher in this group (29,6 vs 9,1%; p=0,043). No differences were found between groups in days of mechanical ventilation, ratio CRP/Albumin, CRP, Albumin, NT-proBNP, leukocytes count, hemoglobin or blood transfusions. No differences were found between two groups regarding sepsis in admission.

Conclusion: Mortality rates in acute surgical patients are still very high in Intensive Care Unit and several scores of severity of critically ill patients can predict their mortality like APACHE II and SAPS 2. In our study these scores are higher in non-survivors patients and can be associated with greater severity of the disease and their higher in-hospital mortality. Serum lactate levels are related with mortality and can be associated with tissue hypoxia and elevated inflammation during postoperative care. Glomerular Filtration Rate is lower in non-survivors, reflecting acute kidney injury and renal failure with the need of Renal Replacement Therapy. Studies have showned that sepsis is frequently complicated by acute kidney injury which increases the mortality risk.

Intraoperative hemodynamic changes as a risk factor for postoperative complications in patients undergoing elective laparoscopic colorectal surgery

V. Panafidina¹; I. Shlyk¹

¹Anesthesiology and intensive care, Pavlov First State Medical University of St. Petersburg, Sankt-Peterburg, Russia

Correspondence: V. Panafidina

Intensive Care Medicine Experimental 2020, **8(2)**: 001512

Introduction: Despite the fact that laparoscopic surgery seems to be safe in high-risk surgical patients, it is associated with significant hemodynamic changes. Patients with colorectal malignancies often have a number of cardiovascular and other comorbidities, and severe hemodynamic fluctuations could be a risk factor for postoperative morbidity. Thus, we hypothesis that hemodynamic changes during elective laparoscopic colorectal surgery might be associated with postoperative complications development.

Objectives: The aim of the study is to analyze potentially modifiable risk factors related to hemodynamic changes during laparoscopic surgery in patients with colorectal malignancies.

Methods: A single-center retrospective study was performed in a university clinic in Saint-Petersburg, Russia. We analyzed 100 medical

recordings of patients undergoing elective colorectal surgery in 2017–2019. The analysis considered systolic blood pressure (SBP) changes, changes of mean arterial pressure (MAP), intraabdominal perfusion pressure (IPP), incidence of tachy- or bradycardia during operation time, and complications Clavien-Dindo Grade III–V. Univariate and multivariate analyses were performed in SPSS Statistics 20.0 to identify risk factors for postoperative complications.

Results: Postoperative complications occurred in 16 patients (16%). These patients had significantly more episodes of SBP drop from baseline, MAP < 65 mm Hg, IPP < 65 mm Hg during pneumoperitoneum. SBP lowering, MAP, IPP were significant risk factors for postoperative complications ($p < 0,001$). In multivariate analysis, SBP lowering (OR 1,535, 95% CI 1,095–2,152, $p = 0,013$) and IPP (OR 0,75, 95% CI 0,611–0,932, $p = 0,009$) were independent risk factors for postoperative complications.

Conclusion: Our results may suggest that severe hemodynamic fluctuations could be related to postoperative complications in patients undergoing elective laparoscopic colorectal surgery.

Intensive Care Medicine Experimental 2020, **8(2)**: 001623

Introduction: Vascular surgeries are associated with a particularly high risk of postoperative complications due to a high number of comorbidities in this population as well as increased risk of perioperative bleeding and hypotension associated with these procedures.

Objectives: To assess the incidence of major cardiovascular complications in 1-year follow-up after vascular surgeries.

Methods: This is a substudy of the Vascular Events In Noncardiac Surgery Patients Cohort Evaluation Study (VISION), in which patients aged ≥ 45 years undergoing non-cardiac surgeries and hospitalized at least overnight were enrolled. In this large, international prospective cohort study, each patient had postoperative troponin measurement to assess the association between troponin level and postoperative outcomes. Additionally, patients or their relatives were contacted 30 days and 1 year after the procedure to assess the incidence of complications in short- and long-term observation.

Results: Study group consisted of 2641 patients undergoing vascular surgeries. There were 2047 (77.5%) males and the mean age accounted to 68.2 (SD 9.8) years. The most common comorbidities were hypertension (75.5%), peripheral artery disease (67.5%) and coronary artery disease (38.0%). During the 1-year follow-up 223 patients died (8.4%), 243 patients had myocardial infarction (9.2%), 35 patients suffered a stroke (1.3%), 192 patients underwent amputation (7.3%), 68 patients developed congestive heart failure (2.6%) and 18 patients had non-fatal cardiac arrest (0.7%).

Conclusion: Major cardiovascular complications were common among patients undergoing vascular surgeries in the long-term observation. The most common complications were myocardial infarction, death and amputation.

Perioperative Diabetes Insipidus: Report of two unusual cases

S. Nissar¹; S. Nawaz²

¹Sicu, Hamad Medical Corporation, Doha, Qatar; ²Medical Education, Hamad Medical Corporation, Doha, Qatar

Correspondence: S. Nawaz

Intensive Care Medicine Experimental 2020, **8(2)**: 001227

Introduction: Diabetes insipidus (DI) is a clinical disorder of water metabolism in the human haemostasis, commonly resulting from the deficiency of antidiuretic hormone (ADH) or from renal insensitivity to ADH. DI manifests by the patient passing diluted copious amount of urine. **1** DI is classified as central or nephrogenic and pregnancy induced, in central DI, posterior pituitary gland fails to secrete ADH. Nephrogenic DI is when the renal receptors do not respond to ADH. Pregnancy induced DI is when placenta consumes most of the secreted ADH, leading to ADH deficiency. **2** DI is common after the pituitary gland surgeries. **3** There are a few case reports of DI after general surgical procedures. **4** Although polyuria is common in the post-operative period, it is important to diagnose DI to prevent severe dehydration and life-threatening electrolyte imbalance. We report two unusual cases of DI during the perioperative period requiring hydration and intravenous desmopressin.

Methods: Case Reports.

Results: Case 1: A 49 years old healthy male was diagnosed with cervical vertebral disc prolapse (C5-6), planned for cervical discectomy and cage fusion. General anaesthesia was induced with etomidate and fentanyl, trachea was intubated under the effect of rocuronium, in addition patient received ketamine and ceftazidime during induction. Anaesthesia was maintained by propofol and remifentanyl target controlled infusion (TCI). Foley's catheter was in place and he was pouring 50 and 70 ml of urine per hour. His hemodynamics were stable. In the 2nd hour of surgery he became polyuric and passed 700 to 800 ml diluted urine in next 2 hours until the surgical procedure was over. He was started on 50 ml/hour of 0.45% saline and shifted to post anaesthesia care unit. He remained polyuric and keep passing 400 and 300 ml of diluted urine next 2 hours. He developed hypernatremia, renal functions were within normal range and urine specific gravity was < 1005, diagnosed to have central diabetes insipidus and given intravenous (IV) 2 micrograms (μ grams) of desmopressin. For the next hours his urine became concentrated and urine output dropped to 50, 60 and 70 ml/hour. He was transferred to high dependency unit (HDU), remained stable, from there discharged home and followed up in neurosurgical outpatient clinics.

Case 2: A 36-year-old healthy male presented with on and off headache. Computer tomography (CT) and MRI (magnetic resonance tomography) diagnosed to have 3rd ventricular cyst. He underwent right frontal craniotomy and excision of ventricular cyst. Anaesthesia was induced with propofol and remifentanyl, trachea was intubated under the effect of rocuronium. He received ceftazolin during the induction of anaesthesia. Anaesthesia was maintained with remifentanyl and propofol infusion. Patient remained hemodynamically stable. His urine output remained 50 to 70 ml/hour during the surgical period. Patient was transferred to the surgical intensive care unit (SICU) for further monitoring. In the SICU during the 1st and 2nd hour he passed 600 ml and 700 ml of diluted urine respectively. His serum sodium jumped to 148 mmol/litre, renal functions were normal and urinary specific gravity was < 1005. Patient was started on 100 ml/hour of 0.45% saline and desmopressin 2 μ gram was administered intravenously. From the next hour his urine became concentrated and urine output dropped to 50 to 100 ml/hours. Patient remained hemodynamically stable and serum sodium became normal. He was transferred to the ward the next day and from there discharged home. Followed up in the neurosurgical outpatient clinic without any issues.

Conclusion: The occurrence of DI in above mentioned surgeries is very rare. Both surgical procedure and anaesthesia medications can cause perioperative DI.

Comparison of dynamic parameters of fluid responsiveness based on the analysis of arterial waveform in high-risk surgical patients

B. Cenkova¹; M. Chobola¹; V. Sramek¹; P. Suk¹

¹Department of anaesthesiology and intensive care, St. Anne's University Hospital, Brno, Czech Republic

Correspondence: P. Suk

Intensive Care Medicine Experimental 2020, **8(2)**: 001486

Introduction: Dynamic indices of fluid responsiveness (e.g. pulse pressure variation – PPV and stroke volume variation – SVV) differ between hemodynamic monitors, which use proprietary algorithms, and vary even over a short period of time.

Objectives: The aim is to compare the stability and predictive value for fluid responsiveness of PPV and SVV measured by various minimally invasive devices in high-risk patients undergoing general surgery.

Methods: In this prospective study, clinically indicated fluid challenges (FC; 500 ml of balanced crystalloid administered over 10 minutes) in patients ventilated with tidal volume of 8 ml/kg were monitored. Increase in cardiac output (CO) \geq 15% defined fluid responders. Two minutes of arterial pressure waveform was recorded with simultaneous video recording of hemodynamic monitors – GE Carescape B650 (measuring PPV), FloTrac/Vigileo (SVV) and LidCO Rapid (PPV and SVV) before and after the FC. All devices used the same arterial line and waveform; arterial line flushing was used for synchronization with the video. Analysis was limited to intervals with regular rhythm and good waveform quality. Up to 17 values were read from the video in 5 s intervals and reference PPV was calculated from the stored arterial pressure waveform at the same timepoints offline. Stability of the parameter was assessed by calculating the range and standard deviation (SD) of the index over observed period up to 80 s before FC. Receiver operating characteristic (ROC) analysis and a correlation of the index with change in CO were used to evaluate the predictive value of the indices.

Results: Twenty three patients were analysed; 14 of 60 fluid challenges were excluded due to changes in vasoactive drugs, patient's position change, arrhythmia or artefacts during the FC. Stability was assessed by variation of parameters – mean values of range (and SD) were 3.8 (1.0) % for reference PPV, 1.8 (0.5) % for GE PPV, 10.8 (3.0) % for LidCO PPV, 8.3% (2.4) for LidCO SVV and 2.3 (0.9) % for Vigileo SVV. Mean value of the indexes during 80-second interval before FC was used to calculate the area under the ROC curve (AUROC), optimal threshold, correlation with Δ CO (r) and specificity/sensitivity for threshold values of 10% and 13%, which are presented in the table. Mostly, an average value of the index had better AUROC than minimal or maximal observed values within the observed period.

index	median	AUROC	threshold	r	spec/senz@10%	spec/senz@13%
ref. PPV	8.0%	0.692	9.4%	0.511	74 / 58	85 / 37
GE PPV	7.8%	0.722	7.5%	0.553	73 / 50	89 / 39
LidCO PPV	13.6%	0.734	13.5%	0.472	42 / 95	64 / 74
LidCO SVV	10.7%	0.739	12.2%	0.512	58 / 76	75 / 53
Vigileo SVV	9.6%	0.703	10.2%	0.425	67 / 68	81 / 53

Conclusion: LidCO displayed higher fluctuation of indices than the other monitors. Although a significant span of threshold values was observed, the predictive value of PPV and SVV from all the monitors was comparable. Despite ideal conditions, the diagnostic ability of all parameters was only moderate and lower than expected.

Metformin associated lactic acidosis: a case series of 20 patients

R. Amaral¹; H. Santos¹; C. Carvalho¹; J. Carvalho¹; B. Costa¹; A. Pais¹

¹Intensive Medicine, Centro Hospitalar De Trás-Os-Montes E Alto Douro, E.P.E., Vila Real, Portugal

Correspondence: R. Amaral

Intensive Care Medicine Experimental 2020, **8(2)**: 001323

Introduction: Metformin associated lactic acidosis (MALA) has been reported as from 1977, but full understanding of this entity has yet to be achieved. It is the major toxicity of metformin with high attributed mortality rate. In the most severe cases intensive care admission and renal replacement therapy (RRT) are required.

Objectives: To report on our experience with the MALA patient's characteristics, severity scores, supportive measures required in the last 5 years.

Methods: Retrospective analysis of the clinical information of patients admitted in intensive care level 2 and 3 with main or additional diagnosis of MALA from 2015 to 2019.

Results: We obtained 20 patients of which 13 (65,0%) had principal diagnosis of MALA. Most of the patients were female (n=11), mean age 75,9 \pm 5,9. 14 patients (70,0%) were admitted on level 3 care. Antibiotics were administered to 60,0% (n=12) of patients with only 41,6% of those (n=5) having clinically confirmed infection. Initial lactate levels were 12,6 \pm 3,5 and 24 h lactate levels were 3,2 \pm 3,3. 60,0% of patients required renal replacement therapy (n=12). The RRT modalities were: continuous veno-venous hemodiafiltration in 33,3% (n=4), continuous veno-venous hemofiltration in 33,3% (n=4) and conventional haemodialysis in 33,3% (n=4). Invasive mechanical ventilation was necessary in 25,0% of patients. Severity scores were: APACHE II 25,5 \pm 7,3; SAPS II 50,9 \pm 11,5; SAPS 3 69,2 \pm 16,2; SOFA at admission 9,0 \pm 3,8. Mean length of stay in intensive care was 3,5 \pm 4,2 days and in hospital was 16,0 \pm 9,1 days. Hospital mortality was the same of net mortality: 2 patients (10,0%).

Conclusion: Although with limitations due to its retrospective nature, known under-report of the condition in matter, and varied concurrent pathologies of patients reported, this study presents our reality while treating MALA. We confirmed high use of antibiotics compared to clinically confirmed infection, something referred in the literature. Continuous veno-venous renal replacement was used in the majority of the patients requiring renal replacement. Patients with diagnosis of MALA present with high severity scores but have low mortality in our experience.

Impact of Mental Health Assessment on Intensive Care Stay in Drug Overdose – A Retrospective Observational Study

A. Jayasinghe¹; J. Collins¹

¹Broomfield hospital, MEHT NHS Trust, Chelmsford, United Kingdom

Correspondence: A. Jayasinghe

Intensive Care Medicine Experimental 2020, **8(2)**: 001423

Introduction: Studies on characteristics, outcome and clinical burden of Intensive Care Unit (ICU) admissions following drug overdose are scarce despite the significant health and social impact caused.

Methods: A retrospective observational study was carried out from 2015 to 2019 in an ICU of a district general hospital in Essex, UK with the aim of identifying the demographic and clinical characteristics and factors affecting delay in discharge of the patients admitted to ICU following drug overdose.

