Abstract: Six lactic acid bacterial (LAB) strains were isolated from traditionally fermented Xinjiang cheese and evaluated for functional and probiotic properties and potentials as starter cultures. The isolated six LAB strains comprised *Lactobacillus rhamnosus* (one strain), *Lactobacillus helveticus* (one strain), and *Enterococcus hirae* (four strains). All of the six strains were tolerant to acidic and bile salt conditions. Among which, the *L. rhamnosus* R4 strain showed more desirable antimicrobial, auto-aggregation, and hydrophobic activity. In addition, the strain *L. rhamnosus* R4 exhibited the highest level of free radical scavenging activity (53.78% of 1,1-diphenyl-2-picrylhydrazyl (DPPH) free radicals and 45.79% of hydroxyl radicals). *L. rhamnosus* R4 also demonstrated cholesterol and triglyceride degradation by 50.97% and 28.92%, respectively. To further examine the health-promoting effects of these LAB strains on host lifespan, *Caenorhabditis elegans* was used as an in vivo model. Worms fed LAB as a food source had significant differences in lifespan compared to those fed *Escherichia coli* OP50 (as a negative control). Feeding of *L. rhamnosus* R4 extended the mean lifespan of *C. elegans* by up to 36.1% compared to that of the control. The results suggest that the strains isolated from Xinjiang fermented dairy products have high potential as starter cultures in the cheese industry.

Key words: Xinjiang cheese, Lactic acid bacterial (LAB) strains, Probiotic properties, *Caenorhabditis elegans*, Lifespan

1 Introduction

Lactic acid bacterial (LAB) strains belong to beneficial bacteria. They are normal inhabitants of the healthy gut microbiota and present in numerous fer-

mented dairy products such as cheese and fermented milk. Some like *Lactobacillus*, *Streptococcus*, *Pedococcus*, and *Enterococcus* are cultivable and predominant microbes in fermented dairy products, and exert a positive role in human health following oral administration. They improve the balance of the microbial community in the intestine, confer protection against potential pathogenic bacteria, and prevent and/or cure intestinal diseases (Schiffirin *et al.*, 1997; Gionchetti *et al.*, 2000). These effects are mediated by production of antimicrobial metabolites such as organic acids (for example lactate, acetate, and butyrate), hydrogen peroxide, and bacteriocins, and competition with harmful bacteria for nutrients or adhesion receptors (Hudault *et al.*, 1997; Fons *et al.*, 2000).

The therapeutic effects of the beneficial microorganisms include, but are not limited to, enhanced immune function, maintenance of anti-tumor activity, reduction of the population of harmful microorganisms, improvement of the balance of microflora in the colon, prevention against some intestinal infection, increased tolerance to lactose-containing foods, and possibly prevention of cancer (Martini *et al.*, 1987; Wang *et al.*, 2010; Amadou *et al.*, 2013).

The local fermented dairy products in Xinjiang Uygur Autonomous Region of China are made by nomadic people with a natural fermentation process without any starter culture. The production of Xinjiang cheese includes fermenting, drying, and forming into blocks. One of the oldest and most popular cheeses in Xinjiang is the Kurut. As a semi-hard regional cheese, the production environment of Kurut is very similar to that of a Polish cheese, Oscypek (Alegria *et al.*, 2012), which is frequently produced not with the use of starter cultures, but only by the autochthonous microbiota present in milk and the environment. Kurut is manufactured from unpasteurized cow's milk, and fermented spontaneously by microorganisms from the air, raw milk, and the equipment used during the production. The main process of Kurut production is to increase the acidity of milk by cold maturation at room temperature. The soured milk is then mixed with sweet milk and rennet is added. The formed coagulum is beaten and settled in order to remove the whey after coagulation. The cheese knots are then pressed into forms and smoothed. Finally the cheese is dried with facultative cold-smoking (Sip *et al.*, 2012).

Xinjiang cheese is often a dry cheese with a rough skin. The texture can be hard, semi-hard, or soft with a sour or sweet taste. The sweet type is made of milk fat with much aroma while the sour type is less fatty and fragrant but still milky. Sour cheeses are commonly used to make local flour food, such as noodles and bread. The Xinjiang cheese has a high-acid, sharp milky flavor and is thicker and darker than ordinary cheese.

Xinjiang cheese is distinctive, high in nutrients, and always is considered a good staple food. However, the cheese is only consumed in limited areas in China, such as Xinjiang Uygur, Inner Mongolia, and Tibet Autonomous Regions. Furthermore, microbial resources, especially the LAB, in various dairy products

have not been well characterized, which potentially negatively impacts cheese industries and application in human health promotion.

