Phonemic codes are accorded a privileged role in most current models of immediate serial recall, although their effects are apparent in short-term proactive interference (PI) effects as well. The present research looks at how assumptions concerning distributed representation and distributed storage involving both semantic and phonemic codes might be operationalized to produce PI in a short-term cued recall task. The four experiments reported here attempted to generate the phonemic characteristics of a nonrhyming, interfering foil from unrelated filler items in the same list. PI was observed when a rhyme of the foil was studied or when the three phonemes of the foil were distributed across three studied filler items. The results suggest that items in short-term memory are stored in terms of feature bundles and that all items are simultaneously available at retrieval.

Most current models of immediate memory are in agreement on two things: first, that speech-based codes play a dominant role in short-term tasks, and second, that these phonemic codes quickly become degraded if rehearsal is prevented. The latter feature ensures that at recall, a target must be produced from an impoverished trace. Consequently, quite a number of current models specify a redintegration or deblurring process in which an item is derived from a fuzzy approximation of that item (Brown & Hulme, 1995; Henson, Norris, Page, & Baddeley, 1996; Lewandowsky & Murdock, 1989; Nairne, 1988, 1990; Neath & Nairne, 1995; Schweickert, 1993). The specifics of the reconstruction process vary from model to model as a function of representational, storage, and retrieval assumptions.

The most obvious instance of the interaction of coding and reconstructive processes is in the phonemic similarity effect—that is, when items that have similar sound characteristics are mistaken for another, similar item in the list (Baddeley, 1966; Conrad, 1965). Those models that employ localist representations and localist storage—for example, Henson et al. (1996)—explain phonemic confusions by arguing that the short-term episodic trace activates the wrong semantic output node. When distributed representations but localist storage are used, a similar explanation is provided. Nairne (1990), for instance, matched a degraded short-term trace with items in a search set con-

sisting of undegraded, long-term memory traces of the list items. Phonemic confusions emerged when the degraded trace was more similar to the long-term representation of another item in the list than it was to the long-term representation of the target. When both distributed representations and distributed storage are utilized (e.g., Lewandowsky & Murdock, 1989), as is the case with a number of PDP, connectionist, or neural net models, items lose their identity at storage. Retrieval processes produce a noisy trace that needs to be cleaned up. This cleanup process is often accomplished by an autoassociative neural net in which the net attempts to “build” an item from the trace (Chappell & Humphreys, 1994; Lewandowsky & Li, 1994; Murdock, 1995). Autoassociators of the Chappell and Humphreys type converge on the pattern that represents a target item by either activating missing features or suppressing activated features that do not belong to the target item. Errors can be generated as features are turned on or off, so that the net may converge on an incorrect item rather than on the target item. However, under this system, an incorrect item should share a considerable number of features with the target. That is, the incorrect item should be similar to the target.

It is evident that simple similarity effects are readily explained by most current models of short-term recall. However, we think that connectionist models that specify distributed representations have the ability to handle more complex similarity effects that are not readily handled by more traditional models. In the following set of experiments, we look at some of the predictions of the Chappell and Humphreys (1994) model with respect to item interactions in the context of short-term proactive interference (PI) effects. We think that PI effects are proving to be a very useful mechanism for constraining assump-

tions concerning representation, storage, and retrieval over brief retention intervals.

The Chappell and Humphreys (1994) model is a connectionist model in which representational, storage, and retrieval processes are well specified. The model uses distributed representations in which all items are represented by the same limited set of features. Storage in this model involves the formation of context-to-item or inter-item associations. Each association is represented by a different pattern of connection weights between the input and output layers in the network. For present purposes, this is a key aspect of the model because items, per se, are never stored, only associations are. This feature makes the model very much like other distributed storage models (Murdock, 1982; Pike, 1984) in which the superposition of memories ensures that the identity of each study item is lost.

Episodic memory access in the model involves finding the intersection of two sources of information. This cuing process can most readily be explained with reference to an example—say, cued recall of a short list using a taxonomic category cue. The instructions to retrieve the item from the list that was an instance of the category ANIMAL would involve finding the intersection of the set's elicited context and category cues. In modeling this process, the context cue elicits all list members and suppresses the representations of all nonlist members. The category cue elicits the representations of all animals and suppresses all nonanimals. Because the model uses distributed representations, the only elements that survive suppression are those that are common to both cues. The intersection process creates a noisy output because it is possible that there will be overlap in some of the features of animals that were not presented and list words that are not animals—for example, the phonemic features of LION and the list word LIGHT. The noisy output from the intersection process then serves as input for the autoassociator, in which patterns representing items have previously been stored (a semantic/lexical memory has previously been created). The autoassociator can turn off the noise, leaving only the prelearned pattern active, or, if some of the elements of a prelearned pattern are initially suppressed, the autoassociator can turn the missing elements on. This process hopefully converges on the pattern representing the animal that appeared on the list.

