

# Strike-induced chemosensory searching in rattlesnakes: A rodent specialist (*Crotalus viridis*) differs from a lizard specialist (*Crotalus pricei*)

ERIC CRUZ, SUSAN GIBSON, KARL KANDLER, GALEN SANCHEZ, and DAVID CHISZAR  
*University of Colorado, Boulder, Colorado*

Prairie rattlesnakes (*Crotalus viridis*) exhibited a sustained high rate of tongue flicking after a predatory strike whether or not rodent odors were present in the poststrike environment. For the lizard specialist, *C. pricei*, strike-induced chemosensory searching was maintained at a high level only when chemical cues were available following the strike.

Rattlesnakes typically release adult rodents after envenomating them (Gans, 1966; Kardong, 1986; Radcliffe, Chiszar, & O'Connell, 1980), allowing the wounded prey to wander freely while the venom takes effect (Brock, 1980; Estep, Poole, Radcliffe, O'Connell, & Chiszar, 1981; Hayes & Galusha, 1984). The predators then locate the dead rodents by following their chemical trails (Dullemeijer, 1961; Duvall, Chiszar, Trupiano, & Radcliffe, 1978; Duvall, Scudder, & Chiszar, 1980; Golan, Radcliffe, Miller, O'Connell, & Chiszar, 1982; Reinert, Cundall, & Busher, 1984). Most rattlesnake species are rodent specialists (Klauber, 1956), but even those that feed heavily on lizards in nature (e.g., *Crotalus lepidus*, *Crotalus pricei*) accept rodent prey in captivity (Chiszar, Radcliffe, Byers, & Stoops, 1986). Moreover, *C. lepidus* and *C. pricei* handle rodents in much the same way that rodent-specializing species handle them (i.e., rodents are struck, released, and trailed) (Chiszar, Radcliffe, Byers, & Stoops, 1986; Chiszar, Radcliffe, & Feiler, 1986). Because these snakes usually hold lizards following the strike (personal observations), and no trail following occurs prior to swallowing them, it was surprising to observe accurate following of rodent trails by snakes that rarely perform such tasks in nature. However, Chiszar, Radcliffe, and Feiler (1986) reported a quantitative difference between behaviors of prairie rattlesnakes (*C. viridis*) and banded rock rattlesnakes (*C. lepidus*). When rodent trails are available following a predatory strike, both species flick their tongues at high rates and follow these trails; however, when no rodent trails are available, only the prairie rattlesnakes exhibit high rates of tongue flicking and extensive searching movements after a strike. The rock rattlesnakes do so for only a few minutes after the

strike before returning to quiescence. In other words, strike-induced chemosensory searching (SICS) is a relatively automatic consequence of a successful predatory strike in the rodent specialist, but SICS requires vomeronasal feedback in order to be maintained in the lizard specialist.

The present report compares poststrike behavior of *C. viridis* with that of another lizard specialist, the western twin spotted rattlesnake (*C. pricei*). Results indicate that *C. pricei*, like *C. lepidus*, exhibited a high level of SICS only when rodent odors were available.

## METHOD

Subjects were 4 *C. viridis* and 4 *C. pricei*, all captured as adults and maintained in the laboratory for 3 years prior to this experiment (see Golan et al., 1982, for details concerning cages, temperature, and photoperiod). The snakes were fed only rodents (*Mus musculus* and neonatal *Rattus norvegicus*) during this period.

The study consisted of four conditions. In two of these, mice were suspended, using forceps, into the snakes' home cages (but held out of striking range) for 10 sec and then withdrawn. Tongue flicks were recorded with hand-held counters for the next 30 min. A petri dish containing soiled mouse bedding was placed into the cage and left there after one no-strike (NS) presentation, whereas a petri dish containing clean bedding (aspen chips) was introduced after the other NS presentation. The two remaining conditions were identical to the NS ones, except that the mouse was moved into striking range at the end of the 10-sec presentation. All presentations were made on regular feeding days (snakes were fed every other week), and all snakes struck when given an opportunity. Envenomated mice were removed immediately following the strikes.

In addition to making a continuous record of tongue flicking for 30 min, we also recorded tongue flicking for 10 min prior to introducing the live mice (i.e., baseline data), and we continued observing the snakes after the 30 min of recording tongue flicking until the first minute with zero tongue flicks (or for a maximum of 150 min).

The four experimental conditions conform to a 2 (NS vs. Strike [S])  $\times$  2 (mouse odors absent [NO] vs. mouse odors present [O]) orthogonal combination. The four conditions were administered in a random order to snakes of both species. Analyses of variance (ANOVAs) were applied to the data, treating taxa as a between-subjects factor and NS versus S and NO versus O as repeated-measures factors. To increase the power of statistical tests in the ANOVAs, all interactions involving snakes-within-species were pooled to generate a composite error term with

This work was completed while K. Kandler was an exchange student at the University of Colorado from Universität Tübingen, Tübingen, Federal Republic of Germany. Reprint requests should be addressed to D. Chiszar, Department of Psychology, Campus Box 345, University of Colorado, Boulder, CO 80309.

$df=18$ . Nonorthogonal contrasts were used to make post hoc comparisons (error rate = .05).