Caenorhabditis elegans is a small, soil nematode, which has been extensively used as a model organism to evaluate longevity extension of LAB strains (Kurz and Tan, 2004). Ikeda *et al.* (2007) have reported that LAB may contribute to host defenses and prolong the lifespan of *C. elegans*. In this study, we wished to evaluate potential traits of probiotic strains selected from Xinjiang cheese products using in vitro tests and the in vivo *C. elegans* model.

2 Materials and methods

2.1 Sample collection

Four traditionally fermented cheese products were collected from Xinjiang Uygur Autonomous Region of China to isolate the lactic acid bacteria in MC, M17, and MRS (de Man, Rogosa, and Sharpe, Sinopharm Chemical Reagent Company (SCRC), Shanghai, China) broth or MRS agar plates. All four cheese samples (30 d ripened) were made of raw cow's milk and made by the nomadic people in Xinjiang with natural fermentation processes without any starter culture. Samples were transported at 4 °C to the laboratory for analysis.

2.2 Isolation and identification of lactic acid bacteria

We used the MC, M17, and MRS agar plates for microflora composition analysis. Appropriate ten-fold dilutions of the samples were prepared with sterile water. The MC, M17, and MRS agar plates supplemented with 0.01 g/ml CaCO₃ were mixed with 100 µl of sample. The plates were incubated at 37 °C in an anaerobic incubator for 2–3 d. Single colonies were picked up based on the calcium-dissolving ring (Tamang *et al.*, 2005). Strains were identified morphologically and biochemically, e.g. the morphology, Gram staining, catalase activity, growth rate at 45 °C, and carbohydrate fermentation.

The genomic DNA of each isolate was extracted from pure overnight cultures grown in MRS broth at 37 °C by the phenol-chloroform extraction method (Schmidt *et al.*, 1991). Each extracted DNA was dissolved in 50 µl distilled water and stored at –20 °C for further analysis.

All cultivable isolates were identified by 16S rDNA sequencing analysis. The genomic DNA was used as a template for polymerase chain reaction (PCR) amplification of a segment of its 16S rDNA gene for each isolate. Two primers were designed as described previously (Mora *et al.*, 2003; Yu *et al.*, 2011), namely 27f (5'-AGAGTTTGGATCCTGGCTCAG-3') and 1492r (5'-CTACGGCTACCTTGTTACGA-3'). The amplification products obtained from the PCR reaction were analyzed by 1.0% (0.01 g/ml) agarose (Hydragene, Xiamen, China) gel electrophoresis before they were sequenced. DNA sequencing was performed by the Shanghai Sangon Bio-sciences Corporation (China). The sequencing data were aligned using DNAMAN software (ver. 7.0 DNAMAN, Lynnon Biosoft Company, Foster City, CA, USA), and sequence homology was examined by comparing the obtained sequences by the BLAST program in the National Center for Biotechnology Information (NCBI) database (<http://blast.ncbi.nlm.nih.gov/Blast.cgi>). The accession numbers of these six strains were as follows: *Enterococcus hirae* H4, KU198310; *E. hirae* K4-8, KU198311; *E. hirae* K4-9, KU198312; *E. hirae* R5, KU198313; *Lactobacillus rhamnosus* R4, KU198314; and, *Lactobacillus helveticus* S4, KU198315.

2.3 Acid and bile tolerance tests

The acid resistance was performed by the viable plate count method (Maragkoudakis *et al.*, 2006). Bacterial cells grown in MRS broth at 37 °C overnight were harvested (10000 r/min, 10 min, 4 °C), washed twice with phosphate buffer saline (PBS) of pH 7.2 and resuspended in PBS of pH 3.0. The viable colony counts were enumerated on MRS agar after incubation at 37 °C for 0 and 3 h simulating the acidic environment in the human stomach. The experiment was repeated three times. The survival rate (SR) was calculated according to the equation below:

$$SR=(N_1/N_0)\times 100\%,$$

where N_1 (log CFU/ml) is the total viable count of selected strains after treatment and N_0 (log CFU/ml) represents the total viable count of selected strains before treatment. CFU is colony-forming unit.

The bile tolerance test was carried out in 96-well plates (Walker and Gilliland, 1993). Briefly, cells of the selected strains were grown in MRS broth at 37 °C

overnight, and then subcultured in MRS broth containing 0.1%, 0.2%, and 0.3% (1%=0.01 g/ml) bile salts (SCRC, Shanghai, China). The growth rate of each strain was measured by its absorbance at 600 nm after 24 h.

The ability of isolates to tolerate the bile salt condition was also determined by the viable plate count method. Bacterial cultures were grown at 37 °C overnight and the bacterial cells were harvested (10000 r/min, 10 min, 4 °C), washed twice with PBS of pH 7.2 before being resuspended in PBS solution containing 0.3% bile salts. The viable counts were enumerated on MRS agar after incubation at 37 °C for 0 and 4 h. The survival rate is calculated according to the above-mentioned equation.