The interesting aspect of this process centers on what happens when two patterns (e.g., there are two animals on the list) plus noise survive intersection. In such instances, Chappell and Humphreys (1994) have asserted that the autoassociator can move toward one of three states. It can suppress noise and one of the two patterns converging on the representation of the other item, or it can converge to a state in which all units are turned off or all the units are turned on. In either of these cases, no item is produced. This issue becomes important in PI experiments, in which two similar items can act as competitors at recall. Before exploring how the Chappell and Humphreys model might advance our knowledge of short-

term recall, we review some of our recent work looking at PI effects using a short-term cued recall task.

In the experiments that follow, we explore target similarity effects within a short-term cued recall task in which PI was manipulated (Tehan & Humphreys, 1995). On each critical trial in this task, subjects studied two four-item blocks under directed forgetting instructions. Subjects were told that once they had realized that a trial was a two-block trial (one-block trials were also included in the experiment), they were to forget the first block and concentrate on remembering the items in the second block. On each PI trial, two members of a category were presented in the list. The to-be-forgotten, interfering foil was always presented in the first block amid three unrelated fillers, and the to-be-remembered target item was embedded among unrelated filler items in the second block. Figure 1 presents an example of one such trial. In the no-interference or control version of these trials, the target appeared in the second block without any foil in the list at all. The list items were presented at a 1-sec rate. After the final item had been presented, a cue was shown either immediately or after 2 sec of verbal shadowing. Subjects were requested to recall the instance of the category that was in the most recent block. Primary interest lies in the extent to which the presence of a to-be-forgotten foil intrudes as a response to the cue or has an impact on target recall.

Tehan and Humphreys (1995) have found that on delayed test, performance is invariably prone to the effects of the interfering foil. Target recall is lower than in control conditions and recall of the foil is a major source of error. On an immediate test, the pattern is a little different. In most situations, recall is immune to the effects of PI. Target recall under interference conditions is as good as under control conditions, and the foil is rarely recalled in place of the target. These findings replicate other re-

Figure 1. A sample trial sequence illustrating proactive interference.

search testing immediate memory of short lists (Halford, Maybery, & Bain, 1988; Wickens, Moody, & Dow, 1981). Tehan and Humphreys demonstrated, however, that PI can be observed on an immediate test if the foil and the target rhyme. Thus, when target and foils come from the same rhyming category (e.g., WRENCH and BENCH) and the cue is an ending cue (_ENCH), or when target and foils are rhyming instances of taxonomic categories (e.g., CAT and RAT with ANIMAL as cue), PI is observed on an immediate test as well as a delayed test.

Tehan and Humphreys (1995) explained the materials differences on an immediate test by appealing to the discriminative information that transient phonemic codes supply in short-term tasks. They argued that short-term recall involves both transient phonemic information and longer lasting semantic information. They were able to demonstrate that 2 sec of distractor activity was sufficient to attenuate the effects of the phonemic codes, so that on a delayed test, recall was based primarily on the semantic features (Tehan & Humphreys, 1995, Experiments 1–2). When the semantic attributes of both target and foil were present, they suggested that discriminating one item from the other became problematic. To explain immunity to PI on an immediate test, they first assumed that the phonemic features of the target would be maintained but that those of the foil would be lost due to lack of rehearsal and subsequent interference. Given that the semantic features of both target and foil were present, the phonemic features of the target would provide information that would generally allow the subject to discriminate between the target and foil. The only instance in which these phonemic codes would not discriminate was if the target and foil where rhymes of each other.

Tehan and Fallon (in press) have sketched out an adaptation of the Chappell and Humphreys (1994) model to show how the model might encompass this explanation. They proposed two changes. First, given the role of phonemic codes in short-term performance, they argued that some of the features used to represent an item should reflect the phonemic characteristics of that item. Second, they assumed that the phonemic features of an item are quickly activated and thus support rapid learning, but they are transient in that they are also very quickly suppressed (see Schneider & Detweiler, 1988, for a discussion on fast- and slow-weight learning in connectionist models).

Given the experimental procedure and the retrieval dynamics of the Chappell and Humphreys (1994) model, the list cue activates the list items and the category cue elicits all the items in the category. Given that in interference trials there are two instances of each category, the representations of both the target and the foil should survive the intersection process. The autoassociator should sometimes converge on the target and other times converge on the foil. Thus, the model readily produces PI. However, to produce immunity to PI, the autoassociator must converge on the target and not on the foil. That is, the features of the foil have to be turned off on almost all occasions. Tehan and Fallon (in press) have argued that in the case

of nonrhyming items, the active phonemic features of the target are crucial in producing this outcome. Given the assumption that the phonemic features of the target survive the intersection process, but those of the foil do not, the input to the autoassociator contains more active features of the target (semantic and phonemic) than of the foil (semantic only). As the autoassociator begins the cleanup process, the phonemic features of the target will tend to reinforce the semantic features of the target while suppressing the noise and the active semantic features of the foil. In this way, the autoassociator converges on the target. However, if the phonemic characteristics of the target are also common to those of the foil, as is the case with rhyming items, the chances of the foil being converged upon are very much enhanced in that the phonemic features of the target support the semantic features of both the target and the foil.