Results: Total number of admissions with illicit or prescription drug overdose over the last 5 years were 202 (4.3% of total admissions). 56% were females. Mean age was 38.7 years and patients in the age range of 30-39 years had the highest number of admissions (n = 51, 25.2%). 74.2% were known patients with mental health disorders and 49.5% had a previous history of self-harm. 25 were readmissions which comprised 12.43% of total admissions. Psychoactive medications were the commonest drugs used. Average ICU stay was 2.85 days (Median - 1.8 days). 93.7% were discharged and mortality was 4.4%. The majority were home discharges (43.5%). All home discharges were reviewed by the mental health team (MHT) except 11 self-discharges. All ward discharges (30.7%) were referred to MHT to be reviewed in ward. Delay in discharge from ICU for more than 6 hours since being declared 'Medically Fit for Discharge' was identified as a late discharge. 40.5% of admissions got a delay in discharge. Average delay in discharge was 1.05 days and it ranged from 8 - 96 hours. 72% of the delays occurred due to late assessment by MHT to ensure mental fitness for safe home discharge or in arranging a mental health ward bed if not fit for discharge. Reasons for delay and the frequency are shown in the following table.

Reason for delay	Number of cases	Percentage
Delay in review by mental health team	43	53.4%
Delay in transfer to a mental health ward bed	16	19.5%
Delay in getting a ward bed	23	28%

Notably the duration of ICU stay had a rising trend over the years along with a proportional increase in delay in discharge as shown below.

Conclusion: Drug overdose continues to be a growing public health concern worldwide. Importantly, younger generation is mainly

affected, most are preventable and many require ICU care. A striking proportion of our study; 75% had mental health issues and 50% had a previous history of self-harm. Readmission rate was high, highlighting the importance of psychological support these patients continue to require more. Hence review by MHT is essential before a safe discharge. However, a significant percentage (40.5%) had a late discharge, longest being 96 hours. The main reason was a delay in MHT's review and arranging further psychological care. Patients who faced delays awaiting MHT were otherwise medically fit for direct discharge to home and did not require inward care.

Drug overdose admissions accounted for an average of 115.1 ICU bed days per year. Out of this, 42.42 ICU beds days (36.8%) were occupied due to the delay in discharge. Since the estimated daily cost of a level 2 ICU bed at our institute is 800 pounds, 33,936 pounds/year can be saved by optimising the barriers to prompt discharge from ICU. These may include increasing MHT staff and their availability in ICU and prioritizing ward bed allocation to patients stepping down from ICU.

Correspondence: M. Nijsten

Intensive Care Medicine Experimental 2020, **8(2)**: 001506

Introduction: Renal function changes in COVID-19 patients admitted to the ICU are still poorly delineated. Sole use of plasma creatinine only allows for determination of estimated glomerular filtration rate (eGFR), whereas combined with 24 h urinary creatinine excretion, direct determination of measured creatinine clearance (mCC) is possible.

Objectives: Our goal was to assess renal function with mCC in critically ill COVID-19 patients and also assess its relationship with vancomycin dosing.

Methods: Consecutive COVID-19 patients admitted to our ICU until May 2020 were analyzed over the first 30 ICU days. Vancomycin was administered as a loading dose followed by continuous infusion with dose adjustments based on therapeutic drug monitoring (TDM) with a target vancomycin plasma concentration between 20 and 25 mg/L. Plasma creatinine, eGFR, mCC as well as vancomycin concentrations

were regularly obtained. We defined augmented renal clearance as an $mCC > 130 \text{ mL/min/1.73 m}^2$ [1]. Our current vancomycin TDM algorithms do not use mCC but are based on weight and $eGFR$.

Results: We evaluated 90 patients (73% male), with a mean (\pm SD) age of 62 ± 10 years. Unadjusted hospital mortality was 21%. Mean weight, BMI and BSA were $90 \pm 16 \text{ kg}$, $28.5 \pm 4.6 \text{ kg/m}^2$ and $2.07 \pm 0.20 \text{ m}^2$. In total 1063 mCC measurements were available. In 31 (34%) patients an $mCC < 30 \text{ mL/min}$ was observed at any time and 11 of these patients required renal replacement therapy (RRT). In patients not requiring RRT the mean mCC was $112 \pm 48 \text{ mL/min}$. Augmented renal clearance was observed in 39 patients (43%) for a total of 194 (18%) mCC measurements.

Vancomycin was prescribed for 35 episodes in 30 (33%) patients with a mean loading dose of $1724 \pm 574 \text{ mg}$ ($19.0 \pm 4.9 \text{ mg/kg}$), and a mean maintenance dose of $2268 \pm 886 \text{ mg}$ ($25.3 \pm 10.8 \text{ mg/kg}$). 181 vancomycin levels were determined with a mean concentration of $22.7 \pm 6.7 \text{ mg/L}$ with 17 (57%) patients having at least 2 measurements below 20 mg/L . Daily vancomycin dose was more correlated ($P < 0.01$) with mCC ($R^2 = 0.66$) compared to $eGFR$ ($R^2 = 0.43$).

Conclusion: Although we observed renal failure in our cohort of COVID-19 patients treated in the ICU, a considerable subgroup showed augmented renal clearance when mCC was employed, likely explaining the failure to reach therapeutic vancomycin levels. Determining mCC in COVID-19 patients has therefore clear benefits over the use of $eGFR$.

Tramadol metabolism and systemic inflammation after major abdominal surgery: a prospective observational study

N. Nesković¹; S. Kvolik¹; D. Mandić²; Z. Debeljak²; V. Serić²; S. Skiljić¹; S. Marčić³

¹Anesthesiology and ICU, Osijek University Hospital; Medical Faculty, Osijek, Croatia; ²Department for clinical and laboratory diagnostics, Osijek University Hospital; Medical Faculty, Osijek, Croatia; ³Transfusion medicine, Osijek University Hospital; Medical Faculty, Osijek, Croatia

Correspondence: S. Kvolik

Intensive Care Medicine Experimental 2020, **8(2)**: 001618

Introduction: A systemic inflammation may affect tramadol metabolism within first 24 postoperative hours.

Objectives: The aim of this study was to examine concentrations of tramadol, *O*-demethyltramadol (ODT) and *N*-demethyltramadol (NDT) in patients admitted to the intensive care unit (ICU) after major abdominal surgery in the patients with and without criteria for systemic inflammation.

Methods: For this study Ethics committee approval was obtained and all the patients wrote informed consent. In between of 50 postoperative patients, a group of 47 patients who had both *CYP2D6* gene polymorphism analyses and tramadol and its metabolites measured were analyzed. The development of a systemic inflammation was assessed based on preoperative levels of CRP, PCT, leukocyte count, plasma cholinesterase activity (ChE), arterial blood gas, and postoperative clinical indicators. Postoperatively, patients received 100 mg of tramadol IV every 6 hours for the next 24 hours. Tramadol, ODT and NDT levels were determined 1, 2 and 4 hours after the first dose, and before the second, third and fifth doses of tramadol by high-performance liquid chromatography. Pain was assessed before and 30 minutes after tramadol administrations.

Results: According to *CYP2D6* polymorphism there were 2 poor (PM), 22 intermediate (IM), 22 extensive (EM) and 1 ultrafast metabolizer (UM). Tramadol effectively reduced pain in all patients except PM. The highest levels of ODT were measured in the EM and IM, 97.4

($52.5\text{--}139$) and 51.7 ($25.7\text{--}93.5$) $\mu\text{g/L}$, respectively ($P = 0.03$). ODT levels in all measurements were higher in EM compared to IM and PM, $P < 0.05$. ChE activity of 44244 U/L was a cut-off value in prediction of systemic inflammation. There was a statistically significant increase in NDT levels in IM and EM patients with low ChE activity (LChE group, $n = 18$) compared to patients with normal ChE activity (NChE group, $n = 25$). The ranges were from 11.58 ($4.2\text{--}21.9$) to 59.31 ($18.5\text{--}92.6$) $\mu\text{g/L}$ vs. 3.93 ($3.5\text{--}5.6$) to 26.31 ($17.4\text{--}48.9$) $\mu\text{g/L}$ in LChE and NChE, respectively. Genetically determined difference in ODT levels between IM and EM no longer existed in states of systemic inflammation in all measurements. Despite these differences, tramadol was effective in patients who were EM and IM in reducing pain at all measurement points ($P < 0.001$), but not in 2 patients who were categorized as poor metabolizers ($P > 0.05$).

Conclusion: The results of this study confirm that *CYP2D6* polymorphism is a major factor in *O*-demethylation of tramadol. In the systemic inflammation characterized by low ChE activity there is a significant shift in the tramadol metabolism towards *N*-demethylation. Further studies should evaluate whether tramadol dose may be reduced in the patients with systemic inflammation.

Sedation practices made worse by COVID 19

K. Fok¹; S. Jarvis¹; G. Saville¹

¹Critical Care Unit, Royal Cornwall Hospital, Truro, United Kingdom

Correspondence: K. Fok

Intensive Care Medicine Experimental 2020, **8(2)**: 001256

Introduction: Sedation is an integral practice in intensive care units (ICU). Higher sedation requirements were observed in patients with COVID 19 [1]. However, the negative impact of oversedation in the intensive care setting is well established. Patients are at risk of a higher morbidity, increased length of stay, longer time on mechanical ventilation, increased nosocomial infections, haemodynamic compromise and neurological complications such as delirium to name a few [2-5].

Objectives: This is a retrospective analysis of sedation practice pre and during the COVID 19 pandemic at the Royal Cornwall Hospital, a district general hospital in the United Kingdom. IV sedation agents were reviewed for rapid escalation or for exceeding maximum recommended doses.

Methods: All patients receiving continuous IV sedation in January 2020 (pre-COVID 19) and April 2020 (during the COVID 19 pandemic) were screened. Those who had > 24 hour sedation were included. Their charts were reviewed for breaching the maximum doses according to local protocol or the British National Formulary (Table 1) or increasing $\geq 50\%$ in 4 hours. A notes review was carried out around the time of a breach for any documented rationale. The number of adjuvant sedative medications a patient received in the duration of their ICU admission was also recorded. This included oral clonidine, intermittent doses of benzodiazepines (IV and oral), haloperidol and quetiapine.

Table 1. Sedative agents and defined maximum doses

Sedative Agent	Maximum dose
Propofol	4 mcg/kg/hr
Alfentanil	5 mcg/kg/hr
Remifentanil	0.5 mcg/kg/hr
Midazolam	100 mcg/kg/hr
Clonidine	4 mcg/kg/hr

Results: Prior to the COVID-19 pandemic 6/16 (37.5%) of patients had a sedation breach. This is compared to 9/12 (75%) of patients during the pandemic of which half (6) were patients who did not have COVID 19. Of these, 4/6 (66.7%) of the non COVID 19 and 5/6 (83.3%) of the COVID 19 patients had sedation breaches. Breaches recorded were predominantly in exceeding maximum infusion rates. Pre-COVID 19, there were only 2 patients breached for rate increases $\geq 50\%$ versus 5 patients who exceeded maximum rate infusions. During COVID 19 5 patients recorded rate increases $\geq 50\%$ compared to 7 who exceeded maximum infusion rates.

Propofol was the main agent for which sedation breaches occurred in both cohorts -before COVID 19 5/15 (33.3%) and 8/10 (80%) during the pandemic. The main reason for sedation breaches was difficult ventilation in both cohorts (37.5% pre COVID 19 and 42.5% during). Adjuvant sedative medications were used in 9/16 patients pre-COVID 19 and 9/12 patients during COVID 19. During COVID 19 the patients received 3 or more adjuvant agents 6/9 compared to pre-COVID 19 2/9.

Conclusion: The sedation of patients at this ICU was less compliant to guidance and experienced more sedation infusion rate increases $\geq 50\%$ during the COVID 19 pandemic in keeping with experience elsewhere that they had a higher sedation need. However, these patients also received a larger number of adjuvant sedative medications. This could also relate to a change in sedation practices by pre-emptive concerns about difficult to sedate patients or other factors such as routine ICU medication stock levels.

Although there were fewer sedation breaches pre-COVID 19, over a third of patients still received high doses of sedation in normal times. This suggests more can be done to optimise sedation administration through a multimodal approach which addresses education and ergonomic clinical environments. Recommendations implemented at this centre include: training for staff new to the ICU environment, an easily accessible "sedation user guide" which to highlight common clinical considerations for sedative choice and encourages staff to review why sedation requirement may have changed, a standardised whiteboard to record sedation targets and infusion rates, and once per shift reminders to check sedative infusion rates. A review is due in the autumn of 2020 subsequent to the adoption of these practices.

Intensive Care Medicine Experimental 2020, **8(2)**: 001258

Introduction: Management of pain in critical patients is one of the most important part of the treatment and it is necessary to improve it in order to get better prognosis.

Objectives: To describe prevalence of pain detection and analgesic prescriptions in patients admitted to an ICU of a tertiary hospital.

Methods: Weekly registration for 1 month in 2 consecutive years (2018-2019) of: type of admission, treatment phase, analgesic regimen and assessment of pain through Visual Analogue Scale (VAS), Behaviour Indicators of Pain and Richmond Agitation Sedation Scale (RASS), as appropriate; as well as pharmacological non-pharmacological interventions.

Results: In a total of 184 patients, of which 56.5% of them were males; respiratory failure (45.7%), followed by neurological deterioration (32.6%) and shock (17.4%) were main causes for admission. 58.7%

of the patients were awake and able to self-report pain, and the rest were under sedation or non-collaborative. Of all of them, 69% required mechanical ventilation (MV) (invasive MV 54.9% and non invasive MV 14.1%) and 20.7% had tracheostomy.

Attending to analgesic regimen, 99.5% of the patients had established analgesic regimen: 29.3% of them had a fixed regimen without adjuvant therapy, 13.6% were only prescribed in case of pain, and 56.5% had a fixed regimen plus adjuvant therapy during pain episodes. and rescues. 66.8% of the patients had up to 2 medications for pain and the rest of them, had more than 3 medications.

Attending to registration of pain episodes: In every patient it was recorded at least once per day. In 1.6% it was only registered once a day, in 20.7% twice a day; in 54.3% three times per day, and 13.4% four or more times per day. There was also a explicit reference of that in in 79.3% of nursery registration during mornings, 78.3% during afternoon, and 72.3% during night, as well as in 80% of medical comments. According to the degree of pain, 44% of the patients did no show pain, 36% of them showed mild pain (VAS 1-3), 13.5% showed moderate pain (VAS 4-6) and 6.5% had episodes of severe pain (VAS $>$ 7). Over 20% of episodes of moderate or severe pain (VAS $>$ 4), 97% of them were treated and solved.

Regarding non-pharmacological measures, calm environment was detected in 86% of the records, adequate light in 97.8%, proper sound in 77.2% and pleasant temperature in 90.2% of them. Every patient had postural changes. 81% of them were mobilized to chair, and only 25% of the patients who required physical therapy, received it. In comparison between the 2 years, differences were only observed in the highest registration of pain episodes by nursing staff (68% vs. 85% p0.03). Attending analgesic regime, the one prescribed just in case of pain, was related to more pain episodes.