2.4 Antimicrobial activity

The Oxford cup assay was used as reported (Wang *et al.*, 2009). The indicator strains of antimicrobial activity included *Escherichia coli* O157 882364, *Salmonella typhimurium* S50333, *Shigella flexneri* CMCC (B)51592, *Staphylococcus aureus* ATCC 1448, and *Listeria monocytogenes* C53-3, which were obtained from our laboratory and cultured in Luria-Bertani (LB) medium, nutrient broth (NB) medium, tryptic soytone broth (TSB), and broth brain-heart infusion agar (BHI), respectively. All LAB strains were subcultured twice prior to being used in the experiments. Strains were incubated with the MRS medium for 24 h at 37 °C. The bacterial cultures were centrifuged at 10000 r/min for 10 min. Supernatants were filtered through a 0.22-μm filter. The inoculum of indicator (pathogen) strains was then spread on the surface of solid nutrient agar (NA) plates. A total of 200 μl bacterial cultures of each LAB strain were added to the Oxford cups which were placed on the agar plates. The plates were incubated for 24 h at 37 °C and the zone of inhibition was determined. The inhibitory effect of MRS was tested as a negative control on each plate. The inhibition zones were measured in millimeter (mm).

2.5 Auto-aggregation activity and hydrophobicity

Auto-aggregation activity was measured as described by Collado *et al.* (2008). Overnight cultures were centrifuged and washed twice with PBS and resuspended in the same buffer. Equal volumes of each of the microbial suspensions were combined in

sterile test tubes and mixed for 10 s on a vortex mixer, and then incubated anaerobically at 37 °C for 24 h without agitation. The auto-aggregation activity (AA) was calculated using the equation:

$$AA = (1 - A_{\text{time}}/A_{\text{initial}}) \times 100\%,$$

where A_{initial} and A_{time} are the culture absorbance before and after incubation, respectively.

Hydrophobicity assay was carried out according to the study of Collado *et al.* (2008). Overnight bacterial cultures were harvested by centrifugation at 5000 r/min for 15 min at 4 °C and washed twice in PBS. The absorbance of cell suspensions was measured at 600 nm. A total of 1 ml cell suspension was mixed with an equal proportion of hydrocarbons (xylene), and the aqueous phase was removed after 30 min at room temperature for the determination of absorbance (at 600 nm). The hydrophobicity (H) was calculated according to the following formula:

$$H = (A_0 - A_1)/A_0 \times 100\%,$$

where A_0 and A_1 represent the absorbance before and after mixing with xylene, respectively.

2.6 Antioxidant activity

2.6.1 Preparation of the intact cells and the cell-free extracts

The strain was grown in MRS broth at 37 °C for 18–24 h. Cells were suspended in PBS. The bacterial cell pellets were adjusted to 10^8 CFU/ml, which was determined as the preparation of intact cells. Cell-free extracts were prepared according to the method described by Lin and Yen (1999). The cells were adjusted to 10^8 CFU/ml followed by ultrasonic disruption three times, and had 2-min intervals in an ice bath using an ultrasonic cell crusher (Ningbo Scientz biotechnology Company, China). After centrifugation (10000 r/min, 15 min, 4 °C), the supernatant was obtained as the cell-free extract of the strains.

2.6.2 DPPH radical scavenging activity

The 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical scavenging activity was measured by the method of Kao and Chen (2006) with modifications. Reaction mixtures containing 1.0 ml of 10^8 CFU/ml bacterial cells and 1.0 ml of 50 µmol/L DPPH (Aladdin In-

dustrial Corporation, Aladdin, Reagent Company, China) in ethanol (SCRC, Shanghai, China) were incubated at 37 °C in the dark for 30 min. The absorbance of the resulting solution at 517 nm was measured in triplicate. The DPPH scavenging activity (SA_{DPPH}) was defined as:

$$SA_{\text{DPPH}} = [1 - (A_{\text{sample}} - A_{\text{blank}})/A_{\text{control}}] \times 100\%,$$

where A_{sample} is the absorbance of bacterial cells, A_{blank} is the absorbance of only cells and ethanol, and A_{control} is the absorbance of the deionized water and DPPH solutions.

2.6.3 Hydroxyl radical scavenging activity

The hydroxyl radical scavenging activity was determined by a sulfosalicylic acid method (He *et al.*, 2004), also known as the Fenton type reaction method. The reaction mixture including 1.0 ml of salicylic acid, FeSO_4 , and H_2O_2 (6, 2, and 6 mmol/L, respectively, all from SCRC, Shanghai, China), and 1.0 ml of bacterial cell or cell-free extract with the concentration of 10^8 CFU/ml was incubated at room temperature for 20 min, and the absorbance was determined at 510 nm. Hydroxyl radical scavenging activity (SA_{hydroxyl}) is expressed as:

$$SA_{\text{hydroxyl}} = [1 - (A_s - A)/A_c] \times 100\%,$$

where A_s is the absorbance in the presence of the sample, A is the absorbance without H_2O_2 , and A_c is the absorbance of the control in the absence of the strain sample.