This explanation of PI on an immediate test with rhyming items boils down to an item interaction effect. That is, parts of one item, in the case the phonemic codes of the foil, are being supplied by another item, in this case the target. However, there is nothing in the model that necessitates that only the target and foil should interact. The critical determinant is what features survive the intersection process. If features lose their identity at storage, it is conceivable that the phonemic codes of the foil could be provided by any other item—say, one of the filler items in the list. Thus, if our interpretation of PI effects is correct, we should be able to produce PI effects with nonrhyming instances if the phonemic features of the foil can be provided by another word. The following experiments set out to explore this prediction of the Chappell and Humphreys (1994) model. To preview the results of the study, we show that items do interact with each other in the predicted fashion and that PI can be produced on an immediate test when the target and foil do not rhyme.

EXPERIMENT 1

The first experiment set out to test the notion that the phonemic codes of an interfering foil can be provided by another list item. By having a rhyme of the foil as one of the filler items in the second block, we hoped to produce an approximate representation of the foil that contained both phonemic and semantic components. To give a concrete example, suppose that in a trial subjects see DOG as the to-be-forgotten foil, CAT as the target, and LOG as one of the filler items late in the second block. We would argue that the semantic features of both the target and the foil would survive the intersection process, as would the phonemic features of the target. In addition, we think that the phonemic features shared by LOG and DOG would also survive. Consequently, given that we have a noisy representation that contains the phonemic and semantic features of both the target and the foil, the autoassociator would be somewhat less likely to converge on the target CAT and somewhat more likely to converge on the foil DOG than is the case in the standard interference condition, in

which there is no rhyme of the foil in the list. In other words, we would expect to observe PI.

In the first part of the experiment, we attempted to capitalize on recency by placing a rhyme of the interfering foil as the last filler item on the list. Although recency effects in immediate serial recall are not as pronounced with visual presentation as with auditory presentation, there is often a modest improvement in recall for the last serial position with visual presentation (Crowder, 1976). Furthermore, those models that posit rapid retroactive interference with phonemic codes still tend to maintain some semblance of recency for visually presented items (Nairne, 1990). Consequently, we thought that our best chance for observing PI would be if the rhyme of the foil occurred in the final serial position.

However, our argument implies that phonemic codes are not limited to the terminal item; they should be present across all serial positions in the second block. Thus, in the second part of the experiment, we put the rhyming foil in either the second or third serial position, the within-block positions occupied by the target. This meant that on each trial, the target and the rhyme were in adjacent positions in the second block.

The experiment consisted of three conditions—the standard control and interference conditions, plus the interference condition, which included a rhyme of the foil. The expectation was that we would observe immunity to PI in the case of the standard interference condition, in which no rhyme was present, but that we would observe PI when a rhyme of the foil was present in the list. Furthermore, although it is possible to make four types of responses on this task (target recall, foil recall, extralist intrusion, or omission), the strongest test of our assertions concerns differential rates of recalling the interfering foil. Consequently, although measures of correct target recall and omissions are presented, the primary interest in the following experiments is in the number of Block 1 intrusions (recall of the foil from Block 1 in place of the Block 2 target) that were made.

Method

Subjects. The 40 people who participated in the experiment were either 1st-year psychology students from the University of Southern Queensland who participated for course credit, or second- and third-level undergraduate students who participated for a ticket in a lottery for a small cash prize. Twenty participated in Part A of the experiment and 20 participated in Part B.

Procedure. At the beginning of the experiment, subjects were informed that they would be studying a series of one-block and two-block trials in which a block consisted of four words. However, it was also stressed that at any one point in time, they only had to remember the most recent block of four items. Consequently, if the trial was a two-block trial, signified by the presence of an exclamation mark (!) as the block separator, they were to forget the first block and concentrate on remembering the second block because it would be on this block that they would be tested. They were told that one- and two-block trials would be randomly interspersed throughout the experiment and that since they would not know in advance what type of trial it was, it was in their best interest to treat each trial as a one-block trial until they learned otherwise.

Each trial began with a READY sign displayed on the computer monitor for 2 sec. The study items were then displayed individually in lowercase at a rate of one word per second, and subjects were instructed to remain silent throughout the presentation of the study items. On two-block trials, the block separator (!) was presented for 1 sec after the fourth word in the first block and before the first word in the second block. At recall, a category cue was presented in uppercase for 2 sec. On an immediate test, the cue appeared immediately after the fourth item in the block. With the appearance of the cue, subjects were requested to verbally recall the item from the most recent block that was an instance of the category. Subjects had 5 sec to make a response before the next trial began. The experimenter recorded the subjects' responses (correct recall, intrusion errors, omissions, etc.) on a hard copy of the subject's input file.

Materials. The interfering foils and the target items used in this experiment were selected from the taxonomic categories generated by Nelson and his colleagues at the University of South Florida (McEvoy & Nelson, 1982). The filler items were selected from the unused categories from the South Florida norms and from the Shapiro and Palermo (1970) norms in such a way that there was no overlap between the category membership of filler and critical items. This ensured that filler items were always unrelated to the critical items, although they tended to have similar characteristics. That is, they tended to be one- or two-syllable concrete nouns, as was the case with the critical items. As such, we felt that fillers, foils, and targets could not be discriminated on the basis of common word characteristics and that strategies based on these features would not be employed.