Conclusion: We consider pain awareness and registration are well established in our Unit; although it is still needed to minimize episodes of moderate or severe pain and to improve physical therapy in our patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 001311

Introduction: Agitation is a common behavior in intensive care patients following acute traumatic brain injury (TBI), which can prolong recovery of TBI patients due to delayed mechanically ventilation weaning and/or mobilization. Actigraphy, which measures rest-wake rhythms using movements with an accelerometer, has been used as an alternative to polysomnography to estimate sleep and to measure physical activity in outpatient settings. In the ICU setting, actigraphy has been used for the same purposes, but more studies are needed as it has only been studied in patients in whom analgesedation has been

discontinued. Our hypothesis is that actigraphy could be a useful tool to monitor agitation and sleep-wake cycles in TBI patients.

Objectives: The primary study objective was to evaluate the feasibility of using wrist actigraphs in critically ill TBI patients who were receiving analgesedation. The feasibility aims were to measure recruitment rate, to describe actigraphy recording duration, to assess missing activity count per day, and to identify impediments to its use.

Methods: We prospectively recruited adult patients admitted to the ICU of Hôpital du Sacré-Coeur de Montréal with acute TBI and abnormal CT scan within 48 hours of ICU admission. Exclusions criteria included: spinal cord injury, prior history of TBI, major neurological or psychiatric disease, high risk of short-term mortality, expected stay <48 hours. Actiwatch-Spectrum actigraphs (Philips/Respironics, Murrysville, PA) were placed in patients' non-paralyzed wrists after ICU admission and study inclusion. Reasons for not using actigraph were documented. Actigraphy data such as the amount of missing data and total recording time were analysed.

Results: Between September 2018 and July 2019, 47 patients were considered eligible and 30 patients were recruited. Median age was 64.5 years (IQR 41.3) and 73% were males. TBIs were severe, moderate and mild complex in 30%, 43% and 27% of cases, respectively. One patient was discharged before actigraph was placed and four patients had less than 24 h of recorded data. These 5 patients were excluded from analyses. A total of 214 completed days of actigraphy data were recorded. The mean number of completed days per patient was 6.5 (SD 5.1), with a minimum of 1 completed day and a maximum of 27. The mean missing activity count per day was 20.3 minutes (SD 81.7) and 89% of the days had less than 30 minutes of missing data per day. Actigraphs were removed for surgery or exams outside the ICU, as well as to download recorded data. Electronic interferences between ICU equipment, tissue oedema and neuromuscular blocker use were found as barriers on the use of actigraphy.

Conclusion: This study supports the feasibility of actigraphy use to monitor agitation and sleep-wake cycles in TBI patients during their stay in the ICU. However, specific aspects of analgesedated TBI-patients should be considered when monitoring patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 001315

Introduction: Patients in need for sedation during mechanical ventilation are at risk for adverse effects of currently used intravenous sedatives, such as long and unpredictable wake-up times, development of delirium, propofol infusion syndrome or life-threatening bradycardia. A number of publications and increasing clinical use indicate that inhaled isoflurane for sedation may be a good option. This study was performed with the aim to evaluate the efficacy and safety of isoflurane via the AnaConDa (SEDACONDA).

Objectives: To compare the efficacy and safety of SEDACONDA with propofol as the sole sedative regimen for up to 48 hours in invasively ventilated patients in a phase III randomized controlled registration trial.

Methods: After ethical approval (Ärztchamber des Saarlandes, 11/17), German and Slovenian competent authority approval and trial registration (Eudra CT#: 2016-004551-67), 300 adult invasively ventilated patients with clinical need for sedation were recruited in 23 study sites in Germany and Slovenia. Written informed consent was obtained from the patient or legal representative according to national laws and regulations. Patients were randomized to either SEDACONDA (Sedana Medical, Danderyd, Sweden) or intravenous propofol, until extubation or for up to 48+/-6 hours, whichever was first. Sedation efficacy was assessed as the proportion of time within RASS-1 to RASS -4 without rescue sedation (primary outcome measure). Wake-up times after stop of sedation, opioid dosing over time, percentage of time with spontaneous breathing, ventilator-free and ICU-free days in the first 30 days, adverse events and 30 day mortality were also monitored. For the primary outcome, the non-inferiority margin for isoflurane was pre-defined to 15% relative the mean proportion of time in target RASS for propofol.

Results: Between July 2017 and January 2020, 301 patients were included. The percentage of time patients were sedated in the target RASS range without rescue sedation was similar for the SEDACONDA and propofol groups (mean percentage of time [CI] 90.7 [86.8-94.6%] vs 91.1 [87.2, 95.0]). Thus, the lower CI of SEDACONDA was above the non-inferiority margin (77.5%). Secondary outcome measures are under statistical evaluation and will be presented during the congress.

Conclusion: The preliminary results indicate that SEDACONDA is efficacious as a primary sole sedative, in the same efficacy range as propofol. Further evaluation of study data and future studies will answer clinically important questions regarding other effects of isoflurane for long-term sedation of critically ill patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 001438

Introduction: Delirium is under-recognized, misdiagnosed and undertreated. Research focusing on associations, prevention and treatment of delirium has increased tremendously in the last decade, but still little is known about patient's experience of delirium. Up to 80% of intensive care unit (ICU) survivors remember their delirium. Delirium has been described as highly unpleasant and distressing with vivid hallucinations and scary delusions. Delirium has been linked to subsequent cognitive dysfunction, psychological sequelae and post-traumatic stress disorder. Knowledge on how delirium is perceived by patients has the potential to improve recognition, management and treatment of delirium.

Objectives: This study investigates how ICU patients recall and experience delirium. We aim to identify predictors of delirium recall and interventions that might reduce distress and symptom severity related to delirium. We aim to understand recollections of delirium and thereby highlight the importance of early recognition and guide future management to relieve patient distress related to delirium.

Methods: This study has a mixed-methods design involving both quantitative measurements and qualitative assessment. Subjects were adult critically ill patients that were CAM-ICU positive during ICU stay. We conducted interviews after ICU discharge when patients were delirium-free assessed by 'rapid clinical test for delirium' (4AT). The interviews were semi-structured and took place at the general ward or patient home. Interviewees used an interview-guide to gather detailed information on recall, experiences and various symptoms related to ICU delirium. The interviews were transcribed and thematically analysed by the research team.

Results: To date sixteen of twenty-five patients have been interviewed. A univariate analysis comparing patients with and without memory of delirium using background characteristics as co-variables (age, admission type, SMS-ICU and delirium motor subtype) will be performed. At present, an 81% of participants remember some part of their delirium during their ICU stay. Fourteen out of sixteen participants found their delirium experience to be very distressing, including two patients who did not remember their ICU stay at all. Twelve participants remembered being confused/disoriented, eleven remembered sleep disturbance and nine had one or more clear memories of hallucinations and/or delusions. Patients tend to experience delirium as a mix of fact and fiction where realistic events merge with delusions and frightening hallucinations. Final results of the thematic and statistical analysis will be presented at the congress.

Conclusion: The conclusion will be presented at the congress.

Intensive Care Medicine Experimental 2020, **8(2)**: 001503

Introduction: Administration of opioids to patients during hospitalization can induce its chronic consumption. Analgo-sedation strategies based on 1st analgesia, 2nd sedation, can cause the administration of high doses of opioids.

Objectives: Assess the impact of opioid use during ICU admission in patients mechanically ventilated for ARDS secondary to SARS-CoV-2, as well as factors modifiable in their discharge treatment in this subgroup of patients.

Methods: Prospective study approved by the Hospital's Ethics and Research Committee. This includes all patients admitted to the ICU between March and May 2020 for ARDS secondary to SARS-CoV-2 who were discharged from the ICU and subsequently from the hospital. Demographic factors and clinical data related to admission to the ICU and hospitalization were analyzed. The cumulative dose of opiates is expressed in mg of iv morphine (10 mg morphine iv = 100 µg fentanyl iv = 100 µg remifentanyl = 20 mg oral methadone). Data expressed in mean (± standard deviation), median (IQ25-IQ75) or with frequency and percentage. To compare means, the Mann-Whitney U test was used.

Results: 54 patients are included, 41 males, with mean age 62 years (± 12), stay included median ICU of 13 days (8–25) and 14 days (8-20) in the hospitalization. APACHE II 16.9 (± 4.6), SOFA at income 6.6 (± 2.1). No patient received opioids prior to admission. In ICU, patients received continuous infusion opioids for a median of 216 hours (133-348), and a cumulative median dose of 2910 mg (969-7892). At discharge from the ICU, in 16 patients (30%), they prescribed opiates (6 iv morphine if needed, 5 IV prescribed morphine and 5 transdermal fentanyl). Four patients were discharged from the hospital with opiates, all with fentanyl transdermal already prescribed for discharge from the ICU. The average cumulative dose of opiates administered in ICU in patients discharged from the hospital with opiates was 12,450 mg, and 4,883 mg in those without opiate prescribed at discharge (U of Mann-Whitney 45.00, p = 0.07).

Conclusion: 7% of survivors were discharged from the hospital with opiates, all with transdermal fentanyl. In 80% of patients discharged from the ICU with fentanyl transdermal, this was maintained at hospital discharge. A study with a larger number of patients is necessary to assess whether the total dose of opiates during ICU admission influences their maintenance at hospital discharge.

Intensive Care Medicine Experimental 2020, **8(2)**: 001545

Introduction: Administration of opioids to patients during hospitalization can induce its chronic consumption. Analgo-sedation strategies based on 1st analgesia, 2nd sedation, can cause the administration of high doses of opioids.

Objectives: Assess the impact of opioid use during ICU admission in mechanically ventilated patients with ARDS secondary to SARS-CoV-2. In addition, we studied the presence of chronic analgesic

consumption, the quality of life perceived three months after hospital discharge, and its possible relationship with the administration of opioids during admission to the ICU.

Methods: Prospective study approved by the Hospital's Ethics and Research Committee. This includes all patients admitted to the ICU between March and May 2020 for ARDS secondary to SARS-CoV-2 who were discharged from the ICU and subsequently from the hospital. Demographic factors and clinical data related to admission to the ICU and hospital ward are analyzed. The cumulative dose of opioids is expressed in mg of iv morphine (10 mg iv morphine = 100 µg iv fentanyl = 100 µg remifentanyl = 20 mg oral methadone). Three months after hospital discharge, a phone call is made to assess the chronic consumption of analgesics drugs, assess the perceived quality of life and the existence or not of chronic pain. Information is collected on the usual analgesic treatment and will be verified by reviewing the electronic medical record and MUP (single prescription module in the Community of Madrid). For the evaluation of quality of life, the Euroqol EQ-5D questionnaire will be used. In patients who answer >1 to item number 4 of this questionnaire (existence of pain), the evaluation of pain will be complemented with the Latineen index. Data expressed as mean (\pm standard deviation), median (IQ25-IQ75) or with frequency and%. The Mann-Whitney U test was used to compare means.

Results: 32 patients are included, 69% male, with a mean age of 62 years (\pm 11), median ICU stay of 9 days (7–16) and 11 days (7–14) in hospitalization. APACHE II 16.8 (\pm 4), SOFA at income 6.8 (\pm 2.1). No patient received opioids prior to admission. In the ICU, patients received continuous infusion opiates for a median of 170 hours (116–223), and a median cumulative dose of 1447 mg (672–4960). At discharge from the ICU, opiates were prescribed in 6 patients (19%) (3 prescribed iv morphine and 3 iv morphine if needed). No patient was discharged from the hospital with opioid treatment. At 3 months (phone call made 93 \pm 2 days after hospital discharge), only 1 patient received opioid treatment with tramadol, while 14 (44%) received non-opioid analgesics (paracetamol, metamizole and/or NSAIDs). The mean cumulative dose of opioids administered in the ICU in patients who received analgesics 3 months after hospital discharge was 4141 mg, and 2416 mg in those who had no chronic use (Mann-Whitney U 94.00, p = 0.22). The results of the EQ-5D questionnaire are shown in Table 1, as well as the relationship between the average doses of opiads consumed depending on the scores on quality of life. 50% of patients reported some pain or discomfort 3 months after hospital discharge (EQ-5D pain >1); in them, the mean Latineen index was 5.9 (\pm 4), 56% consumed analgesics but only 1 patient consumed opioid analgesia.

Euroqol EQ-5D	Scores	n (%)	Mean dose of opioids in ICU	Mann-Whitney U test (p)
EQ-5D Mobility	1	25 (78%)	2720mg	57,00 (0.16)
	>1	7 (22%)	4780mg	
EQ-5D Cares	1	32 (100%)	3171mg	-
	>1	-	-	
EQ-5D Activities	1	21 (66%)	2571mg	90,00 (0.31)
	>1	11 (34%)	4316mg	
EQ-5D Pain	1	16 (50%)	2257mg	94,00 (0,20)
	>1	16 (50%)	4084mg	
EQ-5D Anxiety	1	19 (59%)	2546mg	100,00 (0,36)
	>1	13 (41%)	4083mg	

Conclusion: There is no relationship between the doses of opioids administered in the ICU and their maintenance at hospital discharge or chronic consumption. Neither is there a relationship with different aspects of perceived quality of life at 3 months or with the existence of chronic pain. However, a study with a larger number of patients is necessary to adequately assess these findings.

Intensive Care Medicine Experimental 2020, **8(2)**: 001557

Introduction: Large numbers of Covid-19 patients simultaneously needed invasive mechanical ventilation in many countries, leading to shortages of ICU beds and intravenous sedatives [1,2]. Some report that ventilated CoV19 patients need high doses of sedatives and neuromuscular blocking agents (NMBA) [3]. For those patients, inhaled sedation with isoflurane (ISO) applied with the AnaConDa system (Sedana Medical, Danderyd, Sweden) may be beneficial [4,5].

Objectives: We investigated dosing of propofol (PRO) and ISO in Covid-19 patients in need for deep sedation with and without extracorporeal membrane oxygenation (ECMO) treatment.

Methods: In a chart review, we analysed the patients' needs of PRO, ISO, use of co-sedatives, NMBAs, opioids, documented sedation scores (Richmond Agitation Sedation Scale, RASS), minute ventilation (MV) and ECMO treatment during the first 30 days of treatment in our ICU as long as the patients were in need for deep sedation. Sedation days were classified according to the sedative used (PRO, ISO, or both). All parameters were averaged on a daily basis, and compared between PRO and ISO days with Student's t-Tests for parametric data, or Chi²-tests for frequencies.

Results: 19 consecutive Covid-19 patients, aged 64 \pm 10 years, admitted to the ICU with acute respiratory failure in need for invasive mechanical ventilation and deep sedation were evaluated. Eight patients had been sedated with isoflurane during 7.1 \pm 7.7 days, all but one had received propofol on 9.1 \pm 8.2 days. 9 patients received ECMO treatment for 14 \pm 4 days during this time.

In total, 305 sedation days were recorded, of which PRO had been used on 164 days, and ISO on 100 days. On 41 days, both drugs had been used. These days were excluded from further analysis.

During PRO days, high doses of PRO were recorded. PRO infusion rates (IR) were 8.9 \pm 2.8 ml/h corresponding to 214 \pm 67 ml/24 h. On 24% of PRO days, mean doses higher than 3.5 mg/h/kg predicted body weight (PBW, 22*height [m]²) were used, and on 12%, the recommended maximum dose of 4 mg/h/kg PBW was exceeded. Under PRO compared to ISO, NMBAs (PRO vs ISO: 24% vs 11%, P = 0.010) as well as co-sedatives (32% vs 9%, P = 0.001, mainly clonidine: 26% vs 7%, P = 0.001) were used more frequently and sufentanil doses were higher (5.7 \pm 1.2 vs 4.0 \pm 1.2 mL/h, P = 0.029). RASS scores, as judged by nursing staff, indicated deeper sedation under ISO (-2.9 \pm 1.4 vs -3.5 \pm 0.9, P = 0.001).

