An R package for state-trace analysis

Melissa Prince · Guy Hawkins · Jonathon Love · Andrew Heathcote

Published online: 18 July 2012

Abstract State-trace analysis (Bamber, *Journal of Mathematical Psychology*, *19*, 137–181, 1979) is a graphical analysis that can determine whether one or more than one latent variable mediates an apparent dissociation between the effects of two experimental manipulations. State-trace analysis makes only ordinal assumptions and so, is not confounded by range effects that plague alternative methods, especially when performance is measured on a bounded scale (such as accuracy). We describe and illustrate the application of a freely available GUI driven package, StateTrace, for the R language. StateTrace automates many aspects of a state-trace analysis of accuracy and other binary response data, including customizable graphics and the efficient management of computationally intensive Bayesian methods for quantifying evidence about the outcomes of a state-trace experiment, developed by Prince, Brown, and Heathcote (*Psychological Methods*, *17*, 78–99, 2012).

Keywords State-trace analysis · Dimensional analysis · Bayes factors · R package

One of the most fundamental questions asked in experimental psychology and the neurosciences concerns latent dimensionality: Does a single latent (i.e., not directly observable) variable or dimension mediate the relationship between two or more experimental factors? For example, is recognition memory mediated by one (*memory strength*) or two (*familiarity* and *recollection*) processes (Dunn, 2004, 2008)? Traditionally, researchers have sought particular patterns of data, called *dissociations*, in order to answer this question (Shallice, 1988) and, so, to infer the existence of functionally independent neural (e.g., Teuber, 1955) or cognitive (e.g., Glanzer & Cunitz, 1966) systems. A single dissociation occurs when an experimental factor selectively affects performance under one condition, or in one task or group, or by one measure, but not another. Stronger evidentiary value is often associated with a double dissociation, which occurs when a second factor selectively influences the second condition/task/group/measure but not the first (see Dunn, 2003, for a fuller treatment). Typically, a one-dimensional or one-system account is rejected when a dissociation is confirmed by a significant interaction test.

However, there have been many demonstrations that interaction tests of dissociations can reject only a one-dimensional explanation based on strong assumptions (e.g., Bogartz, 1976; Busemeyer & Jones, 1983; Dunn, 2003; Dunn & Kirsner, 1988; Henson, 2006; Loftus, 1996; Poldrack, 2006). Loftus (1978) described one cause of this problem that commonly plagues bounded response measures, such as accuracy calculated from binary data. When the function mapping the latent variable to the bounded response scale is nonlinear, an observed interaction (or equally, the failure to observe an interaction) might be scale dependent. For example, floor and ceiling effects can mean that neither the presence nor the absence of an interaction is diagnostic of dimensionality. Even when an experiment is calibrated to avoid extreme performance or the data are transformed in an effort to remove the bounds, confounding still cannot be ruled out without making further debateable assumptions that are difficult, if not impossible, to directly test (see Prince, Brown, & Heathcote, 2012, for details).

State-trace analysis (Bamber, 1979), which is also known as *dimensional analysis* (Loftus, Oberg, & Dillon, 2004), avoids these and the other problems that plague traditional dissociation methods (see Newell & Dunn, 2008, for a concise and nontechnical treatment). It does so by making only the weak and arguably plausible assumption that latent variables have a *monotonic* effect on performance—that is,

that the direction of the latent variable's effect does not change with its magnitude. Latent dimensionality can then be assessed in a way that is easily understood and reported, using a *state-trace plot*. This approach is as general and flexible as dissociation analysis; the plot can be made by graphing one type of dependent variable against another (a *dependent-variable state-trace analysis*) or by graphing the same dependent measure taken under different conditions or from different tasks or groups. In all cases, if the plot is monotonic (i.e., does not change from increasing to decreasing or vice versa), performance is mediated by the same latent variable; otherwise, more than one latent variable must be in play.

State-trace analysis has been applied to a diverse range of topics in areas ranging from basic research in perception, attention, short-term and long-term memory, categorization, problem solving, and meta-cognition to applications in aging, legal, clinical, educational, human factors, and developmental psychology (Prince et al., 2012, provide an exhaustive summary and taxonomy). Evidence provided by state-trace analysis that more than one latent variable is in play can support inference about the existence of separate brain regions, cognitive representations, or processes (e.g., is forgetting in short-term memory due to decay as well as interference?; Oberaurer & Lewandowsky, 2008). It can also indicate that a single region, representation, or process has a multivariate structure (i.e., is characterized by more than one latent variable). For example, single-process models of recognition memory, which assume that recognition decisions are based on a single memory-strength dimension, can be either one-dimensional (e.g., equal-variance signal detection theory, where memory strength is characterized by a mean parameter) or multidimensional (e.g., unequal-variance signal detection theory, where both mean and variance parameters characterize memory strength).

Unfortunately, state-trace analysis is unfamiliar to many researchers who could benefit from its use. Prince et al. (2012) attempted to make it more accessible by providing a general methodology for designing and fine-tuning state-trace experiments, as well as statistics suitable for the type of bounded data where state-trace analysis is often needed. Their Bayesian approach can help guide the fine-tuning of experimental designs, as well as inference about monotonicity and, hence, latent dimensionality.

Prince et al. (2012) argued that their Bayesian methods are particularly suited to state-trace analysis for several reasons. First, for accuracy data, they require only a minimal additional assumption (that the binary data are binomially distributed), and so they detract little from the relatively assumption-free nature of state-trace analysis. Second, hypotheses about different dimensionalities vary tremendously in their ability to fit data by chance. Bayesian methods take this into account and so do not inappropriately favor more flexible models. Finally, state-trace analysis has been described as an example of an "equivalence" method that treats the discovery of simplicity and difference as equally important (Loftus, 2002) and so ideally requires a correspondingly even-handed statistical method. In contrast to null hypothesis testing, Bayesian analysis can quantify evidence in favor of a simpler "null" (e.g., a one-dimensional) model, as well as evidence against it.