2.7 Determination of cholesterol and triglycerides

Bacterial cholesterol lowering capability was determined by the ferric ammonium sulfate method with slight modification (Feng *et al.*, 1973). MRS broth containing 0.1% (1 g/L) cholesterol (Solarbio, Beijing, China) was prepared as MRS-CHOL broth. Overnight cultures were inoculated (2%, v/v) into the MRS-CHOL broth and incubated anaerobically at 37 °C for 48 h. An uninoculated sample was used as a control. After incubation, 0.2 ml cultures were mixed with 4.8 ml ethanol. Then the cells were removed after centrifugation (3000 r/min, 10 min, 4 °C). A total of 2 ml of ferric ammonium sulfate color reagent (Aladdin, Shanghai, China) was slowly added to the

2 ml supernatant. The absorbance was determined at 560 nm. The cholesterol removal rate (CRR) from growth media was calculated according to the following formula:

$$\text{CRR} = [(A_{\text{uninoculated}} - A_{\text{inoculated}}) / A_{\text{uninoculated}}] \times 100\%,$$

where $A_{\text{uninoculated}}$ and $A_{\text{inoculated}}$ are the absorbance of uninoculated and inoculated samples, respectively.

Triglyceride micelles were prepared by mixing Tween-80 and triglycerides (both from SCRC, Shanghai, China) at a ratio of 1:5 (v/v), and sterilized for 15 min at 121 °C before determination. The micelles were added to the MRS broth containing bile salt. Isolates were inoculated (2%, v/v) into 5 ml of the above MRS broth and incubated at 37 °C for 36 h. A culture without triglyceride was used as a control. After centrifugation for 10 min at 3000 r/min, the supernatant of the cultures was used for testing the triglyceride reducing activity using the acetylacetone method (Fossati and Prencipe, 1982; Saravanan and Ponmurugan, 2012).

Three isolates were selected for further investigation to see their anti-aging effects on *C. elegans*.

2.8 *C. elegans* killing assay

The effect of selected LAB strains on longevity in *C. elegans* was examined using the killing assay as described by Ikeda *et al.* (2007), with slight modifications. Briefly, the synchronized worms were grown at 20 °C until they reached L4 stage. The worms were then transferred onto treatment plates. The treatment plates were prepared using nematode growth medium (NGM) covered with lawns of standard food resource *E. coli* OP50 (control group) and LAB strains (experimental group) at the concentration of 10^8 CFU/ml. The worms were transferred to fresh treatment plates every 2–4 d and grown at 20 °C. The number of live worms was counted every other day. Worms that failed to respond to a light touch with a platinum wire would be scored as dead and excluded from the lifespan assay. In the present study, all treatment plates were prepared on Day 0 of adulthood of the worms. This test was carried out at least three times.

2.9 Statistical analysis

Statistical analysis of the obtained data was carried out using SPSS (ver. 16.0 SPSS, Chicago, IL,

USA). The comparisons of differences between the means of the treatments were tested by one-way analysis of variance (ANOVA) at a significance level of $P < 0.05$.

3 Results

3.1 Isolation and identification of strains

More than 40 strains were preliminarily isolated from four traditionally fermented Xinjiang cheese products, and six LAB strains from them were selected for further analysis. Based on the biochemical tests, those six isolates showed Gram-positive, catalase-negative characteristics, and colony morphologies of the isolates were rod and coccus (Table S1). The species of the isolates were determined on NCBI by comparing with 16S rDNA sequences of the standard strains. The representative strains and their related type strains were selected to construct a phylogenetic tree using the DNAMAN software to show their identities and diversities (data not shown). R4 and S4 were classified as *L. rhamnosus* and *L. helveticus*, respectively, while H4, K4-8, K4-9, and R5 were classified as *E. hirae*. The strains named with H and K refer to the samples collected from Narat Pastureland, S refers to Ili City, and R refers to Urumqi City.

3.2 Acid tolerance test

The viable counts and survival rates of the selected six LAB strains are shown in Table 1. All tested strains showed resistance to low pH. The viable counts of all strains were found to be $>10^6$ CFU/ml after incubation at pH 3.0 for 3 h and in the presence of bile salt at 0.3%. Overall, all strains showed higher resistance to low pH at the range from 74.6% to 87.1%. The differential survival rates of LAB strains suggested that the survival activity was strain-specific.

3.3 Bile tolerance test

The growth capabilities of six previously selected strains under 0.1%, 0.2%, and 0.3% bile salt conditions were determined by the absorbance at 600 nm after 24 h incubation. As shown in Fig. 1, four strains *E. hirae* K4-8, K4-9, *L. helveticus* S4, and *L. rhamnosus* R4 showed good growth rates at all bile salt concentrations. The results of determination of viable

counts and survival rates also showed that all tested strains were found to be resistant to bile salt of high concentration (Table 1). The strains *L. helveticus* S4 and *E. hirae* K4-8, K4-9, R5 had higher bile salt resistance.