ISO-IR were 4.8 \pm 2.2 ml/h corresponding to 115 \pm 53 ml/24 h with a mean end-tidal concentration (ET) of 1.07 \pm 0.37 Vol%. ET correlated poorly with the IR, negatively with the MV, and best with the ratio IR divided by MV. As the MV during ECMO is reduced, IR were significantly lower during ECMO days (3.5 \pm 1.4 vs 7.1 \pm 3.1 ml/h, P = 0.001).

Conclusion: Inhaled sedation with isoflurane is an interesting alternative to propofol in invasively ventilated CoV19 patients in need for deep sedation. High doses of both drugs are needed. Propofol use was associated with polypharmacy, and higher doses of opioids. Isoflurane

consumption is reduced under ECMO treatment. These data may guide stockpiling of sedatives in the future.

Intensive Care Medicine Experimental 2020, **8(2)**: 001443

Introduction: Withdrawal Syndrome (WS) is a common problem in the intensive care unit (ICU). Recognizing WS could be difficult due to lack of a sensitive tool available at the bedside in adult ICUs. Neuro-psychiatric disorders accompanying patients being weaned from sedo-analgesia is another crucial point challenging WS diagnosis.

Objectives: We aimed to validate Withdrawal Assessment Tool-1 (WAT-1) in terms of detecting WS in adult ICU.

Methods: Patients >18 years old admitted to Hacettepe University Medical ICU between March 2019 and March 2020, who were intubated and received sedo-analgesics for >72 hours, were prospectively evaluated. Patients with neuro-psychiatric disorders were excluded. WS was defined according to DSM-5 criteria. Both WAT-1 and DSM-5 assessments were performed by a neurologist. Primary outcome was to define the correlation between WAT-1 and DSM-5 with respect to WS diagnosis whereas secondary outcome was to compare patients with WS with those without WS.

Results: WS occurred in 28 (70%) out a total of 40 patients included in the study. Patient characteristics are seen in Table. All patients survived. Sensitivity and specificity (95% CI) of WAT-1 were found to be 0.78 (0.59-0.91) and 1.00 (0.70-1.00), respectively. Age (< 50 years) was the only independent variable predicting WS when adjusted for ARDS, pulmonary edema, and midazolam dose (Odd Ratio [95% CI]: 8.97 [1.03-77.50], p=0.04).

Table. Comparison of Groups Regarding Withdrawal Syndrome Diagnosis According to DSM-5 Criteria

Total, n= 40	WS (+), n= 28	WS (-), n= 12	p
Age* (years)	50±20	67±18	0.006
Gender (F), n (%)	17 (61)	6 (50)	0.532

Acute pancreatitis in intensive care unit patients: A retrospective study

F. Sequeira¹; L. Linhares¹; D. Castro¹; C. Roriz¹; L. Pereira¹

¹Medicina intensiva, Hospital Santo Andre - Hospital Distrital De Leiria, Leiria, Portugal

Correspondence: F. Sequeira

Intensive Care Medicine Experimental 2020, **8(2)**: 001325

Introduction: Acute pancreatitis (AP) is an inflammatory condition, the worldwide incidence is 13 to 45/100,000. Severe acute pancreatitis (SAP) is associated with serious morbidity and mortality and these patients require intensive care unit (ICU) admission. Factors predicting mortality and morbidity need to be identified for improving outcome.

Objectives: The aim of our study was evaluation of demographic and outcome of patients with SAP admitted to our ICU from June 2018 to June 2020. The secondary objective was to identify the factors responsible for adverse outcome.

Methods: Retrospective analysis of patients with SAP admitted to the ICU between June 2018 and June 2020.

Results: Eleven SAP patients were admitted to ICU (54.5% female, mean age 64.3).

The most common aetiologies were gallstones (72.7%) and hypertriglyceridemia (18.2%).

The severity of AP as depicted by Ranson's score showed mean score of 3.2 at admission, and 3.5 after 48 hours. On admission to ICU, the median Acute Physiology and Chronic Health Evaluation (APACHE) II score was 22.3 and the median Computed Tomography Severity Index (CTSI) was 3 (range 2-4).

During the ICU stay, 72% of patients required mechanical ventilatory support, ranging in duration from 1 to 35 days; 90.9% developed acute kidney injury (AKI) and 18.2% required continuous renal replacement (CRR); 72.7% needed vasopressor support.

A significant number of patients (54.5%) tolerated early enteral nutrition via either a nasogastric tube or a nasojejunal tube, while total parenteral nutrition (TPN) was used in 18.2% of patients.

The disease course was complicated with pancreatic abscess (45.5%), abdominal compartment syndrome (18.2%) and pseudo cyst formation (9%). Surgical intervention was required in 50% of these patients. The median length of stay in ICU and hospital were 13 (ranged from 1 to 74) and 25 (ranged from 1 to 110) days, respectively.

ICU mortality and hospital mortality were 45% and 9%, respectively. Mean APACHE II score of these patients was 28.7. All these patients had AKI and two patients who needed RRT died.

Conclusion: Acute pancreatitis remains a challenging disease for intensive care medicine and this retrospective data showed high mortality of AP requiring ICU admission.

Predicting the outcome of ICU patients with AP remains a difficult task despite the availability of scoring systems. In our study, the APACHE II score was higher between non-survivors. The mean of Ranson score in our study population was 3.2 and 3.5 at and after 48 hours of admission, which has a predicted mortality of 11 to 15%, so the predictive value of this scoring system is questionable in our study. Although AKI itself was not an independent risk factor of adverse outcome in our study, patients who need CRR died.

The authors wish to highlight the need to early severity assessment and management for those patients at risk of SAP.

Intensive Care Medicine Experimental 2020, **8(2)**: 001204

Introduction: Macrovascular thrombi are a common complication of COVID-19. Risk factors for COVID-related thrombi are not well understood (1).

Objectives: To examine the incidence of macrovascular thrombi in patients admitted to the intensive care unit (ICU) with COVID-19, and to explore factors associated with thrombi in COVID-19.

Methods: We retrospectively enrolled all patients aged >18 admitted to ICU between 1/3/2020 and 30/4/2020 with a laboratory-confirmed diagnosis of COVID-19 (n = 93). 1 patient was excluded as an incidental diagnosis of COVID-19 admitted to ICU for post-operative monitoring. Data was extracted from health records using a standardised data collection tool. Patients were followed up to 24/5/20.

Results: The median age was 57 (IQR 48 - 62), 70 (76.1%) were male. The population was diverse; 37 (44.6%) were Caucasian, 26 (31.3%) were Black, 18 (21.7%) were Asian, 2 (2.4%) were of mixed ethnicity and in 9 cases ethnicity was not recorded. Median duration of illness prior to hospital admission was 7 (IQR 4 - 9) days.

Cardiovascular risk factors were common; 44 (47.8%) were hypertensive, 30 (32.6%) were obese and 30 (32.6%) were diabetic. Fourteen (15.2%) patients had a cardiovascular condition, 10 (10.9%) had chronic respiratory disease, 13 (14.1%) had a baseline eGFR <60 ml/min, and 5 (5.4%) had known cancers. Several patients used coagulation-modifying drugs; 9 (9.8%) took antiplatelet agents, and one was anticoagulated with warfarin.

All patients received anticoagulation during their admission. Treatment dose anticoagulation was given to 22 (23.9%), whilst 70 (76.1%) received only prophylactic anticoagulation. The median duration of COVID-19 symptom onset to thromboprophylaxis initiation was 8 days (IQR 6 - 10).

Macrovascular thrombi were detected in 22 (23.9%) of the population. Of these, 7 (33.3%) were pulmonary emboli, and 7 (33.3%) were venous thrombi. There were 2 strokes, 2 arterial occlusions, 1 myocardial infarction, 1 renal vein thrombus and 1 ventricular thrombus (fig 1). During the same period, 8 (8.7%) patients developed significant haemorrhages; 4 had an upper gastrointestinal bleed, 2 an intracranial haemorrhage, and there was one pulmonary and one urinary tract haemorrhage.

Fig 1: Diagnosed thrombi in the study population

On univariate analysis, there was a non-statistically significant reduction in the incidence of major thrombi in Black (OR 0.336, 95% CI 0.085 - 1.111, $p=0.090$) and Asian patients (OR 0.231, 95% CI 0.033 - 0.986, $p=0.076$) compared to Caucasian patients. APTT ratio prolongation >1.8x was more frequent in patients not developing thrombi ($p=0.032$), whilst Fibrinogen levels <1.8 g/L occurred more often with thrombosis ($p=0.015$).

Conclusion: Critically ill patients with COVID-19 face high incidence of thrombotic complications despite anticoagulation. Low levels of fibrinogen are associated with thrombi. Clinicians must remain vigilant to the development of thrombi even in anticoagulated patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 001330

Introduction: Blood transfusions are common in critically ill patients; 30 to 45% patients receive red cell transfusions of, 10-30% plasma transfusions and 10-20% platelet transfusions during their ICU stay.

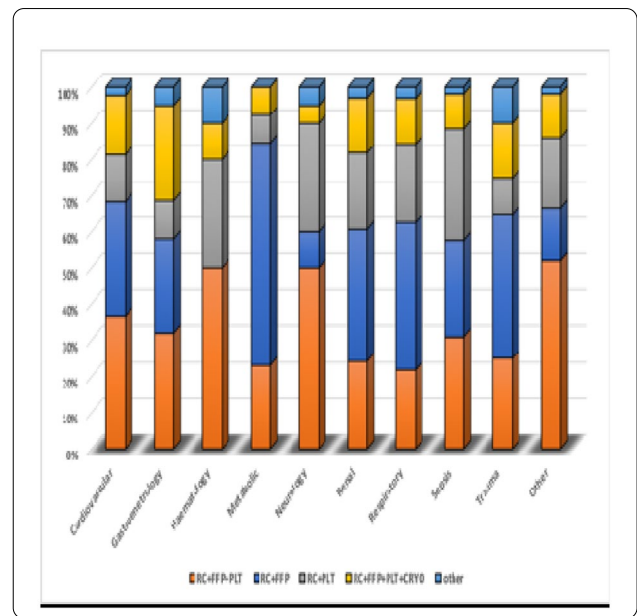

Each of the studies that have reported on plasma and platelet use and outcomes in ICU has reported separately for each blood product type. There are limited studies that have reported on the transfusion of red cells, plasma, platelets and cryoprecipitate concurrently in ICU.

Objectives: The primary outcomes of the study were to examine the prevalence of red cells and multicomponent transfusion during ICU stay.

Methods: A retrospective study of 5783 patients enrolled in the INFORM trial including 2332 patients that were admitted at the Flinders Medical Centre ICU between April 2012 and October 2015 was performed. Total red cells (RC) and blood products transfused at any point between ICU admission and discharge were analysed leading to three specific categories - RC only transfusion (RC-only), MCT and non-transfusion (NT). Multicomponent transfusion included RC-MT [RC co-transfusion with plasma (FFP), platelets (PLT) and cryoprecipitate (CRYO) or combination of components without RC (MT)]. The common types of RC-MCT included RC+FFP, RC+ PLT, RC+FFP+PLT and RC+FFP+ PLT+CRYO.

Results: Of the 2726 ICU admissions analysed, 1323 (48.5%, 95% CI 46.6-50.4) received no transfusion (NT), 660 (24.2%, 95% CI 22.6-25.9) received MCT and 743 (27.7%, 95% CI 25.6-28.9) received RC-only during ICU stay. Besides trauma (33.7%) and haematology admissions (31.8%), half or more than half of the admissions in each clinical groups did not receive a transfusion during ICU stay. RC-MT ranged from 9.2% to 45.6% across all clinical groups, highest being in haematology (41.5%) and gastroenterology (GIT, 32.1%) admissions (Figure 1). Amongst all types of RC-MT, RC +FFP+PLT (36.1%) was the commonest type, followed by RC+FFP (27.3%), RC +PLT (16.5%) and RC +FFP+PLT +CRYO (16.5%). RC-MCT varied across clinical groups, with 61.5% of metabolic admissions received RC+FFP, 30.8% of sepsis admissions received RC +PLT and 26.3% of GIT admissions received RC+FFP+PLT+CRYO (Figure 2).

Fig. 1 & 2 - Percentage of non-transfused and transfused admissions including transfused admissions with types of multi-component transfusion for various admitting ICU diagnoses

Conclusion: Almost half of ICU admissions were transfused. Fifty percent of those transfused received red cells and the other half received multicomponent transfusion. Multicomponent transfusion including the various types of multicomponent transfusion varied between clinical groups. Further studies are required to study outcomes in patients receiving multicomponent transfusion in ICU.

Intensive Care Medicine Experimental 2020, **8(2)**: 001379

Introduction: Coronavirus disease 2019 (COVID-19), caused by SARS-CoV-2, has recently emerged in Wuhan, China, and rapidly spread worldwide [1]. Apart from respiratory failure, coagulopathy is a common abnormality in COVID-19 patients and is associated with poor prognosis [2, 3]. Regardless of increasing evidence of coagulation dysfunction, the data available for the most severe patients is still scarce.

Objectives: To describe the coagulation parameters of critically ill COVID-19 patients and evaluate its association with mortality.

Methods: Observational retrospective study of coagulation parameters and outcomes of all COVID-19 patients admitted to a polyvalent

intensive care unit (ICU) of a Portuguese tertiary hospital between March 15th and May 10th 2020.

Results: Thirty-six patients required ICU admission from a total of 264 COVID-19 patients admitted to our hospital. Median age was 62 [58.3; 65.8] years, 23 (63.9%) were men and median APACHE II score and SAPS II were 18 [13.0; 23.7] and 42 [31.0; 51.5], respectively. Twenty-nine (80.6%) patients had chronic diseases, mainly arterial hypertension (n=21, 58.3%), diabetes (n=11, 30.6%), respiratory disease (n=7, 19.4%) and coronary heart disease (n=5, 13.9%). Median ICU length of stay was 16 [6.8; 22.3] days and the overall mortality was 25% (n=9). All patients received at least prophylactic doses of low molecular weight heparin. The coagulation parameters were analyzed from admission to day 14 of ICU stay. No difference in ICU stay was found between survivors and non-survivors (17 vs 14 days, p=0.494) and none of the coagulation parameters at admission were correlated with ICU length of stay. Non-survivors had significantly higher D-dimer levels at admission (2.89 vs 1.47 mg/mL, p=0.04), and longer prothrombin time (PT) and activated partial thromboplastin time (APTT) at day 10 (17.67 vs 16.43 sec, p=0.016 and 38.07 vs 33.30 sec, p=0.046, respectively). Despite high fibrinogen levels at admission (mean 675 ± 156 mg/dL) and during ICU stay, no statistical significance was found between the two groups. Sepsis-Induced Coagulopathy (SIC) and International Society on Thrombosis and Haemostasis Disseminated Intravascular Coagulation (DIC) scores were significantly higher in non-survivors at day 10 (3 vs 2, p=0.006 and 4 vs 2, p=0.001). Furthermore, 44.4% (n=4) of non-survivors and 16.6% (n=4) of survivors met the SIC criteria, but only one (11.1%) non-survivor and 2 (7.4%) survivors matched the ISTH DIC score. From these, only one patient actually developed clinical DIC.