In this article, we describe the scope and capabilities of StateTrace, a package written for the freely available R language (R Development Core Team, 2011), which implements Prince et al.'s (2012) methods using computationally intensive posterior sampling to perform Bayesian estimation and model selection. R is freely available for Windows, Mac OS X, and Linux and can be downloaded from http://www.r-project.org/. The StateTrace package can be installed within R by typing `install.packages("StateTrace")` on the command line, and the package functionality is made available by typing `library("StateTrace")`. StateTrace has been tested using the standard Rgui on PCs running Windows 7 and XP, as well as the standard R console under Mac OS X and Linux systems. Note, however, that problems can sometimes occur with other commonly used interfaces (e.g., RStudio), and therefore, we do not recommend their use with this package.

StateTrace is designed for users with no experience implementing Bayesian analyses. Functions can be accessed through a GUI, so it is also suitable for users with relatively minimal experience of R. The GUI functionality is provided by Hoffman and Laird's (2009) fgui package. It is important to note, however, that the aim of this article is to provide an overview of the capabilities of StateTrace, including the type of statistical summary results and graphical output that can be obtained. Before the package is used, we strongly recommend that users work though the detailed instructional tutorial provided in the "vignette" document that accompanies the StateTrace package. This vignette provides a step-by-step guide on how to analyze two example data sets, including explanations of each argument available in a function, as well as the argument values required to reproduce the example output presented and further detail regarding how to interpret the various output as one progresses through the analysis. This vignette was developed on the basis of our experience using the package with undergraduate research students. Once the package is installed, the vignette can be accessed within R by typing `vignette(topic = "StateTrace", package = "StateTrace")`

Although designed for users unfamiliar with Bayesian techniques, experienced users otherwise competent in these sampling methods may still benefit from StateTrace in that it provides facilities that manage potentially large demands on

computer time and memory. With these facilities, analysis of appropriately designed experiments is practical on commonly available personal computers. StateTrace also provides convenient tabular and graphical methods for examining and summarizing results, including customizable state-trace plots that address both the individual and group levels of analysis. In the next section we discuss the types of experimental designs and data types that StateTrace accommodates. We then describe its statistical and graphical capabilities.

Design and data

StateTrace can analyze three-factor ($2 \times 2 \times N$) repeated measures experiments that yield a binary dependent measure, including measures calculated either with or without reference to a measured baseline. Accuracy quantified by the difference between a hit rate and false alarm rate are examples of the former type of measure. Proportion correct is an example of the latter type of measure. Since state-trace analysis is not affected by monotonic transformations, equivalent results are produced for related measures, such as d' from signal detection theory. The example data sets presented in this article are taken from recognition memory experiments and address both types, as measured by testing single items that were either studied or not ("yes–no" testing) or by two-alternative forced choice (2AFC) testing.

Prince et al. (2012) labeled the three factors as *state*, *dimension*, and *trace* factors. In this section, we explore the nature of each type of factor and the types of designs that StateTrace can and cannot analyze. A global limitation is that all three factors must be of the repeated measures type, since Prince et al.'s (2012) methods analyze each participant's data separately and then combine the individual results to address the group level. In the final section of this article, we discuss these limitations in more detail and describe how they can currently be addressed using StateTrace.

State and dimension factors

The state factor has two levels that constitute the axes of the state-trace plot. In our example data, the two levels are based on recognition memory decisions made about pictures of houses versus pictures of faces. In the case of a dependent-variable state trace analysis, these levels correspond to different binary dependent measures. For example, they might be the outcome of a recognition decision and a classification of the decision as being made with high versus low confidence.

The dimension factor has levels corresponding to different experimental manipulations. In our examples, the manipulation corresponds to whether the study and/or test presentations used upright or inverted images. The dimension factor can be thought of as interacting with the state factor in a way that changes the dimensionality of the processes underlying performance. For example, upright faces are thought to be able to be encoded both in terms of their constituent features and in a more holistic or relational way, whereas only the former encoding is available for inverted faces (Maurer, LeGrand, & Mondloch, 2002; Valentine, 1988; Yin, 1969).

The state and dimension factors correspond to the two factors examined in a dissociation analysis. For example, traditional dissociation-based evidence for faces being processed in a qualitatively different way from other visual stimuli is provided by an interaction between the class of stimuli (e.g., face vs. house) and presentation orientation (e.g., upright vs. inverted). For a dependent-variable state-trace analysis, assignment of the two factors to state and dimension roles is clear, but otherwise these roles can be interchangeable. An exception concerns measures assessed against a baseline. For such measures, the levels of the dimension factor must have a common baseline for state-trace plot monotonicity to be diagnostic of dimensionality. Since this restriction does not apply to the state factor, assignment can be made accordingly (as was the case with our baseline example), or a measurement method that does not include a baseline must be used (e.g., 2AFC). One of our examples has no baseline (a "B0" design), and the other example has a separate baseline for each level of the state factor (a "B2" design). In the latter case, the baseline conditions correspond to test house or face images that were not studied.

StateTrace assumes that the dimension factor has two levels based on practical motivations related to the size of (i.e., number of cells in) a design. First, the computational method used by StateTrace for the Bayesian analysis rapidly becomes prohibitive as size increases. Second, for large designs it is difficult to run enough trials per cell to obtain estimates that are sufficiently precise to support individual-participant analysis. Hence, using a two-level dimension factor is prudent, perhaps after piloting to select appropriate levels, since this is typically sufficient to test dimensionality.

Trace factor

The third experimental manipulation, the trace factor, has no analogue in dissociation analysis. In Prince et al.'s (2012) method, the effect of the trace factor on dimensionality is not of interest. Indeed, the trace factor is chosen specifically because past research indicates that it is unlikely to affect dimensionality, so that dimensionality evidence can be unambiguously interpreted in terms of the state and dimension factor effects. In our examples, the trace factor was the time spent studying each item. Given that past research indicates that increasing study time increases accuracy for houses and faces both when they are upright and when they are inverted, study time should have a monotonic effect in the state-trace plot. For the same reasons that apply to the dimension factor,

the trace factor cannot have different baselines for different levels.