3.4 Antimicrobial activity

All six strains presented antimicrobial activity against *Escherichia coli* (with an inhibition zone 6.3–10.5 mm in diameter), *Staphylococcus aureus* (4.0–8.2 mm), *Salmonella typhimurium* (2.5–8.5 mm),

Listeria monocytogenes (4.0–8.5 mm), and *Enterococcus faecalis* (5.0–7.1 mm). However, *L. rhamnosus* R4 exhibited the most effective inhibition (Table 2), while *E. hirae* K4-8 and K4-9 strains did not inhibit the growth of *Listeria monocytogenes* and *Enterococcus faecalis*, respectively. The control (MRS media alone) showed no inhibitory effect against the pathogens tested (data not shown).

3.5 Auto-aggregation and hydrophobicity analysis

As shown in Table 3, all tested strains showed increased auto-aggregation activity ranging from 23.33% to 45.83%. *L. rhamnosus* R4 was the best auto-aggregating strain among those tested, resulting in 45.83% auto-aggregation over a period of 24 h incubation at 37 °C. Additionally, the cell surface hydrophobicity of all strains was tested, and the results (Table 3) showed that *L. rhamnosus* R4 exhibited the highest cell surface hydrophobicity in xylene (83.22%).

3.6 DPPH radical scavenging activity

The DPPH scavenging activities of the intact cells and cell-free extracts of selected six strains are shown in Fig. 2. *L. rhamnosus* R4, *L. helveticus* S4,

Fig. 1 Tolerance of six strains to different bile salt conditions
Each value is expressed as mean±standard deviation (SD) of three replicates. There were significant differences ($P<0.05$) among different strains under three bile salt concentrations

Fig. 2 DPPH free radical and hydroxyl radical scavenging abilities of six strains

IC: intact cell; CFE: cell-free extract. Each value is expressed as mean±SD of three replicates. There were significant differences ($P<0.05$) among the DPPH and hydroxyl radical scavenging rates of IC and CFE of different strains

and *E. hirae* H4, R5 had higher scavenging activity than others by measuring the intact cells. Among them, *L. rhamnosus* R4 showed the highest scavenging activity (53.78%), whereas the scavenging activity of the cell-free extract was significantly lower than that of the intact cells. However, *E. hirae* K4-8 showed a different behavior in that the scavenging activity of cell-free extract (32.11%) was higher than that of intact cells (18.95%).

3.7 Scavenging of hydroxyl radicals

Among the six tested strains, *L. rhamnosus* R4 showed the highest hydroxyl radical scavenging activity (45.79%), verifying the result of DPPH scavenging activity (Fig. 2). All measured strains exhibited higher scavenging activity of the intact cells than that of the cell-free extract. As can be seen from the results, both DPPH radicals and hydroxyl radicals can be scavenged by these tested strains, which showed the significant free radical degradation activity of these strains.

3.8 Degradation of cholesterol and triglycerides

The degradation rates of cholesterol and triglycerides of the isolated strains are shown in Fig. 3. The results revealed that all examined strains were able to degrade cholesterol and triglycerides, though the cholesterol and triglyceride degradation rates of supernatants of strains were significantly higher than that of intact cells of strains. Among the tested strains, the degradation rates of the supernatants of *L. rhamnosus* R4 (50.97%, 28.92%) and *L. helveticus* S4 (52.85%, 24.56%) showed the highest cholesterol and triglyceride reducing activities compared to those of intact cells during growth. The supernatant of *E. hirae* H4, R5 also exhibited better degradation activity than the intact cells.

Fig. 3 Cholesterol and triglyceride degradation activities of six selected strains

IC: intact cell. Each value is expressed as mean±SD of three replicates. There were significant differences ($P<0.05$) among cholesterol and triglyceride degradation rates of IC and supernatants of different strains

3.9 *C. elegans* killing assay

Wild-type adult *C. elegans* have an average lifespan of approximately 20 d at 20 °C. In our laboratory conditions, wild-type control worms lived for an average of (18.47±0.30) d (maximum of 25 d).

Here, the effect of LAB strains on lifespan of *C. elegans* was determined to further evaluate the health promoting effects of the isolates. Three out of the six strains were able to enhance the health-span of *C. elegans*. The results (Fig. 4) showed that feeding worms with *L. rhamnosus* R4 increased the average lifespan compared to the *E. coli* OP50 feeding group. The lifespan of worms supplied with *L. rhamnosus* R4 was (31.05±0.54) d, which was 36.1% greater than that of the control worms ((22.81±0.62) d; $P<0.05$).