For the critical items, two instances were sampled from each category. The item selected to be an interfering foil in Block 1 was a high-dominant instance of the category (using controlled association procedures, on average the item was produced by 36% of the subjects and was either the most frequently or second most frequently produced item). Block 2 target was a relatively weak member of the category (produced by 1.5% of the subjects, it was, on average, the 12th most frequently produced instance in the category). The materials used are presented in the Appendix. The targets and foils were matched for word frequency.

In the standard version of this task, category-specific proactive interference is manipulated in the two-block trials: On an interference trial, an interfering foil from the same category as the target item is presented in the first block, and the target appears in the second block. On control or no-interference trials, a target item is presented in the second block with no related item in the first block. Both parts of the present experiment involved a third condition in which a target and interfering foil were present (an interference condition), but one of the filler items in the second block was a rhyme of the foil. The rhyming instance for each of the interfering foils was generated by going through the South Florida rhyme category norms (Walling, McEvoy, Oth, & Nelson, 1983). The selected rhyme had the same characteristics as the other filler items in that it was not a member of the relevant taxonomic category, and it was in nearly all instances a concrete noun.

In creating the trials for each subject, the target and foil were first randomly assigned to the various experimental conditions. On the 10 interference trials, the target and foil were then embedded among randomly selected filler items, which were also all concrete nouns, in such a way that two four-item blocks were created. In the case of the 10 control or no-interference trials, the interfering foil was replaced by a filler item so that the target was the only instance of the category in the list. On the interference trials, foil and target always appeared in the same serial position (on half the trials, position 2, and the other half, position 3) in their respective blocks. This was done to reduce the influence of primacy and recency on absolute levels of recall. The remaining 10 two-block trials were interference-plus-rhyme trials in which the foil was present in Block 1 and the target and a rhyme of the foil were in Block 2. In Part A of the present experiment, the

rhyme of the foil always appeared as the last item in the list. In Part B, the rhyme was always presented in position 2 or 3.

All experiments also contained a number of one-block trials that were also tested via immediate cued recall. These trials were included to ensure that subjects attended to the first block in a two-block trial and to allow serial positions 1 and 4 to be tested. Generally speaking, performance on these trials indicated that they served their purpose, and as such they are not considered any further in any of the analyses. The order of the filler and experimental trials was randomized for each subject. This ensured that subjects never knew in advance whether the trial would be a one-block filler trial, a two-block interference trial, or a two-block control trial.

Results

In reporting and analyzing our data for this and all the following experiments, we first present the means for the control, standard interference, and interference-plus-rhyme conditions for correct recall, omissions, and Block 1 intrusions. Extralist intrusions were a minor source of error in all experiments and appear to have had no relationship to the different types of interference trial. In short, it seems that our subjects, when in doubt, preferred to make an omission rather than to guess. For the correct recall, omissions, and Block 1 intrusions, we provide 95% confidence intervals for the population means, based on the pooled error term for the three interference conditions (Loftus & Masson, 1994). This information is supplemented by effect size estimates based on the following comparisons, which remain constant throughout the following experiments. PI effects were primarily determined by comparing performance on the interference conditions with performance on the control trials, in which no foil was present in the list. Thus, the first comparison involved target recall in the control and the standard interference conditions. Here we expected to see immunity to PI, which would be reflected in small effect sizes. The second comparison looked at target recall in the control and interference-plus-rhyme condition. This was the condition under which we expected to find PI, which would be reflected in larger effect sizes. We did the same comparisons for omission errors. The final comparison involved the strong test of our hypotheses—the difference in number of Block 1 intrusions between the standard interference and the interference-plus-rhyme conditions. We expected to observe large effect sizes here. In each of the comparisons, effect size was calculated by dividing the difference between treatment means by a pooled estimate of the population standard deviation. The comparison of Block 1 intrusions for the standard interference condition and the interference-plus-rhyme condition was complicated by the fact that on an immediate test in the standard interference conditions, very few Block 1 intrusions occurred. This makes parametric tests somewhat dubious. Since the strong test of our theory involves the frequency with which the foil was mistakenly produced as the target, we wanted to adopt a conservative test in the first instance. Thus we first selected the nonparametric Wilcoxon signed ranks test as the most appropriate way to analyze these differences. The statistic we report is a

Z statistic in which the sum of the signed ranks is divided by the square root of the sum of the signed ranks. We supplemented the nonparametric test with an effect size estimate based on a repeated measures t test, knowing that there is some doubt as to the validity of this measure. It should be said that in all experiments, the parametric and the nonparametric tests suggested the same conclusion.

Part A. A summary of the different response types is presented in the top panel of Figure 2. As far as correct recall goes, the data in Figure 2 suggest that there was little difference between the control and standard interference conditions. A small effect size of .08 confirmed this observation. In contrast to this, the difference between the control and interference-plus-rhyme conditions was more substantial, with an effect size of .52. The differences in omission errors were not all that great across the three conditions. The effect size for the control and interference comparison was .22. For the control and interference-plus-rhyme conditions, it was .19.

For the Block 1 intrusions, 11 of the subjects produced more intrusions in the interference-plus-rhyme condition than in the standard interference condition, 2 subjects showed an advantage for the standard interference condition, and 7 subjects produced tied scores. The Wilcoxon test on these data indicated that this pattern was highly reliable ($Z = 2.80, p < .005$). An effect size of .73, based on parametric techniques, likewise confirmed that intrusions were more likely to occur in the interference-plus-rhyme condition.