The trace factor's role is to ensure that state-trace analysis is diagnostic of dimensionality. A state-trace plot can be nondiagnostic for two reasons. When state and dimension factors have only two levels and there is no trace manipulation, the state-trace plot has only two points, and so is always monotonic. However, if the plot has more than two points, it can still be nondiagnostic if the dimension factor effect is so large that results do not overlap on either axis of the plot. The remedy is to induce overlap using the trace factor. In our examples, greater accuracy for the upright condition is counteracted by a longer study time for the inverted condition, inducing overlap.

StateTrace can accommodate any number of trace factor levels. Prince et al. (2012) recommended three to four levels with evenly spaced effects. Too many levels can cause the sort of design-size-related problems discussed previously. Too few levels and unevenly spaced effects risk the state-trace plot being nondiagnostic due to an unlucky configuration of estimated points even when overlap is achieved. Choosing an appropriate number and spacing of trace factor levels can require some calibration through pilot testing. When doing so, it is important to recognize that it may be most efficient to use different trace factor levels within each level of the dimension factor (i.e., the design need not be fully factorial). For example, we used generally longer study times in the inverted than in the upright condition in order to counteract generally greater accuracy for upright than for inverted items. A trace factor can sometimes be created by the post hoc construction of a factor according to criteria set to obtain the most diagnostic outcome. For example, Heathcote, Freeman, Etherington, Tonkin, and Bora (2009) constructed a post hoc trace factor in a recognition memory experiment by dividing test trials on study–test interval.

Input data formats

StateTrace reads in text data files made up of equal numbers of entries on each line. Data files may contain *trial data*, with a column indicating the response on each trial, or *summarized data*, with columns indicating the number of correct responses and number of trials for each condition. StateTrace accepts either a single file with all the participants' data or individual-participant files. Columns can be delimited in a variety of common ways, and relevant columns can be selected from a larger set either by name or by number. The relevant columns indicate the response (number of trials for summarized data) and the state, dimension, and trace levels for each row.

StateTrace accepts data files formatted as coming from designs either with no baseline (B0) or with a different baseline condition for each state level (B2). Since baseline conditions cannot differ over dimension and trace levels, a B2 design is automatically detected through the presence of blank or "NA" entries in these columns. Designs where accuracy in all conditions is measured relative to a single baseline can be treated as coming from either a B0 or a B2 design. In the former case, the baseline data are omitted, whereas in the latter case, they are included twice. The outcome of state-trace analysis is the same in both cases, but the B2 format may be preferred since accuracy results can be displayed by differences between nonbaseline and baseline results.

Statistics and graphics

Figure 1 shows example state-trace plots for our 2 (state: face, house) × 2 (dimension: upright, inverted) × 3 (trace: study duration) design for both individual participants (Fig. 1a, b) and the group aggregate for the no-baseline example (Fig. 1c) and for the baseline example (Fig. 1d). Plots such as these can be visually inspected to assess whether all of the points fall on a monotonic function—that is, whether the order of points on the *x*-axis is the same as the order of points on the *y*-axis. However, inference about dimensionality based on the visual inspection of state-trace plots can sometimes be misleading due to measurement noise. This is particularly the case for individual-participant data (e.g., Fig. 1a, b), where levels of measurement noise can be high. However, individual analysis is required to make strong inferences on the basis of state-trace analysis, because neither the monotonicity nor the nonmonotonicity of state-trace plots is necessarily preserved when they are averaged over participants (Prince et al., 2012). Hence, a quantitative approach to state-trace analysis provides an important complement to visually assessing a state-trace plot.

StateTrace obtains evidence about questions relevant both to refining an experimental design and to diagnosing dimensionality by selecting among four mutually exclusive models. In defining these models, it is convenient to refer to "data traces," lines joining data points from the same level of the dimension factor (e.g., the solid and dashed lines in Fig. 1a, b).

1) *Nontrace model:* The trace factor does not always have a monotonic effect (i.e., one or more data traces are nonmonotonic), and so any nonmonotonicity in the state-trace plot cannot be unambiguously attributed to the interaction between the state and dimension factors.
2) *No-overlap model:* Data traces do not overlap on either axis, so that even though the state-trace plot is monotonic, no conclusions can be made about dimensionality.
3) *Unidimensional model:* A single latent variable mediates performance; that is, the state-trace plot is monotonic and provides a valid basis for inference about dimensionality.
4) *Multidimensional model:* More than one latent variable mediates performance; that is, the state-trace plot is nonmonotonic.