Fig. 4 Survival curves of *C. elegans* fed with *L. rhamnosus* R4, *L. helveticus* S4, *E. hirae* H4, and *E. coli* OP50, respectively

Day 0 represents the first day that the L4 stage worms were transferred to NGM plates

4 Discussion

In this study, six LAB strains isolated from cheese samples were investigated for their probiotic properties. Tolerance to acidic condition is the most commonly used method to detect the viability and activity of probiotic bacteria in the small intestine and stomach. According to a previous study (Usman and Hosono, 1999), the survival rate at pH 3.0 is considered as optimal acid tolerance for selected probiotic strains. All strains from this study were able to tolerate pH 3.0 with a survival percentage of more than 70%, and therefore they can be considered as acid-tolerant LAB strains. This tolerance capacity of lactic acid bacteria warranted the production of various antimicrobial substances which might create unfavorable conditions for the growth of pathogens as well as toxigenic and spoilage organisms in humans and/or animals (van der Meulen *et al.*, 2007).

Tolerance to bile salts is usually considered a basic property for LAB strains to survive in the small intestine. In the human gastrointestinal tract, the mean bile concentration is about 0.3% and is considered crucial and high enough to screen resistant strains (Gilliland *et al.*, 1985). In this study, there was extreme variability of resistance to bile salts in *E. hirae* K4-8, R5 and *L. rhamnosus* R4 isolates. *Lactobacillus* strains, which grow and metabolize in normal physical bile concentration, could survive in gastrointestinal transit (Sanders *et al.*, 1996). All six tested strains indicated a proportion of growth above 65% in the

presence of bile salt, which demonstrated good bile salt tolerance. These results were consistent with a previous study (Turchi *et al.*, 2013).

To further investigate the safety and functional characteristics of these strains as probiotics, several tests were also conducted to assess their antimicrobial activity, auto-aggregation capability, and cell surface hydrophobicity.

As a potential probiotic, antimicrobial activity is one important property to avoid gastrointestinal infection (Kanmani *et al.*, 2013). In the present study, the antimicrobial activities of six selected strains were assayed. Isolate *L. rhamnosus* R4 inhibited the growth of all tested pathogens, and these pathogens are commonly found in fermented foods, making these products potentially hazardous (Ferreira *et al.*, 2007). The ability to inhibit the pathogens of tested strains could be explained by the production of antimicrobial compounds. According to the study of Amenu (2013), the antimicrobial effect of LAB is due to the production of metabolites, such as lactic acid, acetic acid, diacetyl, fatty acids, aldehydes, bacteriocins, and other compounds, among which, lactic acid, acetic acid, and bacteriocins are the most powerful antimicrobial agents and are the production of the probiotics. The inhibition of pathogens' growth suggests that the presence of LAB microorganisms in the Xinjiang cheese might influence the reduced survival of bacterial pathogens in spite of the simple and crude home-based fermenting preparation process, and these tested isolates may also have potential application in food preservation.

The aggregation capability of LAB may be of interest for both food preservation and therapeutic impact on gut microbiota. In the auto-aggregation test, all tested strains indicated various auto-aggregation abilities. *L. rhamnosus* R4 strain showed the highest percentage of auto-aggregation, namely 45.83%. This result suggested that the R4 strain possessed a proportionally high potential capability to adhere to epithelial cells and mucosal surfaces. Previous studies (Pelletier *et al.*, 1997; Dunne *et al.*, 2001) stated that the aggregation abilities of LAB might enable them to form a barrier that prevents pathogenic colonization.

Cell surface hydrophobicity analysis is also a key step for selection of functional probiotic LAB strains. For all tested strains, a significant difference in cell surface hydrophobicity was observed, ranging

from 48.57% to 83.22%. Cell surface hydrophobic activity is one of the physical-chemical characteristics that promote the first contact among the host tissues and microorganisms. Hydrophobicity was found to be correlated to auto-aggregation properties as most of the strains with higher adhesion to hydrocarbons showed high auto-aggregation activity. The present study was consistent with the results of Collado *et al.* (2008), which showed that bacterial strains with higher adhesion to hydrocarbon (xylene) showed high auto-aggregation activity. The hydrophobic properties of the cell surface of microorganisms have been related to the attachment of bacteria to host cell. This may confer a competitive advantage and be important for bacterial maintenance in the human gastrointestinal tract (Schillinger *et al.*, 2005).

After screening a number of potential bacteria based on their above-mentioned important selection criteria, we tested the antioxidant activity of the six isolates using free radical scavenging assays. The DPPH radicals were generally used to determine the scavenging activities of natural compounds. All tested six strains exhibited potent scavenging activities of cellular toxic substances DPPH and hydroxyl radicals to various degrees, indicating detoxificative effects by reactive oxygen species (ROS) removal. The intact cell of *L. rhamnosus* R4 was found to be the most effective in removal of the DPPH radicals. The scavenging activities of the intact cells of *L. helveticus* S4, *E. hirae* H4, R5 exhibited better behavior for scavenging the DPPH radicals than those of cell-free extracts, indicating that cell integrity was a factor that affected scavenging activity.