Part B. The means for the different measures when the rhyme appeared in the middle serial positions are presented in the bottom panel of Figure 2. Target recall appears to have been equivalent in the control and the standard interference conditions (effect size was .14), but PI effects appear to have been present in the interference-plus-rhyme condition (effect size was .53). There were more omission errors in the control condition than in either the standard interference (effect size was .61) or the interference-plus-rhyme (effect size was .64) conditions. Block 1 intrusions were more frequent in the interference-plus-rhyme condition than in the standard condition, with 15 subjects showing an interference-plus-rhyme advantage, 3 showing a standard interference advantage, and 2 producing tied scores. According to the Wilcoxon test, the difference in intrusions was reliable ($Z = 2.37, p < .05$). The effect size, based on a repeated measures t test, was .62.

Discussion

There are a number of important features of the present results. First, both parts of the experiment produced the same pattern of effects. The position that the rhyme of the foil occupied did not appear to change performance in any way. Both parts of the experiment replicate previous research indicating immunity to PI for subspan lists of items from taxonomic categories (Halford et al., 1988; Humphreys & Tehan, 1992; Tehan & Humphreys, 1995,

Figure 2. Performance measures as a function of interference condition in Experiment 1.

1996; Wickens et al., 1981) in that there was no reliable difference between performance on the standard interference and the control trials. However, when a rhyme of the foil appeared in the second block, the likelihood that the target would be recalled substantially diminished, and this was primarily due to the fact that the interfering foil was more likely to be recalled than the target. Moreover, effect

sizes were reasonably similar across the two parts of the experiment, at least for target recall and foil intrusions.

Immunity to PI in the absence of a rhyme but its emergence in the presence of a rhyme is precisely the pattern of performance predicted from the Chappell and Humphreys (1994) model. In any event, the results are consistent with the idea that a rhyme can provide some of the phonemic in-

formation that has been lost from the representation of the foil, making the foil a more potent competitor for the target.

The fact that a filler item that is unrelated to the cue can have an impact on target recall and foil intrusions is a strong test of distributed representations. An even stronger test would involve the distribution of the phonemic components across several of the filler items. In the next experiment we set out to provide this strong test of the distributed storage assumption by putting the rhyme phonemes of the foil into separate filler items in the second block. For example, we decomposed the rhyme component of the foil DOG—OG—into its components, O and G, and then put the components in the same within-word position in other filler items—for instance, putting the O in MOP and the G in FIG. We expected the same results as in the first experiment.

EXPERIMENT 2

Method

Subjects. A further 20 undergraduate students from the University of Southern Queensland participated in the experiment for course credit or a ticket in a cash lottery.

Materials and Procedure. The materials and procedure in the present experiment were identical to those in Experiment 1 in all respects save one. In the control and the standard interference conditions, the filler items were randomly allocated to condition, block, and position within block. In the interference-plus-components condition, two nonrandom filler items appeared in the second block. The vowel phoneme of one of the fillers shared the vowel phoneme with the foil, but initial and terminal phonemes differed. The second filler item shared the terminal phoneme with the foil,

but the initial and vowel phonemes differed. The filler with the shared vowel always appeared in the list before the filler with the shared terminal phoneme. That is, phoneme order was maintained.

Results and Discussion

The results of the present experiment are shown in Figure 3. The results can be summarized quite simply: There were no reliable differences across any of the measures. Thus, the effect sizes for target recall were .12 and .32 for the comparisons involving the standard interference condition and the interference-plus-components conditions, respectively. With omissions as the dependent measure, the effect sizes for the standard interference and the interference-plus-components conditions were .24 and .62, respectively. More importantly, for Block 1 intrusions only, 3 subjects produced an interference-plus-component advantage, 6 produced a standard interference advantage, and there were 11 ties. The Wilcoxon test suggested that there was no reliable difference between the two means ($Z = -.79, p = .43$). An effect size of .22 confirmed the lack of intrusion differences.

Clearly, a rhyme is greater than the sum of its parts. In the first experiment, a filler item that was a rhyme of the foil influenced the degree to which PI was observed. In the present experiment, when the rhyme was decomposed and the parts were distributed across other filler items, no additional interference was created. Taken at face value, the present results suggest that distributed storage failed the strong test.

Before abandoning distributed storage completely, we decided to repeat Experiment 2 but this time to ensure

Figure 3. Performance measures as a function of interference condition in Experiment 2.

that all three phonemes of the foil were present rather than just the vowel and terminal phoneme. In the Chappell and Humphreys (1994) model, the more components of a pre-learned pattern that are active at the start of the deblurring process, the more likely it is that the pattern will be produced. In Experiment 2, the lack of the initial phoneme might have proved crucial. Thus, in the interference-plus-components condition of Experiment 3, the three components of the foil were spread across the three filler items: One of the fillers shared the same initial phoneme, one shared the same vowel sound, and the third shared the same terminal phoneme as the foil. If the foil was DOG, the fillers might have been DART, MOP, and FIG. The materials used are presented in the Appendix.