Conclusion: At admission D-dimer was positively correlated with mortality. By the late ICU stay, non-survivors revealed significantly prolonged PT and APTT. The occurrence of DIC was rare. It seems that COVID-19 coagulopathy might not be equal to the known sepsis coagulopathy, so DIC diagnostic criteria applied to this specific disease should be reviewed. Further studies are needed to clarify the effective prognosis value of coagulation parameters in critically ill COVID-19 patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 001383

Introduction: Coronavirus Infectious Disease 2019 (COVID-19) is reported to be associated with a high rate of venous thromboembolism (VTE). Most published reports to date (1-3) are retrospective, do not systematically screen for deep venous thrombosis (DVT) and suggest a higher frequency of pulmonary embolism (PE) than DVT.

Objectives: To determine the rate of DVT in critically ill patients with COVID-19. The study is ongoing and the results of the first 15 patients are reported here.

Methods: We conducted a prospective, observational trial to examine rates of DVT in patients COVID-19 admitted to the critical care unit of a large tertiary hospital. We enrolled consecutive patients with COVID-19 confirmed by polymerase chain reaction (PCR) testing. The screening test was compression ultrasound (CUS) of the proximal veins of both legs performed by any of 3 advanced intensive care medicine trainees all of whom had prior experience in CUS for DVT. The leg veins were compressed every 2 cm from the common femoral vein at the inguinal ligament until the trifurcation in the popliteal fossa. A non-compressible vein was considered positive for DVT. Any positive scans were reviewed by several investigators. Positive results were communicated to the treating physician. Scans were performed every 72 hrs up until 30 days or until the patient left critical care. The primary outcome was the rate of DVT by CUS.

Results: We enrolled 15 patients with confirmed COVID-19 between 2nd April and 10th May 2020. Baseline characteristics are shown in Table 1.

Table 1.

Age	60
Ventilated at admission	66% (10/15)
D-dimer at admission (median)	3.24
Fibrinogen at admission (median)	6.25
Platelet count at admission (median)	235
Therapeutic anticoagulation at enrolment	33% (5/15)

No patient had a clinical suspicion for DVT prior to enrolment. All patients were on either therapeutic or prophylactic anticoagulation. At the time of study, COVID-19 patients were being treated with a higher dose of or prophylactic enoxaparin than typical critical care patients at a dose of 0.5 mg/kg twice daily.

We found a single DVT in the popliteal vein of a ventilated patient at time of enrolment to the study. 4 other patients were diagnosed with VTE during the study, 3 with PE and one with an upper limb DVT.

Further enrollment is currently halted due to significant drop off in COVID-19 prevalence in Ireland at the time of writing.

Conclusion: In this ongoing study the rate of DVT in critically ill patients was low with only 1 of the 15 patients having a lower limb DVT throughout their critical care stay, though it is notable this occurred in the setting of higher dose prophylaxis.

However, the observed 20% rate of PE despite this prophylaxis may represent thrombosis in situ or immunothrombosis rather than embolism from a distal venous site.

Intensive Care Medicine Experimental 2020, **8(2)**: 001410

Introduction: Novel oral anticoagulants (NOACs) represent first-line treatment for venous thromboembolism and prevention of stroke in nonvalvular atrial fibrillation. Bleeding complications have been reported in NOACs users during the postoperative period.

Objectives: Aim of the study is to identify if there is any correlation between postoperative hemorrhagic complications and pre-operative use of novel oral anticoagulants (NOACs) in cardiac surgical patients.

Methods: All patients who underwent elective cardiac surgical procedures with the use of cardiopulmonary bypass from January 2019 to March 2020 were evaluated. Patients were divided in 3 categories: Group A consisted of patients with preop use of NOACs : Apixaban(Eliquis), Dabigadran(Pradaxa) and Rivaroxaban (Xarelto). Group B consisted of patients with preop use of vitamin K antagonists and Group C consisted of patients without preop use of any anticoagulant. NOACs were discontinued 3-5 days before surgery. The following perioperative factors were compared: sternal reopening because of hemorrhage, transfusion with at least 1 unit of platelets, transfusion with at least 1 unit of Fresh Frozen Plasma, transfusion with more than 3 units of red blood cells and no transfusion at all. Decisions for transfusion was based on lab results and rotational thromboelastometry – ROTEM. Chi square test was used for statistical analysis.

Results: A total of 581 patients were evaluated. First we compared Group A (n = 41 - 7 Apixaban, 24 Rivaroxaban and 13 Dabigadran) with Group C. Results are shown in table 1

	A (n=41)	C (n=528)	P value
Resternotomy	4 (9,8%)	19 (3,6%)	0,07
PLT	5(12,2)	73(13,8%)	0,65
FFP	7(15,9%)	37(7)	0,03
>3 RBC	8(8,2%)	91(17,2%)	0,87
No transfusion	13(29,5%)	131(24,8%)	0,48

Table 1

Comparison between drugs revealed statistical significant correlation between use of Dabigadran with resternotomy (20/559 -3,6% versus 3/13-23,1% p < 0,005).

We also compared Groups A and B. Results are shown in table 2.

	A (n=41)	B (n=9)	P value
Resternotomy	4 (9,8%)	0 (0%)	0,33
PLT	5(12,2)	2(22,2%)	0,43
FFP	7(15,9%)	1(11,1%)	0,65
>3 RBC	8(8,2%)	1(11,1%)	0,55
No transfusion	13(29,5%)	2(22,2%)	0,77

Table 2

Conclusion: Preoperative use of NOACs correlates significantly with higher incidence of transfusions with FFP after elective cardiac surgical procedures. Dabigadran use correlates with higher incidence of resternotomy because of hemorrhage. No difference in hemorrhagic complications were found between use of NOACs and use of Vitamin K antagonists.

Intensive Care Medicine Experimental 2020, **8(2)**: 001470

Introduction: Between the ages of 1 and 4 years and the ages of 15 and 34 years, trauma is the single most common cause of death in Europe¹. Major uncontrolled hemorrhage after trauma remains the leading cause of preventable death after severe traumatic injury². Any improvement in the quality of care provided to these patients could have a great impact on healthcare systems, reducing associated medical and social costs.

Objectives: The aim of this study was to determine the epidemiology of trauma-related major hemorrhage at our institution and to identify modifiable factors associated with mortality.

Methods: A retrospective analysis of prospectively collected data of adult trauma patients who activated the "Massive Hemorrhage Protocol" (MHP) at Cruces University Hospital (HUC) and received at least one unit of Red Blood Cells (RBC) from 15th February 2017 to 4th September 2019, was conducted. HUC is a trauma regional referral Hospital in the Basque Country (Northern Spain), for an estimated population of 1 million.

Results: A total of 32 patients met the inclusion criteria. All patients were critically injured, with median Injury Severity Score of 34 (IQR 25-43) and with median admission systolic blood pressure of 95 (IQR 70-117) mmHg. Median age was 47 (IQR 38-74) years, and 28% of the patients were 65 years or older. The proportion of male patients was 59%. Regarding the trauma mechanism, most of our patients presented blunt trauma (up to 84%).

Patients received a median of 2 (IQR 0-4) units of Fresh Frozen Plasma (FFP), 5 (IQR 4-9) units of RBC, 0 (IQR 0-1) units of platelets (1:2.5:0 median ratio), and a median of 2 (IQR 0-4) grams of Fibrinogen concentrate. In 41% of patients resuscitation was TEG-guided.

We observed an overall mortality of 44%, with 64% of the deaths within the first 24 h after admission. Exsanguination due to uncontrolled hemorrhage below the diaphragm was the cause 100% of the early deaths in our study population.

The median lactate level and base excess (BE) on admission were 5.2 (IQR 3.0-11.8) mmol/L and -9 (IQR -13.98 - -6.45) mmol/L, respectively. Median International Normalized Ratio (INR) and fibrinogen level on admission were 1.5 (IQR 1.3-1.85) and 189 (IQR 146-264) mg/dl. In the group of patients that survived > 24 h after admission and damage control resuscitation was completed; lactate, BE, INR and fibrinogen values were corrected (median Lactate 1.2 mmol/L, median BE -0.5 mmol/L, median INR 1.2, median Fibrinogen 331 mg/dl).

No statistically significant differences were found between mortality and gender, age, blood product consumption or ISS; however, increased lactate or INR on admission, and the need of damage control surgery were associated to higher mortality rates.

Conclusion: Although a damage control resuscitation strategy proved to be highly effective for critically injured patients (median ISS 34) with adequate hemorrhage control, exsanguination due to uncontrolled hemorrhage below the diaphragm was the cause of 100% of the early deaths in our series.

According to a recent joint statement from the American College of Surgeons Committee on Trauma, the American College of Emergency Physicians, the National Association of Emergency Medical Services Physicians and the National Association of Emergency Medical Technicians regarding the clinical use of Resuscitative Endovascular Balloon Occlusion of the Aorta (REBOA) in civilian trauma systems; this device may be used for traumatic life-threatening hemorrhage below

the diaphragm in patients in hemorrhagic shock who are refractory to resuscitation. This indication resemble the main cause of preventable death identified in our study.

The development of a local REBOA protocol and a quality assurance program could be recommended to reduce early trauma-related mayor hemorrhage mortality of in our setting.

Experience of thromboprophylaxis of patients with COVID-19 disease across two Intensive Care Units in the West of Scotland

A. Taylor¹; F. Mcmorrow²; A. Allison³; R. Hart⁴; E. Black⁵; J. Allan²

¹intensive care, Queen Elizabeth University Hospital, Glasgow, UK, United Kingdom; ²Intensive care, University Hospital Crosshouse, Crosshouse, United Kingdom; ³Intensive care, Queen Elizabeth University Hospital, Glasgow, United Kingdom; ⁴Critical care, Queen Elizabeth University Hospital, Glasgow, United Kingdom; ⁵Department of critical care, Queen Elizabeth University Hospital, Glasgow, United Kingdom

Correspondence: A. Taylor

Intensive Care Medicine Experimental 2020, **8(2)**: 001520

Introduction: The incidence of venous thrombo-embolism (VTE) in intensive care patients is between 5-15% (1). Fixed dosing of once daily low molecular weight heparin (LMWH) is routinely used to mitigate this when appropriate. Target dosing is of 0.5 mg/kg but this is often not achievable at extremes of body weight. It is not routine practice currently to measure anti-xa levels for assessing attainment of therapeutic levels.

Objectives: During the COVID 19 pandemic it became quickly apparent these patients were presenting profoundly pro-thrombotic and hyper-inflammatory, often with d-dimers in tens of thousands and with a high incidence of VTE. After consultation with haematology colleagues we changed our practice of once daily (OD) to twice daily (BD) dosing of LMWH in response, and sought to ensure no increase in patient harm or significant bleeding complications.

Methods: Data was collected for two hospital sites in the West of Scotland: Queen Elizabeth University Hospital and University Hospital Crosshouse. A total of 84 patients admitted over a 9 week period from March 2020 requiring ventilation were reviewed. The regime and dose of LMWH, incidence of VTE and outcome were recorded. Dose adjustment was made for those with renal impairment and extremes of body weight. Anti-xa levels were not routinely measured but were noted when taken. We recorded patients actual weight which allowed calculation of mg/kg dosing. An excel document was used for recording patient data. Patients admitted on treatment dose anti-coagulation and those who were on renal replacement therapy and heparin only throughout their admission were excluded.

Results: During the weeks 1-3 prior to practice change 100% of patients admitted were commenced on OD LMWH. Practice change was introduced in week 4, and from week 5-9 there is a 95% compliance rate with either changing from OD to BD dosing, or commencing on BD dosing. Our sample size is too small to show statistical significance but we see a fall in mortality in the weeks following change and trend to lower incidence of confirmed VTE.

Actual dose was calculated for each of our patients with an accurately recorded weight. We found 63% (N=30) of those who died in the QEUH were on an equivocal dose of <0.5 mg/kg daily.

Anti-xa levels were not routinely measured in patients on OD LMWH however when checked in patients moved to BD dosing levels were between 0.12-0.39.

We did not find any increase in significant bleeding complications or evidence of patient harm from this change.

Week	OD LMWH	OD->BD LMWH	BD LMWH	VTE confirmed	Discharged home	Died	Total no of admissions
1 16/03/2020	4	0	0	0	2	2	4
2 23/03/2020	9	6	0	4	6	9	15 (1 excluded)
3 30/03/2020	17	2	0	6	5	14	19 (2 excluded)
4 06/04/2020	5	6	4	2	5	10	15 (2 excluded)
5 13/04/2020	0	1	3	1	1	3	4
6 20/04/2020	0	1	6	4	6	1	7
7 27/04/2020	1	1	5	1	4	3	7 (1 excluded)
8 04/05/2020	0	1	1	0	2	0	2
9 11/05/2020	0	0	1	0	0	1	1

Conclusion: We have shown the ability to rapidly induce a change in practice across two Intensive Care Units in the West of Scotland. We have not shown any evidence of increase in harm. We have highlighted a variable patient specific dose in this pro-thrombotic patient cohort already at increased risk of significant VTE. It may be in the future we should consider altering our practice further. Dose adjustment for underlying condition, renal function, weight and specific drug half-life with routine measurement of anti-xa levels may allow a more patient specific, targeted approach. This could further help reduce VTE incidence, not just in COVID 19 patients but in all critically ill patients receiving VTE prophylaxis.

001542**AntiXa determination as a guide for anticoagulation in COVID-19 patients in our hospital**R. Carmona¹; C. López¹; J. Rodríguez¹; P. Reyes¹; C. Fernandez²; C. De La Fuente Martos¹¹Intensive care unit, Hospital Universitario Reina Sofia, Córdoba, Spain;²Haematology unit, Hospital Universitario Reina Sofia, Córdoba, Spain**Correspondence:** R. Carmona*Intensive Care Medicine Experimental* 2020, **8(2)**: 001542

Introduction: Many studies are beginning to study the relationship between COVID-19 infected patients and an increased risk of pro-thrombotics. So far, all clinical guidelines suggest starting prophylactic anticoagulation in this type of patient, but we do not really know what is the optimal dose to avoid bleeding complications and at the same time decrease the risk of thrombosis. We hypothesize that monitoring of the antiXa factor may serve to guide anticoagulant therapy, either at prophylactic or therapeutic doses in patients infected with SARS-CoV-2.

Methods: This is a prospective descriptive study in which we included 11 patients infected with COVID19 admitted to the Intensive Care Unit at a tertiary hospital in southern Spain. Variables such as comorbidity, renal function, BMI, initial and final dose of low molecular weight heparin, and laboratory parameters such as factor VIII coagulant activity, Von Willebrand antigen (VW Ag), ristocetin cofactor Von Willebrand's (VWRCo), antithrombin, fibrinogen, D-dimer were collected, as well as bleeding and thrombotic complications.