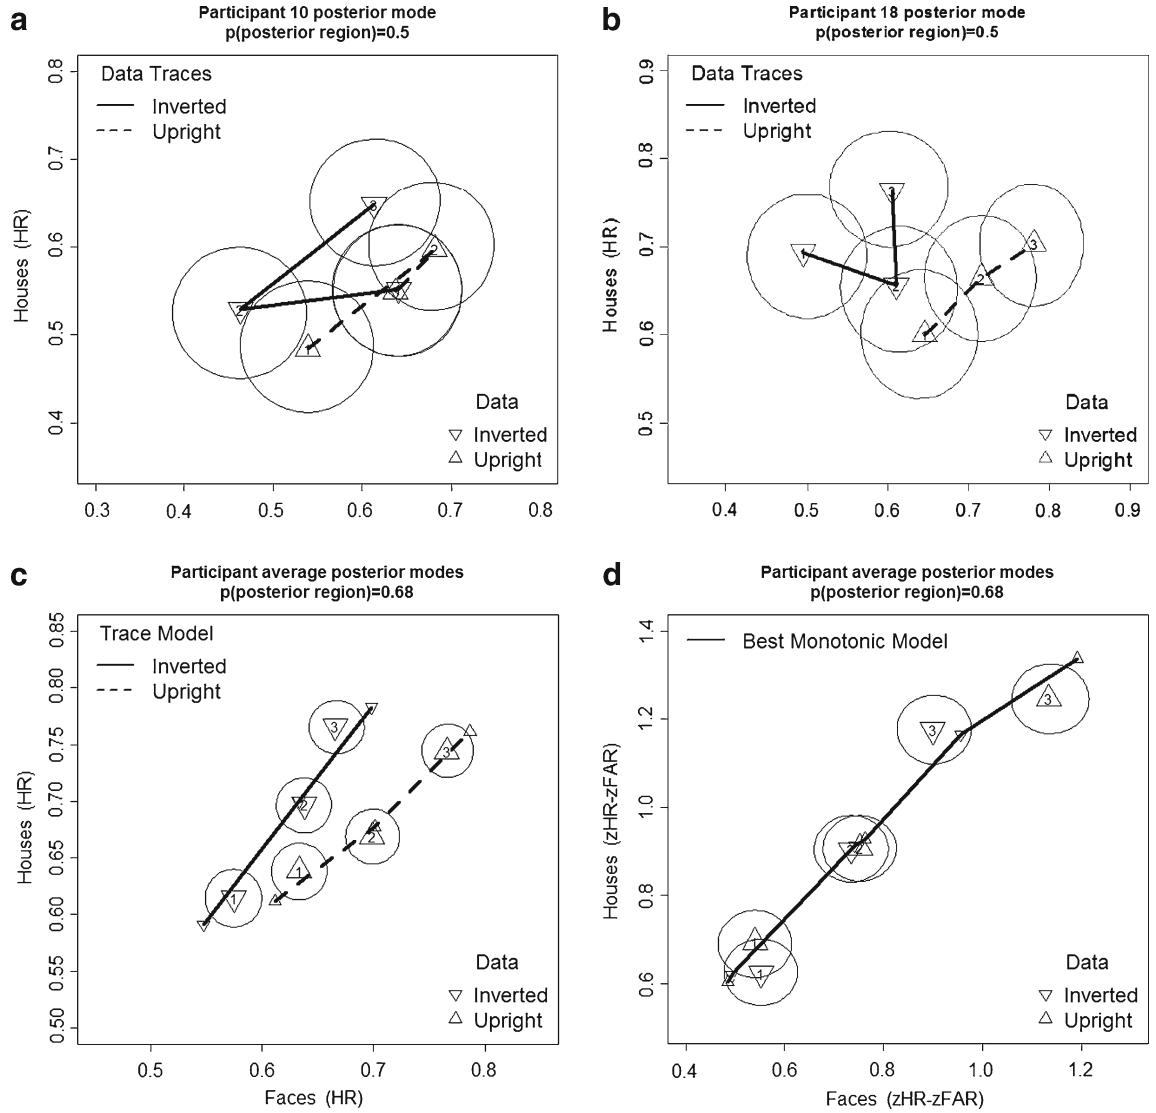

Fig. 1 Accuracy state-trace plots showing modes of the posterior estimates from the encompassing model (large symbols) for the 2AFC data set for **a** participant "J," **b** participant "R," and **c** on average, as well as **d** on average for the yes–no data set. Accuracy is indicated by plotting the hit rate (HR) for the 2AFC data and d' [i.e., z(HR)−z(FAR), where FAR is the false alarm rate] for the yes–no example. For panels a and b, the lines are data traces, joining posterior modes of the encompassing model samples, and ellipses represent the 50% credible regions. For panel c, lines with small symbols join posterior modes of the trace model, and for panel d, they join the highest posterior probability (i.e., most frequently sampled) monotonic model. The ellipses in panels c and d represent 68% credible regions

Each model specifies a set of order restrictions on the points in a state-trace plot. Evidence for each model is quantified using a Bayes factor (BF; Kass & Raftery, 1995). The BF quantifies the change in relative beliefs (odds) about two models caused by observing the data. That is, it is the change from prior odds (odds before seeing the data) to posterior odds (odds after seeing the data). For example, if two models, M1 (the numerator model) and M2 (the denominator model), are initially considered equally likely, BF = 10 implies that M1 is 10 times more likely than M2 after the data have been observed.

BFs can be thought of as measures of relative goodness-of-fit that compensate for differences in model flexibility. Our denominator (M2) is always an *encompassing* model under which all orders are equally likely. Hence, BF > 1 favors the less flexible order-restricted (numerator) model over the encompassing model, which, by definition, fits any data perfectly. If it is assumed that one model among a set of models generated the data (i.e., is the *true* model), BFs for the set of models can be combined to calculate posterior model probabilities, p, which quantify relative evidence. High probabilities provide evidence favoring a model, and low probabilities provide evidence against a model. If the true-model assumption is not made, a posterior probability still provides a number that quantifies relative evidence on an easy-to-interpret zero-to-one scale, even though it cannot

be interpreted as a probability. Additionally, when the trace factor is selected on the basis of strong prior evidence that it has a monotonic effect, it makes sense to exclude the nontrace model when posterior model probabilities are computed.

StateTrace can output both BFs, to quantify absolute evidence about whether the data provide sufficient support for clear conclusions about each model, and posterior model probabilities (calculated either including or excluding the nontrace model), to quantify relative evidence. We suggest (after Raftery, 1995) that evidence for the numerator model can be considered weak for a BF < 3, positive for a BF between 3 and 20, strong for a BF between 20 and 100, and very strong for a BF > 100. Table 1 provides similar conventions for posterior model probabilities. The two sets of conventions are closely related because $p = BF/(1 + BF)$, given BF = 1 by definition for the encompassing model. Like all conventions, these suggestions should not be used uncritically; BFs and posterior model probabilities have a natural scale making their interpretation straightforward.

Computing Bayes factors

Prince et al. (2012) used posterior sampling methods proposed by Klugkist, Kato, and Hoijtink (2005) and Klugkist, Laudy, and Hoijtink (2005) to compute BFs for the four models. Although conceptually straightforward (i.e., they simply count the frequency with which different orders occur in a set of simulated samples), this method is computationally expensive. In order to make it practical, StateTrace uses two types of sampling:

1) *Encompassing sampling*: Monte Carlo (MC) sampling, used to obtain samples from a model that makes no order constraints, and
2) *Trace model sampling*: Markov chain Monte Carlo (MCMC) sampling, used to obtain samples under the trace model constraint.