EXPERIMENT 3

Method

Subjects. Twenty undergraduate students from the University of Southern Queensland participated in the present experiment. Again, course credit or a ticket in a small cash lottery was given for participation.

Materials and Procedure. The materials and procedures were identical to those used in Experiment 2 except that in the interference-plus-components condition, one of the filler items contained an initial phoneme that was shared with the foil. Thus all three filler items in the second block shared one phoneme with the foil. The order of the filler words maintained the order of the phonemes in the foil.

Results and Discussion

The results are summarized in Figure 4. In looking at the target recall data, it would seem that there was no ev-

idence of any PI. Effect sizes for correct target recall were consistent with this—0 and .08 for the standard interference and the interference-plus-components conditions, respectively. The error data tell a different story, however. The error patterns for the two interference conditions were very different from each other. For omissions, the effect size for the comparison between the control and the standard interference conditions was .15, but for the comparison between the control and the interference-plus-components conditions, it was .87. For the Block 1 intrusions, 15 students produced an interference-plus-components advantage, 1 produced a standard interference advantage, and there were 4 tied scores. The Wilcoxon test carried out on these data confirmed that the difference in errors was highly significant ($Z = 3.33, p < .001$). Parametric analysis produced an effect size of .89.

Although the correct recall data suggest that there was very little difference in recall among the three conditions, the error data suggest that the two interference conditions were very different from each other. In the standard interference condition, subjects made relatively more omission errors than Block 1 intrusions. The opposite was true of the interference-plus-components condition, in which a Block 1 intrusion was more likely to be made than an omission error.

Performance was becoming more complex as our series of experiments progressed; in Experiment 3 there was an interaction among error types. However, it is clear that putting all three phonemic components of the foil in the second block increased the likelihood of recalling the foil dramatically. In other words, distributed storage assumptions passed the strong test.

Figure 4. Performance measures as a function of interference condition in Experiment 3.

Given that we did not find strong effects when just the rhyme components were utilized, but we did when all three components were used, we thought it important to replicate the findings of Experiment 3. Furthermore, we were interested in determining whether the order of the filler items was important. In the previous two experiments, the order of the filler items in Block 2 reflected the order of the phonemes in the foil; DART appeared as the first filler, MOP appeared after DART, and FIG appeared after MOP. In the next experiment, there were four experimental conditions: the control and the standard interference conditions and two interference-plus-components conditions. In the first of the interference-plus-components conditions, the order of the filler items reflected the order of the phonemes in the foil. In the second condition, the order of the filler items was not maintained; FIG might have appeared first, DART after that, and MOP as the last filler item. Note that the relevant phoneme still maintained its position within the filler word. We expected that the order of the filler items would not be an essential part of the effect. Both interference-plus-components conditions should produce interference.

EXPERIMENT 4

Method

Subjects. Twenty undergraduate students from the University of Southern Queensland participated in the present experiment. Again, course credit or a ticket in a small cash lottery was given for participation.

Materials and Procedure. The three interference conditions used in Experiment 3 were again used in the present experiment. In addition, a fourth condition was also used. In this condition, again the components of the foil were distributed across three filler items in the second block, but now the order of the filler items was rearranged. In the case in which the target item was in position 3, the order was as follows: filler with terminal phoneme in serial position 1, filler with initial phoneme in position 2, and filler with vowel in position 4. When the target was in position 2, the order was vowel first, terminal third, and initial fourth. As was the case in Experiment 3, the order of the phoneme within word still corresponded to that it had had in the foil.

The use of an additional condition necessitated the selection of a further 10 categories. These were again selected from the McEvoy and Nelson (1982) norms. To ensure that there was no overlap between critical items and fillers, several words had to be culled from the pool of filler items.

As in the previous experiments, separate lists were created for each subject, materials were randomly assigned to conditions, and the order of the lists was randomized.

Results and Discussion

The results of the experiment are presented in Figure 5. In looking at the target recall data, it would seem that PI effects were present across all three interference conditions, although they appear to have been more pronounced in the conditions in which the components of the foil were present. Effect sizes for correct target recall reflect this. For the standard interference condition, the effect size was .48, for the interference-plus-components-in-same-order condition, effect size was .65, and for the rearranged order it was .92. There were no large differences in omis-

Figure 5. Performance measures as a function of interference condition in Experiment 4.

sion errors, with effect sizes of .18, .16, and .25 for the standard interference, the components-in-same-order, and the rearranged components conditions, respectively. In comparing Block 1 intrusions for the standard interference and the components-in-same-order conditions, 7 students produced an interference-plus-components advantage, 2 produced a standard interference advantage, and there were 11 tied scores. The Wilcoxon test carried out on these data indicated that the difference in errors was marginal ($Z = 1.73, p = .08$). Parametric analysis produced an effect size of .41. For the comparison between the standard interference and the rearranged components conditions, 13 students produced a rearranged components advantage, 1 produced a standard interference advantage, and there were 6 tied scores. The Wilcoxon test carried out on these data indicated that the difference in errors was reliable ($Z = 3.08, p = .002$). Parametric analysis produced an effect size of .83.