The following data were collected for each patient: demographics, previous conditions: comorbidities, obesity, Charlson comorbidity index, clinical characteristics, severity of illness (APACHE II and SOFA score), renal clearance, the need for renal replacement therapy (RRT), and cardiovascular risk factors (hyperlipidemia, hypertension, diabetes, ischemic cardiopathy). In addition, initial enoxaparin dose and subsequent goal dose, renal function, and all anti-factor Xa levels were collected. Major and minor bleeding events, Heparine-Induced Thrombocytopenia (HIT) and thrombotic events rule out by CT, were analysed. All patients received at least standard doses thromboprophylaxis (enoxaparin 40 mgr/24 h).

Results: 54% of our patients needed to increase the dose of enoxaparin to reach levels of AntiXa in the prophylactic range (AntiXa 0.3-0.7 IU/ml). Only 2 were maintained with the same initial dose (enoxaparin 40mgr/24 h and 100 mgr/24 h respectively). We performed computed tomography (CT) to rule out thrombosis, and only one of our patients presented jugular thrombosis. 3 of our patients presented bleeding events that required blood product transfusion.

Conclusion: We found that conventional prophylactic dose might not be enough for prophylactic anticoagulation in patients with severe pneumonia and ARDS COVID-19 in the Intensive Care Unit. Most of the time (54%), we needed increasingly higher doses of enoxaparin (up to 100 mg per day) to range prophylactic dose. The study concludes with the need to determine the AntiXa factor in all patients infected with COVID 19 as a guide for anticoagulant therapy or prophylaxis, probably due to the proinflammatory state. Although the sample of our observation is small, we consider a highly relevant topic that has not yet been reported in patients with COVID-19. The importance of the findings will serve as a basis for studies with a larger sample. To further investigate the significance of these findings, we suggest studying these data in depth in future controlled clinical trials.

Layios*Intensive Care Medicine Experimental* 2020, **8(2)**: 001583

Introduction: Early after the beginning of the Covid-19 pandemic, reports of fatal pro-thrombotic complications of the disease led some experts to advocate the use of systemic anticoagulation in critically ill SARS-CoV-2 patients. As a consequence, an institutional algorithm, stratified on severity, was implemented at the Liege University Hospital.

Objectives: The objective of this retrospective study is to highlight the incidence of thromboembolic or hemorrhagic events in critically ill mechanically ventilated patients with SARS-CoV2 who were all treated with systemic anticoagulation, either prophylactic or therapeutic. The primary endpoint was to compare all-cause mortality between the 2 regimens of anticoagulation. The secondary endpoint was to compare the incidence of thrombotic events (deep venous thrombosis, pulmonary embolism, myocardial infarction, mesenteric ischemia, hepatic ischemia, stroke) and hemorrhagic events between the 2 groups of patients.

Methods: Between March 14th and June 1st, 2020, all consecutive patients with SARS-CoV-2 hospitalized in the 7 ICUs at the Liege University Hospital were included in this study. The Institutional Review Board waived the need for consent to use prospectively collected clinical data and the study was appointed the serial number 2020-214. The exclusion criteria included: the lack of use of mechanical ventilation and of anticoagulation. All patients received either prophylactic (enoxaparin 0.5 mg/kg/day) or therapeutic (enoxaparin 1 mg/kg, twice a day) anticoagulation. All patients were sampled for D-dimers, platelets, Fibrinogen upon admission. Calculation of DIC score (ISTH criteria) and severity scores (SOFA, SAPS2) was acquired upon admission for all patients. Arterial and venous thrombotic events led to a diagnostic workup upon clinical suspicion.

Results: Seventy-three patients were included in the final analyses. Demographic and clinical data are shown in Table 1. Mortality was not different between the 2 groups: 19/49 (38.8%) in the prophylactic group versus 7/24 (29.2%) in the therapeutic group. Moreover, there was no difference in the incidence of thrombotic or hemorrhagic events between the 2 groups. Median platelet counts were normal and DIC was predominantly non-overt. However, fibrin monomers taken from 49% of patients and D-Dimers, which should consolidate DIC scoring, were statistically higher in the prophylactic group in which three thrombotic events occurred (3/73, 4.1%). Of note, the latter incidence is substantially lower than in recent reports thus validating a systemic anticoagulation in Covid-19 patients(1, 2). Finally, while not conferring a mortality benefit as suggested by a recent study, the therapeutic regimen appeared safe.

Table 1: Demographic, clinical and biological characteristics of anticoagulated SARS-CoV-2 patients (N=73).

All (N= 73)	Therapeutic anticoagulation n=24 (32.9%)	Prophylactic anticoagulation n=49 (67.1%)	P value
Sex : Male	14 (58.3%)	36 (73.5%)	0.191 *
Age (years)	64 (57 - 67)	64 (56 - 72)	0.402***
Death (N) (%)	7 (29.2%)	19 (38.8%)	0.421 *
Thrombotic events (N) (%)	0 (0%)	3 (6.1%)	0.546**
Hemorrhagic events (N) (%)	1 (4.17%)	3 (6.1%)	1.00 **
DIC score (ISTH)	2 (2- 3)	2 (2 -3)	0.349 ***
Fibrin Monomer detected (N) (%)	3/13 (23.1%)	15/23 (65.2%)	0.035 **
DDimers (mg/L)	0.93 (0.68 - 1.41)	1.98 (0.95 - 4.55)	0.006 ***
Platelets (x10 ⁹ /mm ³)	1. (146 - 254)	201 (146 - 271)	0.822 ***

* Chisquare test

** Fisher exact test

*** rank sum test

Age, DIC score, DDimers, platelets median (IQR)

Conclusion: Taken together, these findings are concordant with previous reports in emphasizing the fact that Covid-19 coagulopathy, while overlapping with many well characterized coagulopathies does not perfectly match any of them(3). They also confirm that systemic anticoagulation is mandatory in critically ill mechanically ventilated patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 001603

Introduction: In COVID-19 patients hyperinflammation, immobilisation, hypoxia and vascular dysfunction may predispose to both venous and arterial thromboembolism. Describing these complications is necessary in order to adjust the intensity of thromboprophylaxis specially in critically ill patients who are at increased thrombotic risk.

Objectives: To identify predictive factors and determine the frequency of thrombotic complications in ICU COVID-19 patients receiving pharmacological thromboprophylaxis.

Methods: Descriptive retrospective study. Statistical analysis was performed with IBM SPSS Statistics 25.

Results: 77 patients with confirmed COVID-19 hospitalized in the ICU of our second level hospital were screened between March 6, 2020

and May 6, 2020. All patients were adults diagnosed with respiratory failure and undergoing mechanical ventilation. Demographics, comorbidities, severity score, inflammatory markers, medical and antithrombotic treatment were collected. All these data were analyzed between patients with thrombotic episodes and those who did not, establishing the incidence of thrombosis, the type, the diagnosis used, and analyzed the significance of the risk factors.

Of the 77 patients included in the study, 64.9% were male. The average age is 58 ± 11 years. At admission, the mean APACHE II was 17 ± 17.32. 40.3% had a history of HT, 70% chronic lung disease, 67.5% DM, 45.5% DL and 74% obesity, with CKD being present in one of the patients and 7.8% previous thrombotic events. 15.5% were oncologic patients. Regarding anti-thrombotic treatment with LMWH, 55.8% received thromboprophylaxis, 16.9% adjusted the dose to weight/renal function, 15.6% received intermediate doses of prophylaxis (1 mg/kg/day) and 10.4% anticoagulant doses. The incidence of venous thromboembolism was 32.5% of the total with DVT being 32% (3 with distal; 2 with distal and proximal; 1 with bilateral; 1 other type) and pulmonary thromboembolism in 76% (6 bilateral; 8 with segmental; 2 with lobar; 3 with massive). Note that, the means of the inflammation parameters were significantly higher in the patients with thrombotic complications compared to those who did not suffer them (D-dimer 63,3 ± 124 vs 16 ± 21 ng/ml, p = 0,001; IL-6 2311 ± 2767 vs 924 ± 1175, P = 0,001; PCR 246 ± 122 vs 215 ± 117, p = 0,016; Ferritina 6012 ± 2014 vs 1827 ± 1560 ng/ml, p = 0,012; LDH 708 ± 388 vs 1344 ± 1552 ng/ml, p < 0,01). Paradoxically, mortality among thrombosed patients is not significantly higher.

Conclusion: In conclusion, despite systematic thrombosis prophylaxis, the 32,5% incidence of thrombotic complications in these patients is remarkably high and well comparable to the VTE incidence in other patient categories, but mortality among these patients is not significantly higher. D-dimer, IL-6, Ferritina, LDH and PCR level-guided more aggressive thromboprophylaxis regimens using higher doses of heparin seem to be a good instrument in critically ill patients but more prospective studies are needed in this regard.

Correspondence: D. Ratano

Intensive Care Medicine Experimental 2020, **8(2)**: 001604

Introduction: Recently published data show that COVID-19 is characterized by a hypercoagulable ROTEM profile and decreased fibrinolysis[1]. Multiple reports suggest that severe COVID-19 infection is associated with an increased thromboembolic risk[2,3]. There are limited data associating a hypercoagulable ROTEM profile and outcomes in the literature. A hypercoagulable ROTEM profile could help identify patients at risk of worse outcome and help target a study population for enhanced anticoagulation therapy or other COVID-19 therapy.

Objectives: To determine if early hypercoagulability on ROTEM is associated with a higher risk of thromboembolic complications or worse outcome, in a population of mechanically ventilated COVID-19 patients transferred to a tertiary ARDS/ECMO referral center.

Methods: All COVID-19 patients receiving mechanical ventilation at our center between April 3 and June 15, 2020 were assessed with ROTEM. Testing performed included at least ExTEM and FibTEM. Patients were classified as hypercoagulable (HC) or not (nHC) using the

following criteria from ROTEM: EXTEM clot formation time (E_CFT) < 40 sec, alpha (α) angle >79° and, either ExTEM or FibTEM maximum clot firmness (E_MCF or F_MCF) >70 mm or >24 mm, respectively. Outcomes, assessed at discharge from our ICU, included thromboembolic events (TE: composite of deep vein thrombosis, pulmonary embolism and ischemic stroke), acute kidney injury (AKI: AKIN 4 stage >2 with or without dialysis[4]), duration of mechanical ventilation, requirement for ECMO, and death. Difference between groups was determined using the chi-square or Fisher-exact test for categorical data and a t-test for continuous variables respectively, using p < 0.05 as significant.

Results: Of 59 patients included, 31 were hypercoagulable (HC) on admission. Mean (SD) age was 52(14), and SOFA score on admission was high 15(2). The severity of disease was similar in both groups especially for the cardiac and respiratory SOFA components (Table 1). The composite outcome of TE was not different between the groups (HC 9/31, nHC 6/28, p=0.7). The composite renal outcome was not different (HC 18/31 vs nHC 16/28). Mortality rate (29%, HC 9 vs nHC 8), and the duration of ventilation in survivors (HC 22 vs nHC 22 days) were similar in both groups. Requirement for ECMO support was similar (HC 8 vs nHC 12, p= 0.27). Patients were tested with daily viscoelastic tests and, neither fibrinolysis nor DIC were documented. All patients received TE prophylaxis and 34 received therapeutic intravenous heparin for ECMO (n=20) or TE treatment (n=14). Initial ROTEM were conducted on the therapeutic heparin in 22 cases (12 HC, 10 nHC)

Table 1:

Variable	Overall (n=59)	Non hypercoagulable (n=28)	Hypercoagulable (n=31)	p-value
Age [years]	52 (±14)	51 (±15)	53 (±14)	0.48
Sex [male] (%)	44 (76)	20 (74)	24 (77)	0.80
BMI [kg/m ²] (IQR)	30.8 (8.3)	30.3	31.3	0.64
SOFA score	14 (±2)	15 (±2)	14 (±3)	0.83
Resp >3	58/58	27/27	31/31	
Cardiac >3	42/58	20/28	22/31	
E_CFT [sec]	55 (16)	68 (13)	43 (6)	<0.001
E_α [°]	79 (3)	76 (3)	83 (1)	<0.001
E_MCF [mm]	75 (6)	71 (5)	79 (4)	<0.001
F_MCF [mm]	43 (12)	37 (13)	47 (9)	0.001

Data are shown as mean or median with standard deviation (±SD) or (IQR)

Conclusion: Our data suggest that in a population of mechanically ventilated patients with severe COVID-19, an early hypercoagulable profile on ROTEM is not associated with an increased risk of thromboembolic events, AKI, prolonged ventilation, ECMO or death during their ICU stay.

Intensive Care Medicine Experimental 2020, **8(2)**: 001613

Introduction: In COVID-19 patients, coagulopathy is frequently reported and is a significant poor prognosis factor. There is particularly high frequency of thromboembolic events, so the use of heparin was associated with reduced mortality in COVID-19.

Objectives: In order to optimize the treatment in these patients, the objective of our study was to analyze the incidence of bleeding complications and what factors were most associated with them.

Methods: We made a descriptive retrospective study with adult patients with confirmed COVID-19 hospitalized in the ICU of our second level hospital between March 6, 2020 and May 6, 2020. Statistical analysis was performed with IBM SPSS Statistics 25.

Results: All were diagnosed with respiratory failure and required invasive mechanical ventilation. We collect demographics, comorbidities, severity score (APACHE, SOFA, SAPS II), medical and antithrombotic treatment, an extensive study of coagulation, mortality and average ICU stay. We try to establish the incidence and importance of bleeding complications analyzing the importance of risk factors associated with them. Our sample included 77 patients. Most of them (64.9%) were male. The average age was 58 ± 11 years. At admission, the mean APACHE II was 17 ± 17.32. 40.3% had a history of HT, 70% chronic lung disease, 67.5% DM, 45.5% DL and 74% obesity, with CKD being present in one of the patients and 7.8% previous thrombotic events. 15.5% were oncologic patients. Regarding anti-thrombotic treatment with LMWH, 55.8% received thromboprophylaxis, 16.9% adjusted the dose to weight/renal function, 15.6% received intermediate doses of prophylaxis (1 mg/kg/day) and 10.4% anticoagulant doses. The incidence of bleeding complications (11.68%, 8 patients) compared with that of thrombosis (32.5%) was low. However thrombotic complications were not significantly associated with higher mortality, while hemorrhagic complications were. There were three patients with cerebral hemorrhage, 2 with digestive hemorrhage, 1 with hemoptysis, 1 with peritracheostomy bleeding and one with muscular hematoma. Of these, 2 patients had LMWH at anticoagulant doses, 2 with intermediate doses (1 mg/kg), 3 with prophylactic doses and one with a dose adjusted for renal function. Only 1 received antifibrinolytic treatment. Comparing the data between patients with hemoptysis and those without SOFA on admission (6.84 ± 18 vs 6.5 ± 3.6 p = 0.003) was the only risk factor that was significantly associated. Clarify, that 3 of them had had concomitant major whirlwind events.

Conclusion: Therefore we can conclude that although hemorrhagic complications have a lower incidence than thrombotic, their mortality is much higher and that it is difficult to establish possible risk factors that help us predict them. It is important to emphasize in order to optimize thrombotic event prophylaxis that heparin doses were not significantly associated with bleeding complications, but we require further studies with a larger sample to try to establish more risk factors that are associated.