In principle only MC methods are needed, but the yield of samples relevant to models 2–4 is often so low that it would be far too inefficient. Although slower per sample, the MCMC method always yields samples from models 2–4 after an initial "burn-in" period and, so, is better in practice.

Table 1 Conventions to aid interpretation of the posterior model probabilities (after Raftery, 1995)

Favoring model		Against model
$p > .99$	Very strong evidence	$p < .01$
$.95 < p \leq .99$	Strong evidence	$.01 \leq p < .05$
$.75 < p \leq .95$	Positive evidence	$.05 \leq p < .25$
$.25 \leq p \leq .75$	Equivocal evidence	

For trace model sampling, initial (burn-in) samples are discarded because it can take some time for the MCMC process to converge to the target distribution (see Gilks, Richardson, & Spiegelhalter, 1996). Our experience is that convergence is very fast and that, at most, 100 initial samples need to be discarded. However, this may not be the case in all applications, so StateTrace provides facilities to check. StateTrace uses Plummer, Best, Cowles, and Vine's (2006) *coda* package to automatically calculate one check, Gelman's "R-hat" statistic (where values close to one indicate convergence), and also allows MCMC samples to be exported in a format suitable for further checks provided by coda.

StateTrace manages the sampling process, enabling estimates to be automatically refined to a specified level of accuracy and allowing the time spent sampling to be limited to convenient periods (e.g., overnight runs). Statistics to support simultaneous selection among all four models (an *exhaustive strategy*) or only models 2–4 (a *trace-true strategy*) are calculated automatically, and raw counts can also be accessed to support other approaches, such as sequential model selection (see Prince et al., 2012).

Overview of functions

Typing `guista()` at the R command line invokes the main StateTrace GUI, which provides access to the main StateTrace functions: stFirst, stSample, stSummary, stProbplot, stBootav, stPlot, and staManage. Alternatively, the GUIs for each separate function can be called by typing "gui" followed by the function name and parentheses (e.g., `guistFirst()`). In general, command line users can remove "gui" from the start of the function and enter argument values within the parentheses. Details on available arguments can be obtained by consulting the function's help, called by typing a? prior to the function name. Each of the GUIs allows users to view default values for function arguments and to enter alternate values via widgets such as text entry boxes, slider bars, true/false check boxes, and multioption lists. In all GUIs, argument values that require input for a function to run are marked by an *, and argument descriptions that contain the term "character string" must have their values contained in double quotation marks.

The stFirst function performs an initial analysis, first reading in data for one or more participants from one or more text files, and then making a quick preliminary assessment of the results on the basis of a limited number of posterior samples. It then creates an object of class *sta* in the R environment, which is named by the user. The *sta* object encapsulates the data and the numerical results based on sampling. Once stFirst is complete, the *sta* object can be saved from the R environment to a file in a compressed

format and restored in a later R session, using the R `save` and `load` functions, respectively.

Three StateTrace functions allow the contents of an *sta* object to be displayed. The stSummary and stProbplot functions provide, respectively, tabular and graphical summaries of the Bayesian analysis. The stPlot function makes state-trace plots (e.g., Fig. 1). All three functions work, to some degree, with an *sta* object created by stFirst. However, for more accurate results from the Bayesian analysis, and to access the full range of state-trace plot options, two other functions may have to be run: stSample and stBootav. These functions perform time-consuming computations whose results are stored in the *sta* object. The stSample function collects enough extra samples to reach a specified level of accuracy in the Bayesian analysis. Some of these extra samples can also be stored in the *sta* object, so that a line representing the trace (e.g., Fig. 1c) or monotonic (Fig. 1d) model that is best supported by the data can be added to a state-trace plot. However, to enable these lines to be added to state-trace plots averaged over participants, the stBootav function must also be run.

The main GUI also provides access to the staManage function, which allows users to manage and export posterior samples stored in an *sta* object. An *sta* object is an R list that can be directly accessed by users, but staManage and the other functions are designed so that this should not be necessary. Samples are stored in an *sta* object to enable efficient generation of graphical summaries of uncertainty in estimation (i.e., credible regions, the Bayesian analogue of confidence intervals—e.g., the ellipses in Fig. 1). However, this can sometimes cause an *sta* object to become so large that it is slow to load and save. The staManage can be used to remove samples after the graphics have been generated. The staManage function also allows users to export a list containing posterior samples with one entry for each participant. Each entry in the list contains samples in a format (the *mcmc.list* class), for which coda provides many easy-to-use analysis methods (e.g., *plot* and *summary* functions).

First steps

Before stFirst initiates sampling, checks are run to ensure that the selected data files are compatible with StateTrace (e.g., state and dimension factors each have only two levels) and the multiple files are compatible with each other (i.e., all have either a B0 or a B2 design). It then obtains 100,000 MC samples for each independent set of design cells (four sets for B2 designs and two for B0 designs) and determines the proportions that follow the order specified by the trace factor. Estimates of 95% credible intervals for each proportion estimate are obtained, and where the precision of the interval is less than 0.0005, it marks sampling as complete. Otherwise, it estimates the time required to get enough samples to narrow the interval sufficiently, based on the time required for the initial 100,000. These time estimates are only approximate and will vary, especially if sampling is completed on a different computer that is faster or slower.

Next, an order-constrained Gibbs sampler (Gelfland, Smith, & Lee, 1992) is used to draw two sequences of 5,000 MCMC samples ("chains") from the trace model for each participant. The proportions of samples following the no-overlap, unidimensional, and multidimensional model orders are tabulated, and the corresponding 95% credible intervals calculated. Sampling for a participant is marked as complete if all intervals are less than 0.005. Otherwise, the additional time required to complete is estimated. A smaller interval criterion is used for encompassing than for trace sampling, since encompassing proportion estimates have a greater potential to reduce precision overall because they multiply the trace proportions in the calculation of BFs. Once the two chains are complete, stFirst reports whether the MCMC process has worked properly (i.e., has "converged"), using Gelman's multivariate R-hat statistic.