In spite of our observing PI in the standard interference condition for the first time, the principal interests of the study were realized in this experiment. When the three phonemic components of an interfering foil are distributed over filler items in the second block, subjects are much more likely to recall the foil than if there is only random overlap between fillers and foil. Furthermore, it seems that the order in which the filler items that share features with the foil is not all that important. If anything, performance in the rearranged condition produced more interference than in the condition in which order was maintained. We note that Li and Schweickert (1995) have shown that it is the presence of similar phonemes, rather than their order (e.g., DISK and SKID), that is important for producing phonemic similarity effects. If order of phonemes within a word is not crucial for producing a similarity decrement, the present results are not all that controversial. In sum, in replicating the findings of Experiment 3, it would appear that we have established reasonable support for the role of distributed representations and storage as a mechanism that underlies short-term PI effects.

GENERAL DISCUSSION

In the introduction to this paper, we reviewed the relevant assumptions of memory models that employ distributed representations and distributed storage. One emergent feature of such models is that items can readily interact with one another. We have looked at the Chappell and Humphreys (1994) connectionist model with respect to how a target and foil might interact with each other in a short-term cued recall task. The present experiments were conceived to explore predictions concerning the presence or absence of immunity to PI on an immediate test, with the basic assumption that phonemic features for one item could be provided by other, unrelated list items. The basic prediction from the Chappell and Humphreys perspective was that if other items in the list could provide phonemic features, PI would be observed. If the other items in the list were all unrelated to the foil, immunity to PI could be expected.

By and large, empirical evidence across a range of short-term tasks employing short lists of taxonomically similar items confirms immunity to PI on an immediate test (Halford et al., 1988; Tehan & Humphreys, 1995, 1996; Wickens et al., 1981). This pattern is reflected in the standard interference conditions in the present experiments. In all the experiments, bar the last, the presence of an interfering foil in the first block had no noticeable effect on target recall, nor did Block 1 intrusions serve as a major source of error. In the final experiment, target recall was depressed, but the effect was not strong and appears to have been due to an increase in omission errors rather than increased recall of the foil.

There are boundary conditions to immunity to PI. In previous research, we demonstrated that PI can be observed on an immediate test if the foil and target rhyme (Tehan & Humphreys, 1995). In the present set of experiments, we have shown that it is possible to produce PI when target and foil do not rhyme. When a rhyme of the foil is presented in the to-be-remembered second block, or when all the phonemic components of the foil are distributed across filler items, recall of the interfering foil is enhanced. We have also demonstrated that if only some of the components are distributed across fillers, PI is less likely to be observed.

These results are consistent with the assumptions of the Chappell and Humphreys (1994) connectionist model and the Tehan and Fallon (in press) adaptation of it. We have presented our explanations for the presence or absence of PI in the introductions to the various experiments and do not wish to reiterate them here. Instead we wish to consider other possible explanations for the effects, something we have not addressed to this point.

The first issue involves possible ceiling effects with target recall and floor effects with errors. Target recall across all conditions and across the four experiments surpassed the 90% accuracy level only once. The task was difficult enough that most subjects made some type of error. With respect to errors, particularly Block 1 intrusions, it is not the case that a few subjects were producing all the errors. In fact, the vast majority of subjects (70%–85% across experiments) made at least one Block 1 intrusion. Furthermore, ceiling and floor effects only address the issue of how much is recalled, rather than providing an explanation for accuracy of recall (Koriat & Goldsmith, 1996). We think that we have provided an explanation for why recall is quite accurate under control and standard interference conditions, but less accurate under conditions in which fillers bear some similarity to the foil.

Subjects might have adopted strategies that could account for the pattern of results that we have observed. With regard to the first experiment, the results might simply be an artifact of subjects' having noticed that a rhyme was present, which in turn would have reminded them of the foil, thereby strengthening its representation (Tzeng & Cotton, 1980). Although we believe that the manipulation of the rhyming filler item was transparent to subjects, we did not do any postexperiment checks to see whether this was so. Even if the manipulation was transparent, a

model of short-term memory based on spreading activation might predict such a result. With the presentation of the rhyme, activation might have spread through a rhyme network in such a way that the foil in the interference-plus-rhyme condition received additional activation from the rhyme and thereby became a stronger competitor than it would have been in the standard interference condition. These explanations of spreading activation and noticing that the rhyme of the foil was present should be limited to the first experiment. Distributing the phonemes across fillers should have severely limited the spread of activation to the foil, thereby reducing the chances of observing PI.¹ Distributing the phonemes across fillers also should have made it impossible for subjects to notice the relationship between Block 2 fillers and the foil.

The final strategy that might have produced PI effects with the rhyme is a generate–recognize access procedure. In the conventional versions of the generate–recognize procedure (Humphreys, Bain, & Pike, 1989; Jacoby & Hollingshead, 1990), the subject would start to generate instances of the category and then attempt to match the output of the generate procedure with episodic traces of the list items. As each item is generated, it is matched to each item in memory, and if a match exceeds threshold, that item is produced as the response. In long-term recognition studies, it has been documented that distractors (new items) that are rhymes of targets are more likely to be falsely recognized than nonrhyming distractors (Byrne & Shea, 1979; Runquist & Blackmore, 1973), although this effect is not large. If we assume that phonemic information in the short-term domain has a privileged role, such false recognition might occur more frequently in the short-term domain. Given that the foil is usually a high-dominant instance of the category, it is likely to be generated. Falsely recognizing the rhyme as the foil may well happen on the odd occasion. When there is no rhyme of the foil in the list, it is unlikely that matching failures are going to occur.