CABARET: Clinical implications of Bromelain Application in buRN patients

S. Provinciael¹; K. Colpaert¹; S. Monstrey²

¹Critical care, Ghent University Hospital, Ghent, Belgium; ²Plastic surgery, Ghent University Hospital, Ghent, Belgium

Correspondence: S. Provinciael

Intensive Care Medicine Experimental 2020, **8(2)**: 001191

Introduction: Bromelain-based enzymatic debridement of burns is a relatively new technique, though it has already shown promising results on wound healing, with limiting blood loss and a lower probability of skin transplantation.

However, a higher degree of inflammation was clinically suspected in patients receiving bromelain. This study examines the association of using bromelain and the initiation of an inflammatory reaction.

Methods: A retrospective survey was performed on the database of burn patients in the university hospital of Ghent (Belgium), during the period of 05/2016-06/2019, with a total of 52 included patients. Inflammatory parameters were studied before and after the application of bromelain. The parameters include vital signs (blood pressure, heart rate, temperature), laboratory findings (such as WBC (white blood cell count), CRP (C-reactive protein), coagulation, renal function, fibrinogen, hematocrit, lactate and blood glucose) and therapeutic measurements (such as use of oxygen, inotropic agents and vasopressin). Sequential Organ Failure Assessment (SOFA) Score was additionally determined.

Results: A statistical difference ($p < 0.05$) was seen in temperature, tension, heart rate, WBC, CRP and coagulation. We observed a higher temperature, hypotension, tachycardia, a higher CRP, a prolonged coagulation and a lower hematocrit. The white blood cell count was significantly lower after application of bromelain. No significant difference was seen in the other variables, neither in SOFA score.

Conclusion: Significant differences of augmented temperature, hypotension, tachycardia, elevated CRP and prolonged coagulation were noticed after the application of bromelain, which suggest that bromelain may induce inflammation. Further research is needed in order to determine a clear causal relationship between the application of bromelain and the induced inflammatory response with the application of standardised prospective study protocol.

³Hematology department, Hospital Doce de Octubre, Madrid, Spain

Correspondence: A. Marcos-Morales

Intensive Care Medicine Experimental 2020, **8(2)**: 001229

Introduction: Different acute critical illnesses such as sepsis or severe traumatic injury share some kind of inflammatory response (1), in which monocytes play an active role (2). Changes in cell volume parameters are related to cell activation, and one of these parameters is the monocyte distribution width (MDW), which is the standard deviation of monocyte volume.

Recently, an elevated monocyte distribution width (MDW) has been found to differentiate patients with sepsis from those with a less severe infection (3-4).

We hypothesized that an elevated MDW would also occur in some trauma patients, especially in those with increased severity and a worse prognosis.

Objectives: The aim of this study was to evaluate the association between MDW value on admission of polytraumatized patients, with trauma severity and prognosis.

Methods: This study took place in a trauma ICU in Madrid. Patients admitted with traumatic injury between August and November 2019 were included, in which the MDW was measured in the first whole blood sample on the UniCel[®] DxH 800 Coulter[®] Cellular Analysis System. No patients were excluded. They were classified according to MDW values (greater or less than 20 U). We compared for each group: injury severity score (ISS), hemodynamic instability, organ failures, length of stay and mortality. For statistical analysis we used SPSS software, version 20.

Results: We included 87 patients with a median age of 43 years (interquartile range IQR 27-52), 77% were men. Half of the patients presented with severe trauma, with a median ISS of 17 (IQR 11-25). Severe

traumatic brain injury occurred in 18% of patients, 20% had severe thoracic trauma, 17% moderate-to-severe orthopedic trauma, and 15% moderate-to-severe abdominal trauma. Demographic variables were well balanced between MDW defined groups: those with a MDW ≥ 20 U represented 43% of patients, median age was 45 years (IQR 31-61), and median ISS was 17 (IQR 13-27). High MDW patients were more likely to present hemodynamic instability on admission (77% vs 23%, $p = 0.013$), as well as acute renal failure during ICU stay (80% vs 20%, $p = 0.017$). These results were still observed after adjusting for age, ISS and metabolic acidosis on admission (base deficit of 4 mmol/L or more). A MDW ≥ 20 U was associated with hemodynamic instability on admission with an OR of 3,8 (IC 95% 1,09-12; $p = 0,03$), with failure of two organs or more with an OR of 12 (IC 95% 1,2-123; $p = 0,034$), and with acute kidney injury (AKI) with an OR of 17 (IC 95% 1,5 - 202; $p = 0,023$). We found no association between an elevated MDW and mortality of length of stay.

Conclusion: In trauma patients, a MDW ≥ 20 U on admission was independently associated with greater hemodynamic instability and a greater risk of multiorgan failure, especially AKI.

The monocyte distribution width is a parameter available from the complete blood count. It could be useful in predicting severity in the initial evaluation of trauma patients.

Femoral veno-arterial carbon dioxide tension difference following severe trauma as organ perfusion index

M. Werner¹; B. Bergis¹; PE. Leblanc¹; L. Wildenberg¹; J. Duranteau¹; B. Vigué¹; A. Harrois¹

¹Anesthesiology and intensive care, Bicetre Hospital AP-HP, Le Kremlin-Bicêtre, France

Correspondence: M. Werner

Intensive Care Medicine Experimental 2020, **8(2)**: 001319

Introduction: Veno-arterial carbon dioxide tension difference (ΔPCO_2) is inversely related to cardiac output. No study has ever assessed ΔPCO_2 as a marker of hemodynamic status following severe trauma.

Objectives: The aim of this study was to assess femoral ΔPCO_2 (ΔPCO_2 fem) ability to predict the need of emergency erythrocyte transfusion following severe trauma.

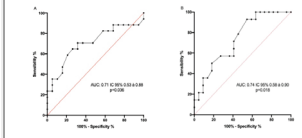

Methods: This is a prospective, observational study, conducted in a French level I trauma center. Patients admitted to the trauma resuscitation room following severe trauma with an Injury Severity Score (ISS) > 15 , who had arterial and venous femoral catheters inserted were included. ΔPCO_2 fem and arterial lactatemia were measured over the first 48 hours of admission. ΔPCO_2 fem and lactate abilities to predict erythrocyte transfusion during the first six hours of admission and emergency hemostatic procedure have been assessed using receiver operating characteristics curve.

Results: 42 trauma patients were included in the study. Median ISS was 27 (22-32). 22 patients (48%) received at least one red blood cell unit and 17 patients (40%) had a hemostatic procedure performed during the first six hours of admission. Mean overall ΔPCO_2 fem at

admission was 9.5 ± 6.3 mmHg and median lactatemia was 2.2 (1.5-4) mmol/l. Δ PCO₂ fem was significantly higher in patients who were transfused than in those who were not transfused (12 ± 7 mmHg vs 7 ± 3 mmHg, $p=0.018$). The best threshold to predict red blood cell transfusion in the first six hours of admission was 8.1 mmHg and the best threshold to predict emergency hemostatic procedure was 5.8 mmHg. Lactatemia was not predictive of red blood cell transfusion or hemostatic procedure in the first six hours of admission.

Table 1 : Comparison between patients who were transfused and those who were not transfused with red blood cell units during the first six hours of admission.

	Transfusion	No transfusion	p
	n=22	n=20	
Age	46±22	47±20	0.08
Women	9 (41)	5 (25)	0,3
ISS	29	25	0.08
ICU mortality	8 (36)	3 (16)	0.17
MBP - mmHg	87±16	73±22	0.027*
HR - bpm	96±23	101±31	0.39
Lactate - mmol/l	1.8 (1.3-3.1)	2.4 (1.9-5.7)	0.06
Δ PCO ₂ fem - mmHg	7±3	12±7	0.018*
Hb - g/dl	12,6±1,3	10±2	<0.001*
TP - %	77±13	65±21	0.047*
Fg - g/l	2,4±0,9	2±0,9	0.14
Crystalloids H6 - ml	876 (500-1967)	2750 (1469-4137)	<0.001*
RBC H6 - ml	0	950 (505-1243)	<0.001*
Catecholamines H6	0.63 (0.38-2.5)	1 (0-1.8)	0.61
Hemostatic procedure H6 (9)		15 (75)	<0.001*

Conclusion: After severe trauma, Δ PCO₂ fem at hospital admission predicts the need for red blood cell transfusion and emergency hemostatic procedure. Δ PCO₂ fem on admission has the potential to stratify patients at risk of severe bleeding following trauma.

A Definite Rib Fracture Pathway in Major Trauma Patients Reduces Critical Care Admissions

Introduction: Queen's Medical Centre (QMC) is a regional major trauma centre in East Midlands of England, serving the population of 4.8 million people. A significant proportion of patients admitted to Major Trauma Ward (MTW) have chest wall injuries.

A trust-wide guideline on management of blunt chest trauma and rib fractures was published in July 2018 to help identify patients with multiple rib fractures who would benefit from an early administration of a thoracic epidural, which is the gold standard of analgesia in those with rib fractures in QMC.

Objectives: This study aims to look at the incidence of escalation to Critical Care (Level 2 & 3 care) from Major Trauma Ward (Level 1 care) in patients with ≥ 3 rib fractures since the introduction of the blunt chest trauma and rib fractures guideline.

Methods: List of patients who were admitted to MTW directly from Emergency Department with ≥ 3 rib fractures between July 2018 and June 2019 was obtained from Trauma Audit and Research Network (TARN) database. Data such as patient demographics, number of rib fractures, whether it was isolated chest injury, a form of analgesia including rib open reduction and internal fixation (ORIF), reason for delay in administration of an appropriate analgesia (including anticoagulant use), escalation to Critical Care, total length of hospital stay were collected and analysed.

Results: A total of 176 patients were admitted to MTW with ≥ 3 rib fractures over one year period. 2 patients were excluded due to insufficient data.

The mean age was 64.5. 44 (25.3%) had an isolated chest wall injury. The mean number of ribs fractured was 5.7. The mean length of hospital stay was 9.9 days.

89 (51.1%) received an oral analgesia and 85 (48.9%) received a regional block. 7 (4%) had a rib ORIF.

Out of 85 with a regional block, 81 (91.0%) received a thoracic epidural, 3 (3.5%) received a morphine PCA and 1 (1.2%) received a paravertebral block.

In terms of escalation, 10 out of 174 (5.7%) were escalated from MTW to Critical Care. 7 were on oral analgesia (for non-respiratory reasons) and 3 on thoracic epidural. All of these 3 epidural patients were escalated for respiratory deterioration. 2 patients had a delay in epidural insertion; one due to deranged clotting due to liver cirrhosis and the other due to being on DOAC.

Conclusion: Early administration of a thoracic epidural in rib fracture patients enhances respiratory function and minimises the risk of respiratory complications. The result showed that only 3 (1.7%) patients were escalated to Critical Care due to respiratory deterioration over one year period. Having a definite rib fracture pathway for analgesia minimises the incidence of admission to Level 2 and 3 care. This potentially increases the cost effectiveness and allows appropriate utilisation of resources in the critical care environment.

Brain-heart interactions: primary cardiac injury in patients with traumatic brain injury

J. Lenstra¹; R. Wiersema²; M. Nijsten²; ICC. Van Der Horst²; J. Van Der Naalt¹

Intensive Care Medicine Experimental 2020, **8(2)**: 001482

Introduction: Cardiac mimicry have been described in patients with subarachnoid hemorrhage(1), which presumably is caused by an elevated sympathetic tone with excessive catecholamine release. This phenomenon has not been extensively studied in patients with traumatic brain injury (TBI). Recently we observed a high incidence of electrocardiographic (ECG) abnormalities in patients with severe TBI. (2) However, primary cardiac injury as cause of ECG abnormalities was not determined systematically by echocardiography.

Objectives: In this study we evaluated brain-heart interactions in TBI patients admitted to the intensive care unit (ICU) with echocardiographic images systematically obtained within 24 h after ICU admission. We aimed to determine the incidence of right ventricle

dysfunction, since it is most at risk due its anatomical position during thoracic injury(3), and their association with brain injury severity in comparison to a trauma-control group.

Methods: Prospective observational study of trauma patients (≥ 18 years) admitted to the ICU of the University Medical Center Groningen between April 2015-July 2019 (SICS-I and SICS-II study(4)). Primary outcome was the incidence of right ventricular dysfunction; right ventricular systolic excursion (RV S') (abnormal ≤ 9.5 cm/s) and tricuspid annular peak systolic excursion (TAPSE) (abnormal < 17 mm). Secondary outcome was the association with brain injury severity scored according to the Glasgow Coma Scale.

Results: In total, 109 patients were included, median (IQR; interquartile range) age was 57 years (38-68), and 69% were male. The 30-day mortality rate was 14%. Brain injury severity groups were as follows: trauma-control (20%), mild- (35%), moderate- (11%), and severe TBI (34%). Overall RV S' was abnormal in 5% of patients with a median (IQR) of 14.0 cm/s (11-16) and TAPSE was abnormal in 10% with a median IQR of 22.2 mm (18.2-25.0). No differences were observed between RV S' and TAPSE with brain injury severity groups ($p = 0.866$ and $p = 0.589$, respectively).

Conclusion: Right ventricular cardiac function remains adequate in patients with traumatic brain injury admitted to the ICU and is not associated with brain injury severity. Despite often observed ECG abnormalities in patients with severe TBI, our data underscores that ECG abnormalities more likely reflect the secondary effect of brain injury (i.e. cardiac mimicry) rather than primary cardiac dysfunction.

The evolution in anaesthetic practice of trauma rapid sequence induction (RSI) in a major tertiary hospital during its transition to a major trauma centre

A. Abdelhadi¹; P. Jonetzko¹; L. Weekes¹

¹Department of anaesthetics, University Hospitals Plymouth NHS Trust, Plymouth, United Kingdom

Correspondence: A. Abdelhadi

Intensive Care Medicine Experimental 2020, **8(2)**: 001561

Introduction: Major trauma is the leading cause of death among children and young adults with more than 16000 annual deaths in the UK. Following advances in trauma care from armed conflicts and excessive mortality and morbidity from inadequacies in delivery of trauma care in the UK, a centralised trauma network system was introduced. University Hospitals Plymouth was designated as a major trauma centre in 2012 with 4 district general satellite trauma units in the South West of England. We analysed various RSI methods used during the transition and incidence of complications and vasopressor use in trauma RSI.

Objectives:

- Evaluate the change in practice of trauma RSI during transition to a major trauma centre between 2012 and 2019.
- Compare clinical practice to existing RSI standard operating procedure (SOP) during the transition period 2012-2019.

- Review complications associated with different induction agents and vasopressor use in trauma RSI.

Methods: Patients were identified from UK's Trauma Audit & Research Network (TARN) database. We selected trauma cases across three years encompassing the transition period (2012, 2015 and 2019). Data was collected retrospectively based on TARN data base and hospital records. Patients intubated pre-hospitally and transfers from trauma units were included.

Results: We analysed 120 patients in total, only those with complete set of data were included in the final analysis ($n=68$). In our study group, blunt trauma was the main mechanism of injury (95.5%) and 85% of RSIs were performed in patients with an injury severity score >15 . Only 11% of RSIs were done by non-anaesthetists and ketamine/midazolam was used for those. Table 1 details induction agents used.