The intact cells exhibited higher hydroxyl radical scavenging activity than the cell-free extracts. It is probably due to their extracellular antioxidant components, such as polysaccharide, peptidoglycan, and teichoic acid. These basic cell-wall components play an essential role when the host suffers oxidative damage by the free radicals. Their main function is to re significant differences ($P < 0.05$) among cholesterol and triglyceride degradation rates of IC and

Interestingly, *E. hirae* K4-8 showed a different behavior in DPPH radical scavenging activity of the cell-free extract (32.11%) compared to that of intact cells (18.95%). We inferred that some intracellular enzymes such as NADH-oxidase, NADH-peroxidase, and superoxide dismutase (SOD) were likely to be

obtained after breaking up the bacterial cells into cell-free extracts that indicated the antioxidant activity of lactic acid bacteria (Kullisaar *et al.*, 2002).

The antioxidant activities of lactic acid bacteria would be helpful in the dairy food industry. They could beneficially influence the customer by providing LAB with the potential of producing antioxidants during the period of growth in the intestinal tract or providing another dietary source of antioxidants.

In this study, in vitro assay results showed that cultures of *L. rhamnosus* R4, *L. helveticus* S4, and *E. hirae* H4, R5 lowered both cholesterol and triglyceride levels. It is interesting to note that the supernatant of the bacterial cells reduced more cholesterol compared to the intact cells of the bacteria during its growth, especially the strains of *L. rhamnosus* R4 and *L. helveticus* S4. This result implies that the cholesterol reduction activities of *L. rhamnosus* R4 and *L. helveticus* S4 may be due to the activity of certain components in the supernatant of the bacterial culture, in addition to those existing in the live cells.

There have been a few reports regarding cholesterol reduction (Ooi and Liong, 2010) by the extracellular components generated by LAB, which indicated that certain components or specific extracts in the supernatants of LAB were responsible for the reduction of cholesterol (Nguyen *et al.*, 2007; Kim *et al.*, 2008).

Our data in Fig. 3 may explain that supernatant-related cholesterol degradation was not induced by acidic co-precipitation and support a previous study reported by Liong and Shah (2005) who proposed that the co-precipitation of cholesterol was less than 5% of the total cholesterol utilized. Therefore, in this study, one possible mode for the cholesterol degradation activity of the supernatant produced from the tested strains could be mostly mediated by direct activity, including action for cholesterol degradation or inactivation, rather than by an indirect mechanism such as the deconjugation of bile salts and co-precipitation of cholesterol with the bile salts (Kim *et al.*, 2008).

Triglycerides were also decreased by LAB strains in this study. The results revealed that triglycerides inhibited the growth of the strains. This may be due to the fact that triglycerides can be combined with peripheral bacteria for enhancing the peripheral hydrophobicity of bacteria to restrict the entry of some essential nutritive elements into the cell.

From this study, we found that not only the intact cell but also the supernatant of the strains had a triglycerides' degrading activity in a strain-specific manner, which is consistent with the research of Kim *et al.* (2008).

Our results also demonstrated the anti-aging role of LAB in the *C. elegans* model system. Feeding of *L. rhamnosus* R4 has effectively increased the mean lifespan of *C. elegans*, and the life extension rate reached a maximum of 36.1%. This is in accordance with the results described by Ikeda *et al.* (2007), in which feeding nematodes with bifidobacteria or lactobacilli caused increased average lifespans compared to those fed with OP50 and the life extension rates ranged from 17% to 33%. These results suggested that different strains show diverse impacts on lifespan extension. Further molecular research is required to elucidate the precise mechanism of the longevity in *C. elegans*. Nevertheless, our results suggested that these newly isolated LAB strains may have health promoting impacts to the host. They also offer additional support for the use of the nematode as an appropriate *in vivo* model system for screening functional probiotics.

The six strains in this study were also selected through the evaluation of acidification capacity, diacetyl-producing activity and autolysis according to the method described by Scatassa *et al.* (2015). The strains of *L. rhamnosus* R4 and *L. helveticus* S4 were those which displayed the highest acidifying activity, showing an acidity of around 0.40 g/100 ml lactic acid after 6 h and 0.58–0.72 g/100 ml after 12 h (Table S2). After 24 h, the acidity reached values around 0.73–0.86 g/100 ml. *L. rhamnosus* R4 showed an acidifying capacity similar to that of *L. helveticus* S4 strain throughout the incubation time. These LAB strains isolated from Xinjiang cheese showed an acidifying activity after 24 h of incubation similar to that detected for LAB strains isolated from Tunisian dairy products (Fguiri *et al.*, 2015).