We believe that the results of the last two experiments lessen the plausibility of these alternative explanations. The problem posed for generate–recognition by these experiments is the very weak relationship involved. That is, each filler item had only a single phoneme in common with the generated item, so that the contribution of a match between the generated item and one of these fillers would have been very small. Instead, we would assert that these results support two things: representation at the level of features and the simultaneous activation of all the list items at the time of retrieval. We want to address these assumptions in some detail.

The idea that representations can be conceived of as sets of features is not new (Bower, 1967; Underwood, 1969). Models that have taken a feature approach (Drewnowski, 1980; Nairne, 1990) have tended to stress the phonemic features of the stimuli involved and to minimize or ignore semantic features. Empirical support for phonemic features has been readily observed in studies that have examined errors on immediate serial recall. Intrusion errors tend to share the unforgotten phonemic characteristics of the target item (Wickelgren, 1965a, 1965b, 1965c)—for

instance, syllabic stress pattern, stressed vowels, and the beginning and terminal phonemes (Drewnowski & Murdock, 1980). These results imply that partial forgetting of an item in short-term memory is possible, and that items in short-term memory are not stored in a unitary fashion but rather as an aggregate of smaller features.

Empirical support for the contribution of nonphonological features is less pronounced. However, the Chappell and Humphreys (1994) deblurring procedure asserts that all features contribute to identifying the target item. Nairne's feature model makes a similar assertion (Nairne, 1990). At the empirical level, word frequency effects in span (Tehan & Humphreys, 1988; Watkins, 1977) could well stem from semantic features facilitating the deblurring process. Poirier and Saint-Aubin's (1995) demonstration of the facilitative effects of taxonomic similarity on span is a more obvious example of semantic features affecting immediate recall. In any event, we think that a systematic examination of semantic and episodic long-term effects in serial recall is long over due.

The more contentious issue is that the results of the latter experiments appear to require assumptions about the simultaneous activation of all list items at retrieval. That is, it would appear that at the time of recall, the target, the foil, and the three filler items are all participating in the recall process. Such an assumption is not unknown in the literature. In fact, simultaneous activation at retrieval is a central tenet of Hintzman's (1986) *Minerva II* model, which employs local storage, and the distributed storage models such as TODAM (Murdock, 1982) and the *Matrix* model (Pike, 1984).

As noted, the present results raise serious problems for conventional versions of the generate–recognize approach. More sophisticated generate–recognize procedures might be possible, however. For example, in SAM (Gillund & Shiffrin, 1984), all generated items are matched to all the items in memory before a response is made. That is, each match produces some matching strength, and the strengths of all the matches are then summed into a single value. The recognition decision is based on the strength of the composite value. The assumption here is that if a list item is generated, the match to the composite value is going to be stronger than if a list item is not generated. In the case of the phonemic characteristics being distributed across filler items, it is possible that when the foil is generated and matched to the filler items, weak matching strengths are produced on each occasion. However, when the weak strengths are summed prior to decision, it is possible that the combined matching strength might be above threshold level. If so, the foil would be produced as the response.

Although we cannot rule out a generate–recognize process of the type envisioned in SAM, we have indicated a number of times that our preferred alternative is for distributed storage and direct access of the type that is utilized by Chappell and Humphreys (1994). The present results are certainly consistent with the assumptions of that model. As a number of authors have commented, distributed storage does appear to have several advan-

tages. Retrieval dynamics are very much simplified in that (1) access is direct via cues, with no search mechanism needing to be specified; (2) partial losses of memory need not have a devastating effect on performance; and (3) the models lend themselves to associative effects (Lewandowsky & Murdock, 1989; Murdock, 1982). We would also argue that interactions among list items of the type seen in the present experiments are best understood as being an emergent feature of distributed storage.

We started this paper by observing that there was considerable diversity in assumptions concerning representation, storage, forgetting, and memory access in current models of immediate recall. The present results, we believe, suggest a number of constraints. The results strongly support feature-based representations in which phonemic features have a privileged role at very short retention intervals. The item interaction effects of the type that characterize the present findings suggest that specific items have to some extent lost their identity. Our preferred explanation for this is that these item interaction effects are an emergent consequence of distributed storage. However, we cannot rule out the idea that local storage with a global matching retrieval process is involved. Given that very few current models of immediate recall involve distributed representation with distributed storage—let alone consider PI effects—the present results should provide a challenge for existing models and place substantial constraints on the development of future models.

NOTE

1. In spreading activation models of word identification (see, e.g., McClelland & Rumelhart, 1981), there is often assumed to be an interaction between phonemes at the letter level of representation and at the word level of representation. However, this interaction is seen to involve the linkage between peripheral and central codes. In episodic memory, we know of no evidence indicating that items that share a single phoneme are demonstrably more similar than words that do not have any phonemes in common.
