

tion performance shown by the CI-trained Ss demonstrates the ability of this discrete-trial program not only to generate a high rate of operant responding but also to maintain a high degree of operant motivation, at least throughout one day of massed extinction trials. In this respect the CI program appears to act much like the 64% sucrose concentration, as compared with the 16% concentration. As a matter of fact, the programming variable was even more powerful in this experiment than the incentive variable, since the CI program at 16% sucrose concentration reinforcement produced more extinction performance than the CS program at 64% sucrose concentration reinforcement (cf., Fig. 1).

These results are especially impressive in view of the fact that all Ss initially received CI training, and for several days. It is quite probable that had only CS training been used for the CS group those Ss would have shown even less extinction performance.

The present results thus demonstrate that when a determinate number of reinforced responses is used in training more such responses will be emitted

Reply to Baenninger by Stephen R. Goldstein, University of Alberta

In reviewing some recent research on the behavior of the Siamese fighting fish (*Betta splendens*), Goldstein (1967) commented upon Baenninger's (1966) interpretation of extinction data reported in an earlier study by Thompson (1963). Baenninger (1967) has now taken issue with my statements by indicating that his position was, in effect, more subtle than my comments implied.

Baenninger's (1967) present view is evidently based upon the assumption that emission rates of an operant may be influenced by changes in the effectiveness of a reinforcer during the course of an experimental session and upon data which show a waning of both the appetitive and consummatory components of aggressive display.

It might be indicated that of the data which support this position, neither Baenninger's (1967) nor Clayton's (cited by Baenninger) were being called into question—though there is room even for this, since the details of Clayton's work have not, to the best of my knowledge, been published, and since in Baenninger's (1966) study, a temperature of 72°F was apparently employed in maintaining and testing Ss—a temperature, if we may interpolate from existing data, unfavorable to the initiation and maintenance of aggressive display in *Betta splendens* (Lissmann, 1932; Hess, 1952). A temperature of 80°F ± 2°F is recommended by almost all tropical fish texts as ideal for maintaining healthy, active fish and accordingly was used by Thompson (1963) and by myself in replicating his work.

Reference to my paper will indicate, however, that the issue being dealt with was primarily definitional and was not directed at empirical or theo-

during extinction if reinforcement has been on a discrete-trial rather than a free-responding basis. An important implication of this result is the suggestion that the characteristically high rate of operant response generated by certain reinforcement schedules is not a function of the free-operant procedure per se. This suggestion will be strengthened if the same superiority in response rate can be shown to result from CI training when it is compared to training on longer CS intervals and intermittent schedules of reinforcement, which more closely approach orthodox free-operant procedures.

retical problems. In particular, it appeared that Baenninger (1966) had attributed an extinction-induced response decrement not to the termination of the response-reinforcement contingency, but rather to mirror-image habituation. This point is supported by a statement in Baenninger's (1966) discussion section which read, "It would appear that the reinforcing properties of such stimuli may exist for a limited time only, and that *the extinction data reported by Thompson may be due to this decreased tendency to approach mirrors and stimulus fish*" (italics mine). It should be apparent, however, that the extinction data in question could not possibly be due to a "decreased tendency to approach mirrors and stimulus fish" since such stimuli are not available to S under conditions that define extinction. Baenninger (1967) has now clarified his position on this by suggesting that habituation may occur under conditions of acquisition and subsequently affect the course of extinction. The confusion could have been avoided had Baenninger distinguished between variables which may affect extinction and the procedural operations which define it.