## RESULTS

The rate of tongue flicking was 0.6 per minute during baseline recordings, indicating that snakes were quiescent prior to mouse presentations. Mean number of tongue flicks during min 1-30 postpresentation is shown in Figure 1.

The S versus NS effect was robust [ $F(1,18) = 51.87$ ,  $p < .01$ ], and this effect interacted with species [ $F(1,18) = 4.68$ ,  $p < .05$ ]. No other factors were significant in the ANOVA. Post hoc tests showed that *C. viridis* exhibited equal S versus NS differences whether or not rodent odors were present ( $F < 1.0$ ), but *C. pricei* emitted significantly more tongue flicks after S presentations when mouse odors were present than when clean aspen bedding was present [ $F(1,18) = 4.83$ ,  $p < .01$ ].

The rate of tongue flicking dropped to zero (Figure 2) much sooner after NS than after S presentation [ $F(1,18) = 89.29$ ,  $p < .01$ ], and again this effect interacted with species [ $F(1,18) = 4.52$ ,  $p < .05$ ]. No other factors were significant in this ANOVA. Post hoc tests revealed that after S presentations the rate of tongue flicking by *C. pricei* dropped to zero more rapidly when mouse odors were absent than when they were present [ $F(1,18) = 7.07$ ,  $p < .01$ ]. Tongue flicking by *C. viridis* did not differ in the two S conditions ( $F < 1.0$ ), indicating that searching continued equally long whether or not rodent odors were present.

## DISCUSSION

*C. pricei* exhibited a weaker S versus NS effect than did *C. viridis*, especially when rodent odors were absent. This finding may have theoretical importance because it suggests that SICS is a modal action pattern for *C. viridis* but not for *C. pricei*. Once a strike occurred in *C. viridis*, SICS rose to an asymptotic level and continued for at least 2 h whether or not rodent odors were present, implying that the intensity and duration of SICS did not depend on chemical feedback (Chiszar et al., 1985; Chiszar, Radcliffe, O'Connell, & Smith, 1982; Golan et al., 1982). For *C. pricei*, on the other hand, both the intensity and duration

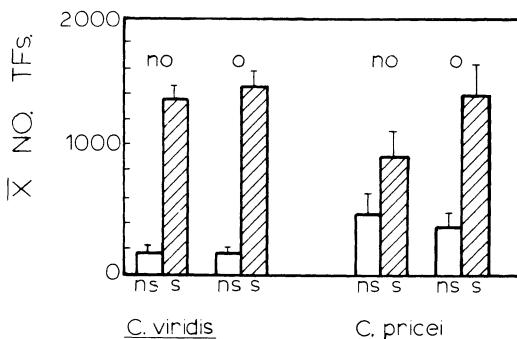

Figure 1. Mean number of tongue flicks emitted during 30 min following mouse presentations by 4 *Crotalus viridis* and 4 *C. pricei*. (NS = no-strike presentation, S = strike; NO = no rodent odors present, O = rodent odors present.) One SEM is indicated above each bar.

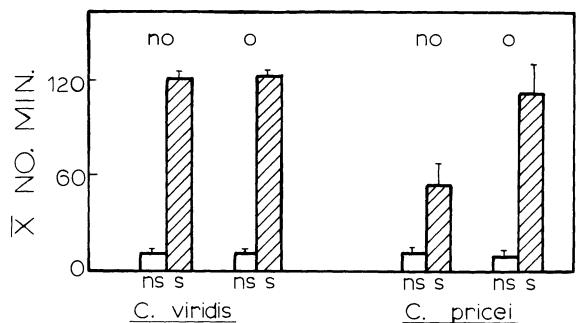

Figure 2. Mean number of minutes before the first minute with zero tongue flicks. (NS = no-strike presentation, S = strike; NO = no rodent odors present, O = rodent odors present.) One SEM is indicated above each bar.

of SICS were enhanced by chemical cues arising from rodent-soiled bedding. Hence, SICS in *C. pricei* did not have the relatively fixed topographic properties that were observed in SICS of *C. viridis*. Chiszar, Radcliffe, Byers, and Stoops (1986) and Chiszar, Radcliffe, and Feiler (1986) suggested that dependence upon rodent prey was responsible for the strong and stereotyped SICS pattern seen in species such as *C. viridis*. The more variable SICS effect in the lizard-feeding *C. pricei* is consistent with this view, and it suggests that both *C. pricei* and *C. lepidus* retain the presumably more primitive trait of requiring chemical feedback for maintenance of a high rate of poststrike tongue flicking.

Klauber's (1956) dendrogram depicting rattlesnake evolution shows *C. pricei* along an early branch of the *Crotalus* tree. Other members of this branch include *C. intermedius*, *C. lepidus*, *C. polystictus*, *C. pusillus*, *C. transversus*, *C. triseriatus*, and *C. willardi*. Since *C. pricei* and *C. lepidus* behave similarly, with both species differing from rodent specialists, it is tempting to speculate that a correlation exists between phylogenetic status and predatory pattern or between diet and predatory pattern. Such thinking, however, must remain at the level of conjecture until additional data are accumulated on other members of this genus (Scudder, Chiszar, & Smith, 1983).