L. rhamnosus is a heterolactic acid bacterium, which can be used to produce flavor compounds like diacetyl and acetoin (Jyoti *et al.*, 2003). The results on the diacetyl-producing activities of these six strains showed that during the cold storage step, the desired fermentation temperature and storage time for reaching a maximum of the diacetyl concentration varied in the final product of cheese. The maximum diacetyl concentration is between 0.68 and 1.76 µg/ml

(Table S3), and the diacetyl-producing activities of *Lactobacillus* strains were stronger than those of *Enterococcus* strains. The active strong-to-weak sequence of producing diacetyl of these six strains is *L. rhamnosus* R4>*L. helveticus* S4>*E. hirae* H4>*E. hirae* R5>*E. hirae* K4-8>*E. hirae* K4-9, which indicated that these strains possess better aroma-producing capability.

The autolysis of the *Lactobacillus* strain has been studied in Cheddar cheese (Hannon *et al.*, 2003), showing increased proteolysis and improved flavor. In this study, with the extension of incubation time, the autolysis of these six strains has increased. After the incubation of 4 h, the autolysis of *L. rhamnosus* R4 and *L. helveticus* S4 reached 12.70% and 11.80%, respectively (Table S4), which were higher than that of the other four strains. The *L. rhamnosus* R4 strain showed high autolysis during all three time periods. There was a great difference of autolysis among these six strains even after 48 h of inoculation. The *L. rhamnosus* R4 strain had a higher rate of autolysis. This is in agreement with the result reported by Kennya *et al.* (2006) who demonstrated that the presence of *Lactobacillus* strains resulted in a better flavor in cheese.

Salmonella sp., *Listeria* sp., and *Shigella* sp. were not detected in the cheese samples, which indicated that the local cheese samples from Xinjiang are generally safe to eat. Moreover, the nutritional value of cheese varies according to the fat content of the liquid used (milk, cream). Xinjiang cheeses always use cows' milk as the liquid. We have determined the nutrient constituents of Xinjiang cheese (data not shown) and compared that with raw milk according to the "National Food Safety Standard of Raw Milk (GB 19301-2010)" (Ministry of Health of the People's Republic of China, 2010; Jia *et al.*, 2014).

In this study, Xinjiang cheeses contain 23.00% of fat and 25.02% of protein, which were 7.4 times the fat and 8.9 times the protein of raw milk, respectively. In addition, Xinjiang cheeses contain 471.2 mg of calcium per 100 g, and also contain 438.5 mg of phosphorus per 100 g, which were more than 4 times of both the calcium and phosphorus in raw milk. The total sugar content (2.17%) of Xinjiang cheeses is less than 50% compared to that of raw milk. Therefore, Xinjiang cheeses are nutritious foods with very low sugar content, high acidity, and various probiotic microorganisms.

5 Conclusions

In summary, of the six different tested strains, *L. rhamnosus* R4 and *L. helveticus* S4 were the more desirable health-promoting bacteria with better acid and bile resistance, antimicrobial activity and aggregation, hydrophobic capability, prominent antioxidant activity, and cholesterol and triglyceride reduction activity. Moreover, these strains were also able to extend the lifespan of *C. elegans*, and the possible mechanism might be that LAB strains could directly scavenge free radicals and protect the *C. elegans* from exogenous stress. This study provides some important knowledge for functional properties of probiotics in Xinjiang cheeses. Therefore, this conventionally fermented dairy product could be considered a valuable resource for probiotic strain screening and starter culture application.

中文概要

题 目: 新疆传统发酵奶酪中乳酸菌的益生特性研究

目 的: 分离鉴定新疆牧民家庭自制的 4 份奶酪样品中的 6 株乳酸菌, 研究其益生特性。

创新点: 通过对新疆传统发酵乳制品中乳酸菌的分离及其抗氧化和降脂特性的测定, 筛选到益生特性良好同时也能延长模式生物秀丽线虫寿命的菌株。

方 法: 对分离自传统发酵乳制品中的乳酸菌进行生理生化分析和 16S rDNA 分子生物学鉴定, 筛选出 6 株乳酸菌, 并测定其耐酸、耐胆盐、抑菌、亲水性和共聚集能力; 测定其抗氧化、降解胆固醇和甘油三酯的能力; 测定乳酸菌对秀丽线虫寿命的影响。

结 论: 实验表明, 该 6 株菌具有较好的耐酸性, 在胆盐环境中也有较好的存活率。同时, 这 6 株菌均有清除自由基和降解脂肪的能力。此外, 其中 3 株具有延长秀丽线虫寿命的能力。综上所述, 这 6 株菌具有较好的益生特性, 可作为优良的潜在益生菌株。

关键词: 新疆奶酪; 乳酸菌; 益生特性; 秀丽线虫; 寿命