In the final stage of computation, stFirst draws 10,000 bootstrap average samples and uses the two-dimensional density estimator provided by Wand and Ripley's (2009) *KernSmooth* package (with its default parameters) to calculate the posterior modes (measures of central tendency) and 68% credible regions (i.e., the analogue of a standard error) around the modes. These calculations are used to display an average state-trace plot, which provides the user with an immediate view of results averaged over participants, as well as state-trace plots for each individual participant. Additionally, the corresponding posterior mode estimates are output in a tabular form to the R console. The stFirst function can be called repeatedly to add additional participants to the *sta* object. A warning will be issued if duplicate data sources are mistakenly specified; however, these data will still be added to the object without replacing the old entries.

Refining estimates

Further sampling may be required if the analysis did not reach completion during the initial pass or the user wishes to alter the credible interval precision criteria from those used by stFirst. This is achieved using stSample, which allows fine-grained control over the defaults used by stFirst. The only required input is the name of an existing *sta* object. Because obtaining enough samples to fulfil stricter criteria can be time consuming, stSample has a "refresh" mode, which allows the predicted time to completion to be calculated for different criteria. This refresh mode is fast to run, since no actual sampling is done, unless none has been done yet, in which case a single pass is made. Since the time information will

vary depending on the computer used, if the most recent pass (e.g., obtained by running stFirst) was on a different computer, it is useful to turn off the refresh mode but leave the maximum run time at zero; this will cause a single pass to be run and to update the timing information for the new computer.

Once a sampling plan is determined, the refresh mode can be turned off, a suitable maximum run time entered, and sampling initiated. Sampling is completed in a series of passes, and users may choose to sample from only the encompassing model, only the trace model, or both. Sampling terminates when precision criteria are satisfied, so stSample may require additional time than that estimated from previous passes (e.g., after running stFirst); it may also complete before the maximum time elapses, and one type of sampling may complete before another. The *verbose* argument (with value 0, 1, or 2) controls information printed to the R console during sampling: 0 is silent, 1 prints the estimated total time remaining after each run for all participants, and 2 adds timings per participant.

The number of samples for each pass of each type of sampling is chosen to satisfy a trade-off. Using a small number per pass inherits a cost in housekeeping between passes, and initial *burn-in* samples on each trace-model run are lost. A large number uses more RAM and can result in more samples being taken than required to achieve the required precision. A larger value is advisable for encompassing than for trace model sampling, since encompassing sampling is usually an order of magnitude faster. In our applications, we have found that the defaults work well and that little is gained in particular cases by altering them. Similarly, we have found that the default criteria (credible interval type—e.g., 95%—and precision) strike an appropriate balance between computation time and the accuracy of BF and posterior model probability estimates.

A second reason for running stSample is to collect samples that enable visualization of each model—that is, samples that follow the order(s) dictated by a model. We have found that the default value of 10,000 encompassing samples collected by stFirst is sufficient for accurate visualization of central tendencies and credible regions, although large regions (which require estimation of distribution tails) can require more. The 10,000 trace samples collected by stFirst are also usually more than sufficient, given that they are used only to estimate central tendency. The stSample function also collects a particular type of trace sample, monotonic model samples, which may be relatively rare, especially when the data are far from monotonic. Monotonic samples are used to plot the central tendencies of the unidimensional or no-overlap model, with the latter type of sample often being extremely rare unless the data are strongly nonoverlapping. Given this, by default, stSample keeps all monotonic samples.

Storing large sets of samples for each participant can greatly increase the size of *sta* objects. The default values (assuming that stored monotonic samples are not allowed to grow too large) are rarely problematic. However, the staManage function can be used to reduce the number of stored samples where problems arise, including the ability to keep only samples for the "best" (i.e., most frequently occurring and, hence, most probable) monotonic order, rather than all samples with monotonic orders. The staManage function can also be used to join multiple *sta* objects; for example, it can be computationally efficient to divide a very large set of participants and then run the sampling for subgroups of participants on separate machines, after which the *sta* objects can be combined and the group aggregate results examined.

Extracting results

The stSummary function produces tabular model-selection results to the R console. It also provides information about the status of sampling for an *sta* object (i.e., whether it is complete or, if not, how much more computation time is required according to the criteria stored in the object). Results can be output as BFs or posterior model probabilities based on either exhaustive or trace-true strategies. By default, stSummary reports results summarized over participants based on group BFs, which are the product of each participant's BFs and assumes that each participant contributes independent evidence (Prince et al., 2012). However, in some cases, the group results can be inappropriately influenced by outlying individual-participant results (e.g., most participants are unidimensional, but a few strongly multidimensional participants dominate the group results). We recommend that users also output and examine individual-participant results in order to check this possibility. This can be done, and outlier participants can then be excluded from the calculation of group results, using stSummary options. Users may also output a large range of additional results, including the prior probabilities for each model (calculated analytically; see Prince et al., 2012), the total number of encompassing and trace model samples, and counts of the number of times the orders specified by each model were sampled.