	Propofol	Ketamine	Thiopental	Etomidate	Midazolam	No Induction agent
2012	79%	8.5%	12.5%	0%		
2015	53%	35%	6%	6%	0%	
2019	48%	41%	0%		4%	7%

Rocuronium largely replaced suxamethonium for muscle relaxation. It was used for half RSIs in 2015, with suxamethonium only being used once in 2019.

Hypotension (systolic blood pressure < 90) was the main complication (24.5%), and has largely occurred with propofol (87%) but also seen with ketamine (13%). 40% of propofol inductions in patients with traumatic brain injury (TBI) required vasopressor use.

Conclusion: The incorporation of major trauma centre RSI protocols required a transition from individual anaesthetist-centred practice to a multidisciplinary trauma team based approach. Whilst adaptation of rocuronium as the preferred muscle-relaxant occurred ahead of updating the trauma RSI SOP in 2018, propofol remained as the induction agent of choice despite SOP suggesting ketamine use. This might be due to most RSIs being delivered by anaesthetists who use propofol more regularly. This may not necessarily worsen outcomes for non-TBI; however, it may do so in traumatic brain injuries where hypotension commonly occurred with propofol. Overall incidence of hypotension was similar to other published data, and the selection of RSI drugs is comparable to RSI practice in the UK.

Intensive Care Medicine Experimental 2020, **8(2)**: 001650

Introduction: Thoracic trauma is a common admission problem to the emergency department, with a wide variety of presentations. Trauma patients may be difficult to access, especially with blunt lesions, considering that the extent of the visible lesions may underestimate its severity. Several scoring systems are commonly used to evaluate severity in these patients, and have been proposed to predict the development of acute respiratory distress syndrome (ARDS), however there is no global acceptance for a single scoring system. Our goal is to design a new score. Combining the Lung Ultrasound Score sectorial points, we hope to enhance sensitivity for severe (more diffuse) lesions. While preparing this new scoring system to be ultrasound based, we decided first to retrospectively evaluate its usefulness reviewing our patient data and their Computerized Tomography (CT) scan, knowing beforehand which have developed such complication.

Methods: We conduct a retrospective, consecutive review of the medical records of patients who were admitted to the ICU with thoracic trauma who were managed at our institution between september 2019 and june 2020. Inclusion criteria were: thoracic trauma, admission in ICU, arterial blood gasometry at admission, and thoracic CT scan within the first 12hours. The score used accessed each patient by gasometry, presence of pneumothorax and hemothorax, and contusion/consolidation extent, ranging from 0 to 20. Then we analyzed the association between the proposed score and evolution to ARDS, need for mechanical ventilation and in-hospital mortality.

Results: 19 patients met the final inclusion criteria. The minimum score was 4 and the maximum 12. In this study we noticed that all patients that didn't evolved to ARDS (from mild to severe) had a score equal or inferior to 7. The same cut-off was noticed to the need of mechanical ventilation. From the 19 patients enrolled, only one died and was one of the 3 patients with the highest score (12).

Conclusion: The present study aims to evaluate all thoracic trauma patients admitted to an ICU for a period of 10 months and evaluate the validity of a new score as a predictor of in-hospital mortality and/or evolution to ARDS, trying to find cut-off above or under which one could decide ICU admission. The authors have in mind the handicaps of these study: 1) the few patients enrolled, 2) the retrospective evaluation, 3) the use of CT. Nevertheless, it was important to notice a clear cut-off for the less ill patients, in spite of their admission in ICU. This emphasizes the need for further research in this area, with a greater number of patients for a longer time. The authors of the study aim for future testing the score using thoracic ultrasonography at admission. This point of care exam would be faster, safer (innocuous to the patient) and cheaper. We add that the operator dependency is easily resolved with basic training and experience.

Communication and Humanization in End-of-life COVID-19 ICU patients

P. Maia¹; D. Mano¹; P. Campos²; C. Vidal¹; I. Madeira³; E. Freire⁴; J. Ramalho¹
¹Intensive Care Medicine, Centro Hospitalar Universitário do Porto, Porto, Portugal; ²Unidade de cuidados intensivos polivalente, Centro Hospitalar e Universitário do Porto, Porto, Portugal; ³Anesthesiology, Centro Hospitalar Universitário do Porto, Porto, Portugal; ⁴Palliative care, Centro Hospitalar Universitário do Porto, Porto, Portugal

Correspondence: P. Maia

Intensive Care Medicine Experimental 2020, **8(2)**: 001216

Introduction: The rapid COVID-19 pandemic spreading, associated with insufficient resources, changed the focus of health care professionals (HCP) from caring with the best quality to preserving as many lives as possible. End-of-life (EOL) procedures (1) implemented in the ICU were changed to minimize the use of scarce personal protective equipments (PPE) and the risk to disseminate SARS-CoV-2 infection among HCP and families of ICU patients. Portuguese authorities implemented restrictions following state of emergency declaration (2): visits were forbidden, EOL decision meetings with families were cancelled, communication was restricted to a physician in charge call to one family member once or twice daily. In addition, institutional religious support was withheld. As many patients admitted to the ICU were previously in a good medical condition they had not a living

will and, though they were awake, conversations with them about EOL issues were short or nonexistent due to severe hypoxia: therefore their will was mostly unknown. Communication of EOL decisions is traditionally variable (3): however, in such conditions, the extent of the impact of these measures on communication and humanization is unpredictable.

Objectives: To describe decision making, communication practices and palliative measures in EOL COVID-19 patients at an university hospital intensive care department.

Methods: Data from all COVID-19 patients admitted to the ICU from 11-3 to 29-4-2020 were studied. No interventions were given to patients. Institutional approval was obtained [2020.084(067-DEFI/068-CE) – TRILIPA 19(TRIage, LImitation of therapy and PAlliative care in COVID 19 patients)].

Results: 51 patients were enrolled (67% male, mean age 65 yo) with a median SOFA score on ICU admission of 7, a median Charlson Comorbidity Index of 4 and median Frailty Score of 3; median LOS in ICU was 8 days. 42 (82%) patients were awake on ICU admission.

21 (41%) patients died in the ICU, 27 had decisions to limit life sustaining treatments (LST); none patient had a living will; no information about patient's wishes was asked. Although only 2 patients had limitation of LST on admission, neither the patient or the family participated on its discussion. Decisions to either withholding or to withdrawing therapy were communicated to the family before death in 22% of the cases. Nurses participated in 8% of EOL decisions. Palliative care measures included sedoanalgesia (100%) to guarantee that patients died gently and tranquilly. There were no visits (100%) for the dying patients.

Conclusion: Procedures related to EOL care of the dying patient in the ICU were changed during COVID 19 pandemic, consequently humanization in EOL was not protected and these patients were not equally treated in rights and dignity. The psychological and sociological effects of the civil liberties and human rights restrictions on both the families and caregivers of the dead and HCP are to be determined.

End-of-life practices in COVID-19 ICU patients: The TRILIPA 19 study

D. Mano¹; P. Campos²; C. Vidal¹; J. Ramalho¹; I. Madeira³; M. Bertao⁴; P. Vita¹; P. Maia¹

¹Intensive care medicine, Centro Hospitalar Universitário do Porto, Porto, Portugal; ²Unidade de cuidados intensivos polivalente, Centro Hospitalar e Universitário do Porto, Porto, Portugal; ³Anesthesiology, Centro Hospitalar Universitário do Porto, Porto, Portugal; ⁴Palliative care, Centro Hospitalar Universitário do Porto, Porto, Portugal

Correspondence: P. Maia

Intensive Care Medicine Experimental 2020, **8(2)**: 001295

Introduction: Though End-of-life practices (EOLP) are variable [1] and change over time [2]. The COVID-19 pandemic brought new dilemmas to ICU physicians concerning triage, limitation of life-sustaining therapy (LLST) and humanization. Many decisions were left to the ICU staff alone (sometimes to the physician in charge alone), being the patient or the family unable to participate in the decision making process. Documentation, which is frequently poor [3], may be even more challenging under these circumstances.

Objectives: To describe EOLP in COVID-19 patients at an university hospital intensive care department.

Methods: All COVID-19 patients admitted to the ICU from 11-3-2020 to 29-4-2020 were enrolled in a retrospective observational study. Institutional approval was obtained [2020.084(067-DEFI/068-CE)

- TRILIPA 19 (TRiage, Llimitation of therapy and PAlliative care in COVID-19 patients)] with a waiver of informed consent. LLST definitions used were: "Do-not-resuscitate (DNR) order" when the order to DNR was prescribed and documented; "failed CPR" when death occurred despite cardiopulmonary resuscitation (CPR) efforts, "withholding life support" (WH) when a decision was made not to start or increase a life-sustaining intervention like cardiopulmonary resuscitation (WH_CPR), vasopressors and/or inotropes (WH_Vas), invasive mechanical ventilation (WH_IMV), renal replacement therapy (WH_RRT) or extracorporeal membrane oxygenation (WH_ECMO); "withdrawing life support" (WD) when a decision was made to actively stop a life-sustaining intervention presently being given, maintaining only closed circuit ventilation to protect health care workers from the risk of contamination.

Results: 51 patients were enrolled (67% male, mean age 65 yo, median LOS in ICU 8 days): on ICU admission, the median SOFA score was 7, the median Charlson Comorbidity Index (CCI) was 4 and the median Frailty Score was 3. The ICU mortality was 41% (n=21) and the hospital mortality was 49% (n=25). At admission a decision to WH was made in 2 patients (WH_IMV). During ICU stay, 25 decisions of LLST in 20 patients were taken: DNR in 1 patient, WH_RRT in 1 patient, WH_ECMO in 2 patients, WH_CPR in 6 patients and WD in 15 patients. Only 1 patient who had LLST survived to the hospital stay. Death occurred after WH treatment in 8 patients (38%) and after WD treatment in 13 (62%). Reasons for the LLST were multi-organ failure or devastating brain injury. 74% of the LLST decisions were partially documented.

Patients	With LLST at admission (n=2)	With LLST during ICU stay (n=20)	Without LLST (n=29)
SOFA at admission	3	8	7
SOFA at day of decision	4	11	NA
CCI	6	4	3
Frailty score	4	3	2
Length of symptoms	4	6	6
LOS	3	10	1

Conclusion: All COVID-19 patients died after a LLST due to multi-organ failure or devastating brain injury. Though these patients had low prevalence of comorbidities and low level of functional disability, none was considered for CPR. LLST decisions were insufficiently documented.

Intensive Care Medicine Experimental 2020, **8(2)**: 001552

Introduction: Spain has developed a successful transplant activity, fundamentally thanks to deceased organ donation, reaching 46.9 million per million inhabitants in 2017. Since 2017, the General Consortium University Hospital of Valencia (GCUHV), a tertiary hospital, has collaborated in the increase and development of such activity and has

included in its protocols for patients that meet the criteria for potential donors the option to donate when the responsible medical team changes its therapeutic objective towards donation-centered comfort measures and end-of-life care.

Objectives: To describe the number and characteristics of patients who deceased in our hospital and were candidates for organ donation in asystole from December 2017 to May 2019.

Methods: Descriptive and retrospective study including patients who deceased in our hospital and were candidates for organ donation in asystole. Variables such as age, intensive care stay in days, cause of death and removed organs were retrieved.

Results: A total of 13 asystolic donors were collected from December 2017 to May 2019 at this tertiary hospital. Of these, 11 were neuro-critical patients and 2 were patients recovered from cardiac arrest. The average age was 60.3 years (40-69) and mean intensive care stay was 7.38 days (3-17). Among the removed organs, it is worth mentioning that kidneys from all 13 patients, livers from 9 of them and a total of 3 pancreas were successfully implanted.

Conclusion: Despite a significant increase in the availability of organs for transplantation in recent years, a gap between supply and demand still persists. The development of new alternative means of organ donation is necessary in order to assure the availability of organs for transplantation. The program was initially very cautious, but its easily improvable. We expect a significant increase in the number of donations for the coming years.

Machine learning to predict ICU admission in septic patients: exploring new strategies to anticipate clinical deterioration

PF. Caruso¹; G. Angelotti¹; M. Greco¹; C. Ciccone¹; N. Stomeo¹; M. Cecconi²

¹Anesthesia and intensive care, Humanitas Research Hospital, Milano, Italy;

²Anesthesia and intensive care, Humanitas Research Hospital, Milan, Italy

Correspondence: PF. Caruso

Intensive Care Medicine Experimental 2020, **8(2)**: 001351

Introduction: Early intervention in sepsis have been shown to be crucial in preventing the transition into septic shock and reducing mortality in this population. Early recognition can be challenging, and many scores have been created to help physicians anticipate clinical deterioration (e.g. qSOFA or NEWS). Main limitations are lack in external validity and inclusion of few parameters only. We propose to predict clinical deterioration by considering all the variables systematically recorded by electronic health records (EHR). With the advent of new techniques in healthcare settings like machine learning, we aim to build tailored-to-patients scores that will improve the ability to anticipate and prevent intensive care admission.

Objectives: Predicting ICU admission in septic patients using machine learning models.

Methods: Our cohort included all the patients with ICD-9 codes for sepsis (995.92) and septic shock (785.52) that were admitted from standard ward to in intensive care units (ICU), among all patients hospitalized in 2018 in Humanitas Research Hospital. Data were anonymized at extraction from repository. Demographics and vital signs available in general wards were extracted from EHR, including heart rate, respiratory rate, peripheral oxygen saturation, temperature and peripheral blood pressure. We divided the features in data windows and the mean of each vital sign was calculated and retained for each block. We began the iterative process of building machine learning models (Logistic Regression and Random Forest Classifier) to

predict the admission in ICU, using a train-test set division and k-fold cross validation. We trained the models with the 72 h hours data before ICU admission for cases and 72 h prior the worst mean arterial pressure for controls (as it was considered the most critical moment in those who were not admitted to ICU), considering age, gender, heart rate, respiratory rate, peripheral oxygen saturation, temperature and the trend of systolic, diastolic and mean arterial pressures.

Results: The cohort comprehends 105 patients of which 15 were admitted to ICU (14%). The median age for those admitted in ICU was statistically significantly lower (69.5[68-79] vs 77 [69-85], p-value < 0.01) and most patients admitted in ICU were males (12 vs 3, p-value = 0.20). The best cross-validated logistic regression model had an AUROC of 0.77, while for random forest the AUROC was 0.74. In logistic regression, male gender, heart rate and respiratory rate were positively correlated, while age, diastolic blood pressure and oxygen saturation were reversely correlated.

Conclusion: In this first preliminary study, we demonstrated that machine learning models might be an innovative solution to predict intensive care admission in septic patients before clinical deterioration using data derived from EHR. Further studies on larger cohorts and wider types of data, like laboratory values, should be performed to assess the real potential of machine learning models.

Ready to submit your research? Choose BMC and benefit from:

- fast, convenient online submission
- thorough peer review by experienced researchers in your field
- rapid publication on acceptance
- support for research data, including large and complex data types
- gold Open Access which fosters wider collaboration and increased citations
- maximum visibility for your research: over 100M website views per year

At BMC, research is always in progress.