The stProbplot GUI allows the distribution over participants of posterior model probabilities to be inspected graphically. Outlying participants can be excluded, and the annotation within the plots customized. Additionally, the posterior probability for the group (based on the group BF) can be displayed numerically in the title and as a line on the plot. As is shown in the output for the 2AFC example data in Fig. 2, the stProbplot plot includes a panel for each model, and each letter in a panel represents the posterior model probability for a single participant. Participants in

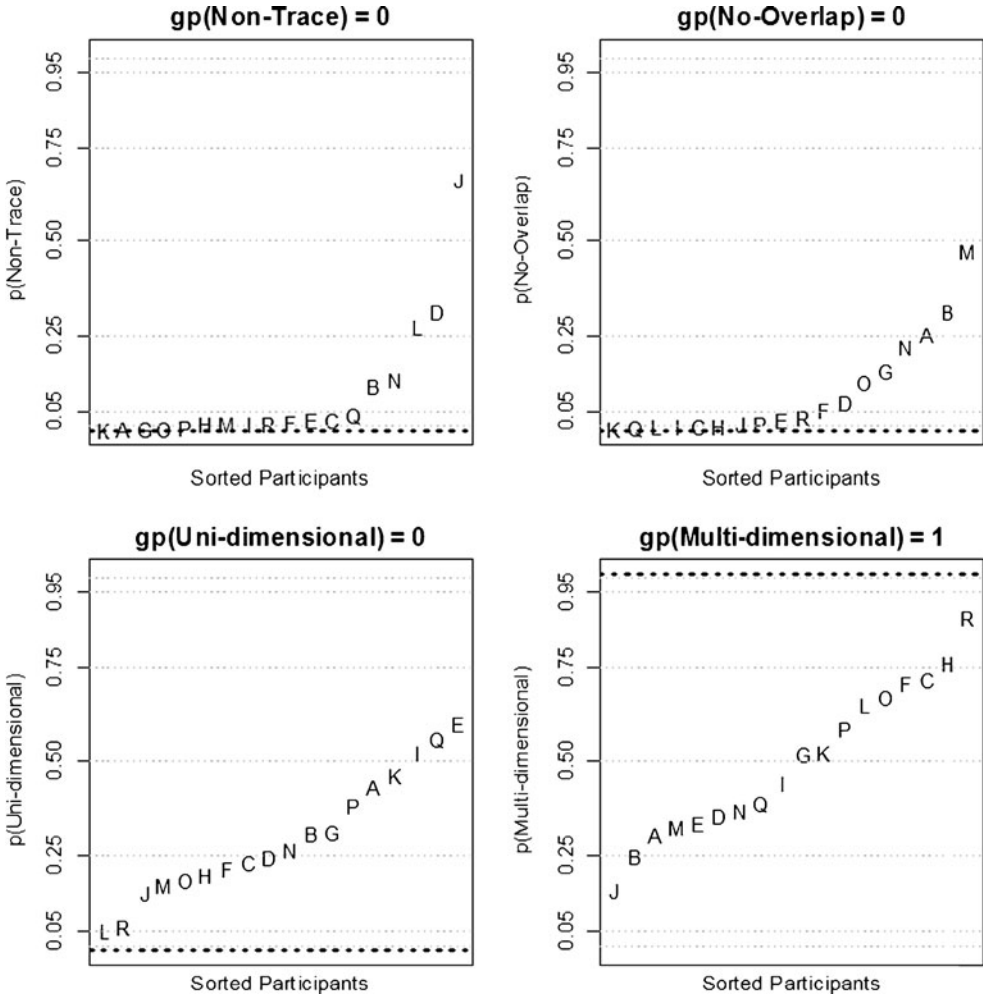

Fig. 2 Posterior model probabilities for each participant (denoted by letters) for the 2AFC example data for each of the four diagnostic models (panels). Group posterior model probabilities for each model are indicated in panel titles and plotted as a heavy dashed line. Within each panel, participant results are sorted in ascending order of their probability estimates, and faint dashed lines demarcate the categories in Table 1

each panel are sorted by their results, allowing those with extreme values to be easily identified. Figure 2 was made using defaults, which produce appropriate annotations in most cases, and by choosing the option to use letter plot symbols in order to easily identify each participant's results.

Inspection of Fig. 2 suggests that participant "J" provides an outlying result in favor of the nontrace model. However, a follow-up analysis excluding participant "J" revealed little influence on the group posterior model probability (*gp* in the panel titles). Overall, these results show positive or greater evidence for the trace model and for data-trace overlap (i.e., low probabilities for the nontrace and no-overlap models). Evidence is weaker and individual variability greater in relation to the dimensionality results, but the group evidence supports a multidimensional outcome. The stProbplot plots can also reveal a potential mixture of unidimensional and multidimensional subgroups, but that is not indicated in Fig. 2.

Figure 1 shows examples of state-trace plots produced by stPlot. The stPlot function can represent accuracy data by the mode, mean, or median measures of central tendency applied to samples from the encompassing model. Since the encompassing model makes no order assumptions, these measures (e.g., large symbols in Fig. 1) provide a model-free estimate of the observed data. The default choice used to create Fig. 1 (the mode) produces estimates that are usually equivalent to the familiar maximum-likelihood estimator (e.g., n/N for the 2AFC hit rate, where n is the number of correct responses on N trials).

The other central tendency measures usually produce similar results, at least for reasonable sample sizes not subject to floor or ceiling effects. For example, for the hit rate and uniform prior used by StateTrace, the mean of a large sample from the encompassing model is equivalent to $(n + 1)/(N + 1)$. For other accuracy measures, such simple formulae are not available. This is also the case for any accuracy measures for any of the order-restricted models. Hence, estimates based on samples have the advantage of providing an easily applied and general approach.

The stPlot function uses the same type of approach to display the degree of uncertainty in central tendency estimates, by drawing contours around regions containing a specified percentage of the posterior encompassing-model samples. Estimating Bayesian credible regions in this way

works with all accuracy measures in a way that takes account of any floor and ceiling effects, which can be very influential when contours are near bounds in an accuracy measure. The regions, and modes, are estimated using the bkde2D function in Wand and Ripley's (2009) *KernSmooth* package, which is included by default with R. Users can choose the percentage contained by the regions and the degree of smoothing, as a multiple of the maximum over data points of the values provided by the dpik function: This *KernSmooth* function and bkde2D are called with default values. The default multiplier of five used by stPlot was chosen to produce very smooth contours even for large regions, which can otherwise be irregular because they require estimation of distribution tails; users are encouraged to experiment with the multiplier as appropriate for their application.

Figure 1a, b plots results for participant "J," who had the strongest evidence for a violation of the trace model in Fig. 2, and participant "R," who had the strongest evidence for the multidimensional model; both state-trace plots are clearly consistent with the model-selection analyses. Individual-participant data are typically quite noisy, so for clarity, the credible regions in these plots contain only 50% of the posterior samples. Both data sets display strong data-trace overlap, consistent with the results for the no-overlap model in Fig. 2.

Figure 1c is a state-trace plot of the average over all participants in the 2AFC example data. Reflecting the reduction in uncertainty associated with an average, the credible regions are much smaller in this case, even though they contain the default value of 68% of the posterior samples. The lines in Fig. 1c join the modes of the average of samples from the trace model. The points joined by the lines are different from the large symbols, which are estimated on the basis of encompassing model samples, since the encompassing model admits samples that violate the trace model. However, the difference is not large, reflecting the fact that for most participants, the trace model provides an excellent description of this data.

Figure 1d plots average results for the yes–no example, using the signal-detection theory *d'* measure of accuracy. The lines in Fig. 1d join the modes of the most commonly occurring order[1] for monotonic MCMC samples (the *best* monotonic model)—that is, MCMC samples from either the unidimensional or the no-overlap model. Because this data is well described by a one-dimensional model, the difference between the best monotonic model and encompassing model modes is relatively small.

[1] It is important to note that the best order may differ between participants. Before interpreting the best (most frequently occurring) monotonic model in the average, such as is plotted in Fig. 1d, it is advisable to use stSummary to examine the degree of variability in the best orders over participants, since strong individual differences may mean that taking an average is not sensible.

Figure 1c and d were created after first running stSample to the default criterion, then stBootav to average the trace and monotonic samples stored by stSample. The stBootav function allows users to choose to calculate bootstrap averages (on the basis of the stored samples for each participant) from one or more of the encompassing, trace, and monotonic models. A set of bootstrap averages is created by repeatedly randomly selecting with replacement one sample from each participant's set of posterior samples for a given model and taking their mean. Each time stBootav is invoked, it can compute averages for only one type of accuracy.

Monotonic samples may be relatively rare for some data (e.g., the 2AFC data, since it is strongly nonmonotonic), and so the averages can be unreliable; to alert users to this possibility, stBootav reports the number for participants who have fewer than 100 samples. A participant with no monotonic samples is automatically excluded from the average. The problem of a lack of monotonic samples might be addressed by calling stSample again with a stricter criterion, but usually a lack of monotonic samples indicates that the monotonic model is not appropriate for the data, and so there is no point in plotting it.

Once averages are stored in an *sta* object, stPlot can make a corresponding average state-trace plot (e.g., Fig. 1d). Data points in average plots represent the central tendency of the set of bootstrap averages. Variability among the averages is used to construct credible regions in the same way as for individual participants. These credible regions reflect uncertainty in the estimated average over the particular set of participants in an experiment. The stBootav function also allows participants to be selected at random with replacement on each bootstrap repetition; this produces a set of averages with the same central tendency but greater variability that is appropriate when the participants are treated as a sample from a population.

Limitations and future directions

StateTrace is limited in a number of ways that we plan to address: It requires a fully repeated measures design, allows only two levels for state and dimension factors, and works with only binary data. This is not to say that it is not both valid and useful to perform a state-trace analysis involving between-subjects factors (e.g., does the dimensionality of memory differ between amnesiacs and controls?). However, statistical analysis of such state-trace plots requires estimation of a population-level model and, so, would require a hierarchical extension of Prince et al.'s (2012) approach. Bayesian methods are suited to this extension, and we hope to pursue it in future work. Until then, we recommend Verhaeghen and Cerella's (2002) multilevel approach to address such designs,

although it requires the assumption of a functional form (e.g., linear) for data traces.

In principle, both state and dimension factors may have more than two levels. We are currently testing a fast approximation for the Bayesian analysis, which removes the computational reason for having only two dimension levels. Hence, this restriction will likely be removed as part of an update incorporating the fast approximation. An extension beyond two state levels requires more fundamental changes, and although applicable methods have been developed (Dunn & James, 2003), further work is required to extend our Bayesian analysis.

For now, when users are interested in the dimensionality underlying the relationship between three state-factor levels (e.g., A, B, and C) or more they can use StateTrace by taking advantage of the transitivity of pairwise state-trace inference (e.g., test A vs. B and B vs. C, with one-dimensional results in both cases indicating that a single latent variable explains variation in all three). A similar approach can be required if more than two dimension-factor levels are required. Finally, the limitation to binary data can be accommodated by collapsing (e.g., a 1–10 confidence rating could be collapsed to high vs. low), but subject to the usual caveats about loss of information. We plan to explore the extension of Prince et al.'s (2012) Bayesian analysis and StateTrace to such finer-grained measures using a multinomial data generating assumption.

Although the range of application is restricted as described above, the advance provided by Prince et al.'s (2012) Bayesian analysis and the current package within this domain is substantial. Rather than judging state-trace plots "by eye," these Bayesian procedures not only quantify evidence about dimensionality (i.e., one or more than one latent variable), but also aid in the process of design refinement. Moreover, the StateTrace package enables the adoption of these methods by researchers who are unfamiliar with the required sampling and estimation techniques. It does so by automating many aspects of a state-trace analysis of binary response data, including the output of both tabular and graphical summary results and customizable state-trace plots. Additionally, StateTrace is a GUI-driven package and, so, is accessible to users who are also not familiar with the R language.

Author Notes Thanks to Cassandra Barrett, Amanda Brown, Christopher Brown, Sara Buller, Anna Charley, Nekia Dalley, Stuart Donaldson, Katie Foster, Jessica Gordon, Alice Grady, Tonelle Handley, Georgia Kelaher, Elaine Yheng Ching Loke, Katherine Moore, Soo Li Quah, Kate Smith, Evelyn Tan, and Lucy West for assistance with stimulus preparation and running of participants for the example data sets.
